NOTICE

Medicine is an ever-changing science. As new research and clinical experience broaden our knowledge, changes in treatment and drug therapy are required. The authors and the publisher of this work have checked with sources believed to be reliable in their efforts to provide information that is complete and generally in accord with the standards accepted at the time of publication. However, in view of the possibility of human error or changes in medical sciences, neither the authors nor the publisher nor any other party who has been involved in the preparation or publication of this work warrants that the information contained herein is in every respect accurate or complete, and they disclaim all responsibility for any errors or omissions or for the results obtained from use of the information contained in this work. Readers are encouraged to confirm the information contained herein with other sources. For example and in particular, readers are advised to check the product information sheet included in the package of each drug they plan to administer to be certain that the information contained in this work is accurate and that changes have not been made in the recommended dose or in the contraindications for administration. This recommendation is of particular importance in connection with new or infrequently used drugs.
AS TO THE ACCURACY, ADEQUACY OR COMPLETENESS OF OR RESULTS TO BE OBTAINED FROM USING THE WORK, INCLUDING ANY INFORMATION THAT CAN BE ACCESSED THROUGH THE WORK VIA HYPERLINK OR OTHERWISE, AND EXPRESSLY DISCLAIM ANY WARRANTY, EXPRESS OR IMPLIED, INCLUDING BUT NOT LIMITED TO IMPLIED WARRANTIES OF MERCHANTABILITY OR FITNESS FOR A PARTICULAR PURPOSE. McGraw-Hill Education and its licensors do not warrant or guarantee that the functions contained in the work will meet your requirements or that its operation will be uninterrupted or error free. Neither McGraw-Hill Education nor its licensors shall be liable to you or anyone else for any inaccuracy, error or omission, regardless of cause, in the work or for any damages resulting therefrom. McGraw-Hill Education has no responsibility for the content of any information accessed through the work. Under no circumstances shall McGraw-Hill Education and/or its licensors be liable for any indirect, incidental, special, punitive, consequential or similar damages that result from the use of or inability to use the work, even if any of them has been advised of the possibility of such damages. This limitation of liability shall apply to any claim or cause whatsoever whether such claim or cause arises in contract, tort or otherwise.
Dedication

To my mother and father, my wife Heather, and our children Elaina, Alex, and Will for their love and inspiration.
— Habib Samady

Thank you to my wife, Yvonne, for her continued love and support!
— William F. Fearon

Thank you to my wife, Elene, and my children for their support!
— Alan C. Yeung

Thanks to my wife, Gail, and my colleagues at Emory and Stanford Universities.
— Spencer B. King III
Contributors
Foreword
Preface

KNOWLEDGE FOUNDATION

1. History of Interventional Cardiology
   Brian W. Kaebnick, Bill D. Gogas, Spencer B. King III

Section 1. Anatomy for Interventional Cardiology

2. Coronary Anatomy for the Interventionalist
   William F. Fearon

3. Cardiac Anatomy for the Interventionalist
   Jonathan Marvin Tobis, Islam Abudayyeh

4. Anatomy of Cardiac Valves for the Interventionalist
   Ganesh Athappan, Samir R. Kapadia

5. Peripheral Anatomy for the Interventionalist
   Joseph A. Walsh, Curtiss T. Stinis

Section 2. Physiology

6. The Coronary Circulation

7. Hemodynamic Assessment of Renal Artery Stenosis
   Angela Ferrara, Julien Adjedj, Bernard De Bruyne

Section 3. Pathophysiology

8. Valvular Pathophysiology
Blase A. Carabello

9. **Arterial Disease**  
   Jeremiah P. Depta, Frederick G.P. Welt

10. **Ventricular Pathophysiology**  
    Michael J. Lim

### PRINCIPLES AND CATHETER LABORATORY

### EQUIPMENT

11. **Operational Radiation Management for Patients and Staff**  
    Louis K. Wagner

12. **Computed Tomography of the Coronary Arteries**  
    Koen Nieman

13. **Intracardiac Echocardiography in the Catheterization Laboratory**  
    Koen Nieman, David P. Lee, Frank E. Silvestry

14. **Cardiac Catheterization Laboratory Physiologic Recorders**  
    John W. Hirshfeld, Jr.

### PHARMACOLOGY

15. **Antithrombin Therapies**  
    Vedant A. Gupta, David J. Moliterno

16. **Antiplatelet Therapies in Contemporary Percutaneous Coronary Intervention**  
    Sasanka Jayasuriya, Steven Pfau

17. **Thrombolytic Therapy**  
    Ryan J. McDonough, James E. Tcheng

18. **Radiographic Contrast Media**  
    Kreton Mavromatis, S. Tanveer Rab
19. Renal Complications of Contrast Media  
   Anand Prasad, Peter A. McCullough

20. Contemporary Patient Sedation and Anesthesia in the Cardiovascular Catheterization Laboratory  
   Igor O. Zhukov, Kathryn E. Glas, Deborah Dunn, Vasilis Babaliaros

IV PROCEDURES

21. Coronary and Left Ventriculographic Procedures: Special Considerations  
   Morton J. Kern, Spencer B. King III

22. Radial Approach to Coronary Angiography  
   Jennifer A. Tremmel

23. Peripheral Angiography  
   Jose A. Silva

   William F. Fearon

25. Adjunctive Diagnostic Techniques: Intravascular Ultrasound, Optical Coherence Tomography, and Spectroscopy  
   Yuhei Kobayashi, Peter J. Fitzgerald, Yasuhiro Honda

26. Emerging Clinical Applications of Physiologic and Intravascular Imaging Tools  
   Olivia Y. Hung, Bill D. Gogas, Habib Samady

27. Coronary Guidewire Manipulation  
   J. Dawn Abbott, David O. Williams

28. Coronary Balloon Angioplasty  
   Ziyad Ghazzal

29. Basic Stent Deployment Techniques  
   Stephen G. Ellis

30. Drug-Eluting Coronary Stents  
   Arie Steinvil, Ron Waksman
31. **Special Stents: Bioresorbable Coronary Scaffolds**  
   Bill D. Gogas, Habib Samady

32. **Drug-Coated Balloon Technologies: Technical Features and Clinical Applications**  
   Juan F. Granada, Yanping Cheng, Bruno Scheller

33. **In-Stent Restenosis**  
   Gennaro Giustino, Roxana Mehran

34. **Coronary Atherectomy: Concepts and Practice**  
   Creighton W. Don, Lou Vadlamani, Mark Reisman

35. **Percutaneous Coronary Intervention in Chronic Total Occlusion**  
   James M. McCabe, William L. Lombardi

36. **Intervention in Venous and Arterial Grafts**  
   John S. Douglas, Jr.

37. **Special Considerations: ST-Segment Elevation Myocardial Infarction**  
   Rahul Sharma, Bruce R. Brodie, Timothy D. Henry

38. **Complex Lesion Intervention: Bifurcation, Left Main Coronary Artery, and Ostial Lesions**  
   Pil Hyung Lee, Jung-Min Ahn, Seung-Jung Park

39. **Special Considerations: Small Vessel and Diffuse Disease**  
   James B. Hermiller, Evan T. Russell

40. **Special Patient Subset: Diabetes Mellitus**  
   Mark L. Villalon, Zoran S. Nedeljkovic, Alice K. Jacobs

41. **Inoue-Balloon Mitral Valvuloplasty**  
   Jui-Sung Hung, Kean-Wah Lau, Alan C. Yeung

41A. **Aortic Valvuloplasty**  
   Ayaz Rahman, Alain Cribier, Vasilis Babaliaros

42. **Patient Selection, Procedural Techniques, and Complications of Balloon-Expandable Transcatheter Aortic Valve Replacement**  
   Ayaz Rahman, Alain Cribier, Vasilis Babaliaros

43. **Balloon-Expandable Transcatheter Aortic Valve Replacement**
Hemal Gada, Susheel Kodali

44. **Clinical Outcomes With Self-Expanding Transcatheter Aortic Valve Bioprostheses**  
   Jeffrey J. Popma

45. **Pulmonary Balloon Valvuloplasty and Percutaneous Pulmonary Valve Implantation**  
   Mike Saji, D. Scott Lim

46. **An Overview of the MitraClip Procedure: Practical Considerations and Evidence Base**  
   Abhimanyu Uberoi, Rahul Sharma, Saibal Kar

47. **Percutaneous Left Atrial Appendage Closure**  
   Jacqueline Saw, Maurice Buchbinder

48. **Percutaneous Closure of Atrial Septal Defect and Patent Foramen Ovale**  
   David P. Lee, Stanton B. Perry

49. **Alcohol Septal Ablation in Drug-Refractory Obstructive Hypertrophic Cardiomyopathy**  
   John S. Douglas Jr.

50. **Device Retrieval Systems**  
   Kirk N. Garratt

51. **Percutaneous Treatment of Coronary Artery Fistula**  
   Sanford Zeigler, Michael D. Dake

52. **Renal Artery Angioplasty and Stenting**  
   Christopher J. White, Jose David Tafur-Soto

53. **Renal Denervation: Pathophysiology, Techniques, and Clinical Data**  
   Frank E. Corrigan III, Chandan M. Devireddy

54. **Peripheral Arterial Disease**  
   Enrique A. Flores, Khusrow Niazi

55. **Treatment of Chronic Venous Disease of the Lower Extremity**  
   Edward G. Mackay, Khusrow Niazi

56. **Endovascular Therapies for Abdominal Aortic Aneurysm**
Ehrin J. Armstrong, John R. Laird

57. Carotid and Vertebral Artery Intervention
Christopher J. White

V COMPLICATIONS AND MANAGEMENT

58. Risk Stratification in Interventional Cardiology
Mandeep Singh, Mohammed Al-Hijji, Nadeem Khan

59. Bleeding Risk Scores
Mikkel Malby Schoos, Roxana Mehran, George Dangas

60. Stent Thrombosis
Sorin J. Brener, Gregg W. Stone

61. Coronary Artery Perforation
James R. Margolis

62. Embolization and No-Reflow During Percutaneous Coronary Intervention
Ted Feldman, Timothy A. Sanborn, Carl L. Tommaso

63. Emergency Surgery Following Percutaneous Coronary Intervention
Michael A. Kutcher

64. Emergency Resuscitation Measures
Ramin Hastings, Ajay J. Kirtane

VI MEDICAL MANAGEMENT OF RISK FACTORS

65. Guideline-Directed Medical Therapy for Patients With Stable Ischemic Heart Disease
Jonathan D. Newman, David J. Maron

66. Appropriate Use Criteria for Revascularization
Lloyd W. Klein
67. Preclinical Laboratory Functions
   Freddy Abnousi, Keith A. Robinson, Nicolas A. F. Chronos, Robert S. Schwartz

68. Cell Therapy for Cardiovascular Diseases
   Jia Shen, Timothy D. Henry, Arshed A. Quyyumi

69. The Core Laboratory: Quantitative Coronary Angiography
   Vivian G. Ng, Alexandra J. Lansky, Johan H. Reiber

70. Reading Clinical Trials
   Manesh R. Patel, David E. Kandzari, Rohan Shah, Robert A. Harrington

71. Publishing Interventional Cardiology Research
   Spencer B. King III

REIMBURSEMENT AND HOSPITAL FINANCE

72. Cost-Effectiveness in Interventional Cardiology
   Pranav Kansara, Sandra Weiss, William S. Weintraub

73. Quality Assurance and Quality Improvement in Interventional Cardiology
   H. Vernon Anderson

PRINCIPLES OF INNOVATION

74. Innovation and Interventional Cardiology: Looking Back, Thinking Ahead
   William R. Overall, Paul G. Yock

75. Principles of Innovation: Transforming Clinical Needs into Viable
Inventions
Joshua Makower, Asha Nayak, Lyn Denend

76. Web-Based Learning
Lawrence W. Gimple

77. Medical Simulation in Interventional Cardiology
Andrew Klein, John C. Messenger

Index
Contributors

J. Dawn Abbott, MD (Chapter 27)
Cardiovascular Institute
Rhode Island Hospital
Providence, Rhode Island

Freddy Abnousi, MD, MBA, MSc (Chapter 67)
Postdoctoral Medical Fellow, Cardiovascular Medicine
Stanford University Medical Center
Stanford, California

Islam Abudayyeh, MD, MPH (Chapter 3)
Assistant Professor of Medicine
Division of Cardiology, Interventional Cardiology
Loma Linda University Health
Loma Linda, California

Julien Adjedj, MD (Chapter 7)
Cardiovascular Center Aalst
Aalst, Belgium

Jung-Min Ahn, MD (Chapter 38)
Assistant Professor, Heart Institute of Asan Medical Center
University of Ulsan College of Medicine
Seoul, South Korea

Mohammed Al-Hijji, MD (Chapter 58)
Professor of Medicine
Division of Cardiovascular Diseases and Internal Medicine
Mayo Clinic College of Medicine
Rochester, Minnesota
H. Vernon Anderson, MD, FACC, FSCAI, FAHA (Chapter 73)
Cardiology Division
University of Texas Health Science Center
McGovern Medical School
Memorial Hermann Heart & Vascular Institute
Houston, Texas

Ehrin J. Armstrong, MD (Chapter 56)
Associate Professor of Medicine
Director, Interventional Cardiology
Denver VA Medical Center
University of Colorado School of Medicine
Denver, Colorado

Ganesh Athappan, MD (Chapter 4)
Department of Cardiovascular Medicine
Mount Sinai Hospital
New York, New York

Vasilis Babaliaros, MD (Chapters 20, 41A, and 42)
Associate Professor, Department of Medicine, Division of Cardiology
Co-director, Structural Heart and Valve Center
Emory University Hospitals
Atlanta, Georgia

Sorin J. Brener, MD, FACC (Chapter 60)
Professor of Medicine
Director, Cardiac Catheterization Laboratory
New York Methodist Hospital
Brooklyn, New York

Bruce R. Brodie, MD (Chapter 37)
Cone Health and LeBauer Cardiovascular Research Foundation
Greensboro, North Carolina

Maurice Buchbinder, MD (Chapter 47)
Director, Foundation for Cardiovascular Medicine
San Diego, California
Clinical Professor of Medicine (Cardiovascular)
Stanford University
Stanford, California

Blase A. Carabello, MD (Chapter 8)
Professor and Chief, Division of Cardiology
Department of Cardiovascular Sciences
Brody School of Medicine
East Carolina University
Greenville, North Carolina

Yanping Cheng, MD (Chapter 32)
Assistant Director of Cardiovascular Imaging
Skirball Center for Innovation
Cardiovascular Research Foundation
Orangeburg, New York

Nicolas A. F. Chronos, MD, FRCP, FACC, FESC, FAHA (Chapter 67)
Cardiology Care Clinic
Eatonton, Georgia

Frank E. Corrigan, III, MD (Chapter 53)
Clinical Cardiology Fellow, PGY-6
Emory University School of Medicine
Atlanta, Georgia

Alain Cribier, MD (Chapters 41A and 42)
Professor, Cardiology
Charles Nicolle Hospital
Rouen, France

Michael D. Dake, MD (Chapter 51)
Thelma and Henry Doelger Professor of Cardiovascular Surgery
Stanford University School of Medicine
Stanford, California

**George Dangas, MD, PhD (Chapter 59)**
Professor of Cardiology and Vascular Surgery
Director, Cardiovascular Innovation
The Marie-Josee and Henry R. Kravis Center for Cardiovascular Health
Icahn School of Medicine at Mount Sinai
New York, New York

**Bernard De Bruyne, MD, PhD (Chapter 7)**
Cardiovascular Center Aalst
Aalst, Belgium

**Lyn Denend, MBA (Chapter 75)**
Director, Academic Programs
Stanford Biodesign
Stanford, California

**Jeremiah P. Depta, MD, MPHS (Chapter 9)**
Rochester Regional Health
Rochester, New York

**Chandan M. Devireddy, MD (Chapter 53)**
Associate Professor of Medicine
Department of Medicine
Assistant Interventional Cardiology Fellowship Director
Emory University School of Medicine
Atlanta, Georgia

**Creighton W. Don, MD, PhD (Chapter 34)**
Associate Professor of Medicine
Director of the Interventional Cardiology and Structural Heart Fellowships
Division of Cardiology
University of Washington Medical Center
Seattle, Washington
John S. Douglas, Jr., MD (Chapters 36 and 49)
Professor of Medicine
Director, Interventional Cardiology Fellowship Program
Emory University School of Medicine
Emory University Hospital
Atlanta, Georgia

Deborah Dunn, RN, BSN (Chapter 20)
Emory University Hospitals
Atlanta, Georgia

Stephen G. Ellis, MD (Chapter 29)
Director of Interventional Cardiology
Senior Academic Officer
Professor of Medicine
Lerner College of Medicine
Cleveland Clinic
Cleveland, Ohio

William F. Fearon, MD (Chapters 2 and 24)
Professor of Medicine
Director of Interventional Cardiology
Stanford University School of Medicine
Stanford, California

Ted Feldman, MD, FACC, MSCAI (Chapter 62)
NorthShore University HealthSystem
Evanston, Illinois

Angela Ferrara, MD (Chapter 7)
Cardiovascular Center Aalst
Aalst, Belgium

Peter J. Fitzgerald, MD, PhD, FACC (Chapter 25)
Professor of Medicine and Engineering (Courtesy)
Director, Cardiovascular Core Analysis Laboratory
Division of Cardiovascular Medicine, Stanford University School of Medicine
Stanford, California

**Enrique A. Flores, MD, FACC (Chapter 54)**
Interventional Cardiologist
Georgia Heart Specialists
Covington, Georgia

**Hemal Gada, MD, MBA (Chapter 43)**
Rutgers Robert Wood Johnson Medical School
New Brunswick, New Jersey

**Kirk N. Garratt, MSc, MD, FACC, FS/CAI (Chapter 50)**
John H. Ammon Chair, Cardiology
Associate Director, Center for Heart and Vascular Health
Christiana Care Health System
Newark, Delaware

**Ziyad Ghazzal, MD, FACC, FS/CAI (Chapter 28)**
Professor of Medicine
Deputy Vice President/Dean
Associate Dean for Clinical Affairs
American University of Beirut Faculty of Medicine and Medical Center
Beirut, Lebanon
Adjunct Professor, Emory University School of Medicine
Atlanta, Georgia

**Lawrence W. Gimple, MD (Chapter 76)**
Professor, Cardiovascular Division,
Department of Medicine
University of Virginia
Charlottesville, Virginia

**Gennaro Giustino, MD (Chapter 33)**
The Zena and Michael A. Wiener Cardiovascular Institute
Mount Sinai Medical Center
New York, New York

Kathryn E. Glas, MD, FASE, MBA (Chapter 20)
Professor, Anesthesiology
Director, Cardiothoracic Anesthesiology
Emory University School of Medicine
Atlanta, Georgia

Bill D. Gogas, MD, PhD, FACC (Chapters 1, 26, and 31)
Andreas Gruntzig Cardiovascular Center, Department of Medicine
Division of Cardiology, Emory University School of Medicine
Atlanta, Georgia

Juan F. Granada, MD (Chapter 32)
Skirball Center for Innovation
Cardiovascular Research Foundation
Orangeburg, New York

Vedant A. Gupta, MD (Chapter 15)
Fellow, Cardiovascular Diseases
University of Kentucky
Lexington, Kentucky

Robert A. Harrington, MD, FACC, FAHA (Chapter 70)
Arthur L. Bloomfield Professor of Medicine
Chairman, Department of Medicine
Stanford University School of Medicine
Stanford, California

Ramin Hastings, MD (Chapter 64)
Herbert and Sandi Feinberg Interventional Cardiology and Heart Valve Center
Columbia University Medical Center/New York-Presbyterian Hospital
New York, New York
Cardiovascular Research Foundation
New York, New York

Timothy D. Henry, MD (Chapters 37 and 68)
Director, Division of Cardiology
Lee and Harold Kapelovitz Chair in Research Cardiology
Cedars-Sinai Heart Institute
Cedars-Sinai Medical Center
Los Angeles, California

James B. Hermiller, MD, FACC, FASCI (Chapter 39)
Interventional Cardiology
St. Vincent’s Medical Group
Indianapolis, Indiana

John W. Hirshfeld, Jr., MD (Chapter 14)
Professor of Medicine
University of Pennsylvania School of Medicine
Cardiac Catheterization Laboratory
Philadelphia, Pennsylvania

Yasuhiro Honda, MD, FACC, FAHA (Chapter 25)
Clinical Associate Professor of Medicine
Co-Director, Cardiovascular Core Analysis Laboratory
Division of Cardiovascular Medicine, Stanford University School of Medicine
Stanford, California

Jui-Sung Hung, MD, FACC, FAHA (Chapter 41)
Professor of Medicine
China Medical University
Chung Shan Medical University
Taichung, Taiwan

Olivia Y. Hung, MD, PhD (Chapter 26)
Cardiovascular Fellow
Department of Medicine
Alice K. Jacobs, MD (Chapter 40)
Professor of Medicine
Boston University School of Medicine
Vice Chair of Clinical Affairs, Department of Medicine
Boston Medical Center
Boston, Massachusetts

Sasanka Jayasuriya, MD, FACC, FASE (Chapter 16)
Clinical Instructor
Yale University School of Medicine
New Haven, Connecticut

Brian W. Kaebnick, MD (Chapter 1)
Andreas Gruentzig Cardiovascular Center, Department of Medicine
Division of Cardiology, Emory University School of Medicine
Atlanta, Georgia

David E. Kandzari, MD (Chapter 70)
Director, Interventional Cardiology and Chief Scientific Officer
Piedmont Heart Institute
Atlanta, Georgia

Pranav Kansara, MD, MS (Chapter 72)
Department of Cardiology
Christiana Care Health System
Newark, Delaware

Samir R. Kapadia, MD (Chapter 4)
Department of Cardiovascular Medicine
Cleveland Clinic
Cleveland, Ohio

Saibal Kar, MD (Chapter 46)
Associate Director, Cardiovascular Intervention Center
Director, Interventional Cardiology Fellowship Program
Director, Interventional Cardiac Research
Cedars-Sinai Medical Center
Los Angeles, California

**Morton J. Kern, MD (Chapter 21)**
Professor
School of Medicine
Chief of Medicine
VA Long Beach Health Care System
University of California, Irvine
Long Beach, California

**Nadeem Khan, MBBS (Chapter 58)**
Mayo Clinical Health System
Hospital and Clinic
Mankato, Minnesota

**Spencer B. King III, MD (Chapters 1, 21, and 71)**
Professor of Medicine, Emeritus
Emory University School of Medicine
Founding Editor, *JACC: Cardiovascular Interventions*
Atlanta, Georgia

**Ajay J. Kirtane, MD, SM (Chapter 64)**
Herbert and Sandi Feinberg Interventional Cardiology and Heart Valve Center
Columbia University Medical Center/New York-Presbyterian Hospital
New York, New York
Cardiovascular Research Foundation
New York, New York

**Andrew Klein, MD, FACC, FSCAI (Chapter 77)**
Staff Interventional Cardiologist
Vascular and Endovascular Medicine
Piedmont Heart Institute
Atlanta, Georgia
Adjunct Professor of Medicine
St. Louis University School of Medicine
St. Louis, Missouri

Lloyd W. Klein, MD, FACC (Chapter 66)
Professor of Medicine
Rush Medical College
Chicago, Illinois

Yuhei Kobayashi, MD (Chapter 25)
Division of Cardiovascular Medicine
Stanford University School of Medicine
Stanford, California

Susheel Kodali, MD (Chapter 43)
Herbert and Sandi Feinberg Interventional Cardiology and Heart Valve Center
Columbia University Medical Center/New York-Presbyterian Hospital
New York, New York

Michael A. Kutcher, MD, FACC, FS urge (Chapter 63)
Professor of Internal Medicine
Director, Interventional Cardiology
Wake Forest School of Medicine
Winston-Salem, North Carolina

John R. Laird, MD (Chapter 56)
Professor of Medicine
Medical Director of the Vascular Center
University of California Davis Medical Center
Sacramento, California

Alexandra J. Lansky, MD, FACC, FAHA, FS urge, FESC (Chapter 69)
Professor of Medicine (Cardiology)
Director, Yale Cardiovascular Clinical Research Program
Yale University School of Medicine
New Haven, Connecticut
Honorary Reader
University College London
London, England

Kean-Wah Lau, MBBS, MMed, FRCP, FACC (Chapter 41)
Consultant Cardiologist
Associate Professor of Medicine
National University of Singapore
Singapore

David P. Lee, MD (Chapters 13 and 48)
Associate Professor of Medicine (Cardiovascular)
Director, Interventional Cardiology Fellowship Program
Director, Cardiac Catheterization and Intervention Laboratories
Stanford University Medical Center
Stanford, California

Pil Hyung Lee, MD (Chapter 38)
Fellow, Interventional Cardiology
Heart Institute of Asan Medical Center
University of Ulsan College of Medicine
Seoul, South Korea

D. Scott Lim, MD (Chapter 45)
Advanced Cardiac Valve Center
Department of Medicine, Division of Cardiovascular Medicine
University of Virginia
Charlottesville, Virginia

Michael J. Lim, MD (Chapter 10)
Jack Ford Shelby Endowed Professor
Director, Division of Cardiology
St. Louis University School of Medicine
St. Louis, Missouri

William L. Lombardi, MD, FACC, FSCT (Chapter 35)
Associate Clinical Professor of Medicine, Division of Cardiology
Director, Complex Coronary Artery Disease Therapies
University of Washington Medical Center
Seattle, Washington

Edward G. Mackay, MD (Chapter 55)
Private Practice
St. Petersburg, Florida

Joshua Makower, MD (Chapter 75)
Adjunct Professor, Medicine–Cardiovascular Medicine
Stanford University School of Medicine
Stanford, California
Chairman and Chief Executive Officer
ExploraMed, Inc.
Mountain View, California

James R. Margolis, MD (Chapter 61)
Miami International Cardiology Consultants
Miami Beach, Florida
Division of Cardiology
University of Miami Hospital
University of Miami Health System
Miami, Florida

David J. Maron, MD (Chapter 65)
Clinical Professor of Medicine (Cardiovascular)
Director, Preventive Cardiology
Stanford University School of Medicine
Stanford, California

Kreton Mavromatis, MD (Chapter 18)
Associate Professor of Medicine
James M. McCabe, MD (Chapter 35)
Medical Director, University of Washington Cardiac Cath Labs
University of Washington Medical Center
Seattle, Washington

Peter A. McCullough, MD, MPH, FACC, FACP, FCCP, FAHA, FNKF (Chapter 19)
Baylor University Medical Center
Baylor Heart and Vascular Institute
Baylor Jack and Jane Hamilton Heart and Vascular Hospital
Dallas, Texas
The Heart Hospital
Plano, Texas

Ryan J. McDonough, DO, FACC (Chapter 17)
Chief, Cardiology
William Beaumont Army Medical Center
El Paso, Texas

Roxana Mehran, MD, FACC, FACP, FCCP, FESC, FAHA, FSCAI (Chapters 33 and 59)
Professor of Medicine
Mount Sinai School of Medicine
Director of Interventional Cardiovascular Research and Clinical Trials
Zena and Michael A. Weiner Cardiovascular Institute
Mount Sinai Medical Center
New York, New York

John C. Messenger, MD, FACC, FSCAI (Chapter 77)
Director, Cardiac Catheterization Labs
David J. Moliterno, MD (Chapter 15)
Jack M. Gill Chair and Professor of Medicine
Vice Dean for Clinical Affairs
College of Medicine
University of Kentucky
Lexington, Kentucky

Asha Nayak, MD, PhD (Chapter 75)
Chief Medical Officer
Intel Corporation
Department of Emergency Medicine
Stanford University School of Medicine
Stanford, California

Zoran S. Nedeljkovic, MD (Chapter 40)
Assistant Professor of Medicine
Boston University School of Medicine
Interventional Cardiologist
Boston Medical Center
Boston, Massachusetts

Jonathan D. Newman, MD, MPH (Chapter 65)
Instructor of Medicine
Division of Cardiology and
The Center for the Prevention of Cardiovascular Disease
New York University School of Medicine
New York, New York

Vivian G. Ng, MD (Chapter 69)
Instructor in Medicine
Department of Medicine
Khusrow Niazi, MD, FACC (Chapters 54 and 55)
Associate Professor of Medicine
Emory University School of Medicine
Division of Cardiovascular Medicine
Atlanta, Georgia

Koen Nieman, MD, PhD (Chapters 12 and 13)
Cardiovascular Institute
Stanford University School of Medicine
Stanford, California
Departments of Cardiology and Radiology
Erasmus University Medical Center
Rotterdam, The Netherlands

William R. Overall, PhD (Chapter 74)
Chief Technology Officer
HeartVista, Inc.
Menlo Park, California

Seung-Jung Park, MD, PhD (Chapter 38)
Chairman, Heart Institute of Asan Medical Center
University of Ulsan College of Medicine
Seoul, South Korea

Manesh R. Patel, MD (Chapter 70)
Associate Professor of Medicine
Member, Duke Clinical Research Institute
Chief, Division of Cardiology
Chief, Division of Clinical Pharmacology
Duke University School of Medicine
Durham, North Carolina
Stanton B. Perry, MD (Chapter 48)
Associate Professor of Pediatrics (Cardiology)
Lucille Salter Packard Children’s Hospital
Director, Pediatric Cardiac Catheterization Laboratory
Stanford University Medical Center
Stanford, California

Steven Pfau, MD, FACC, FSCAI (Chapter 16)
Associate Professor of Medicine
Yale University School of Medicine
New Haven, Connecticut
Director, Cardiac Catheterization Lab
VA Connecticut Cardiology
West Haven, Connecticut

Nico H.J. Pijls, MD, PhD (Chapter 6)
Professor of Cardiology
Department of Cardiology
Catharina Hospital Eindhoven
Eindhoven, The Netherlands

Jeffrey Popma, MD (Chapter 44)
Director, Interventional Cardiology
Department of Internal Medicine (Cardiovascular Division)
Beth Israel Deaconess Medical Center
Boston, Massachusetts

Anand Prasad, MD, FACC, FSCSAI, RPVI (Chapter 19)
Associate Professor of Medicine
Director, Cardiovascular Disease Fellowship Program
Division of Cardiology, Department of Medicine
University of Texas Health Science Center at San Antonio
San Antonio, Texas

Arshed A. Quyyumi, MD (Chapter 68)
Emory Clinical Cardiovascular Research Institute
Emory University School of Medicine
Atlanta, Georgia

S. Tanveer Rab, MD (Chapter 18)
Associate Professor of Medicine
Emory Heart & Vascular Center at Royston
Royston, Georgia

Ayaz Rahman, MD (Chapters 41A and 42)
Structural Heart and Valve Center
Emory University Hospitals
Atlanta, Georgia

Johan H. Reiber, PhD (Chapter 69)
Professor of Medical Imaging
Division of Image Processing
Department of Radiology
Leiden University Medical Center
Leiden, The Netherlands

Mark Reisman, MD, FACC (Chapter 34)
Clinical Professor of Medicine
Section Head, Interventional Cardiology
Director, Cardiovascular Emerging Therapies
University of Washington Medical Center
Seattle, Washington

Keith A. Robinson, PhD† (Chapter 67)
Principal Scientist, Preclinical Division
American Cardiovascular Research Institute
Norcross, Georgia

Evan T. Russell, MD (Chapter 39)
Hospitalist
St. Vincent’s Medical Group
Indianapolis, Indiana
Mike Saji, MD (Chapter 45)
Advanced Cardiac Valve Center
Department of Medicine, Division of Cardiovascular Medicine
University of Virginia
Charlottesville, Virginia

Habib Samady, MD, FACC, FSCAI (Chapters 26 and 31)
Professor of Medicine
Emory University School of Medicine
Director, Cardiac Catheterization Laboratory, Emory University Hospital
Director, Interventional Cardiology, Emory University Hospitals
Andreas Gruentzig Cardiovascular Center
Atlanta, Georgia

Timothy A. Sanborn, MD, FACC, FSCAI (Chapter 62)
NorthShore University HealthSystem
Evanston, Illinois

Jacqueline Saw, MD, FRCP, FACC, FAHA, FSCAI (Chapter 47)
Interventional Cardiology
Clinical Associate Professor
Vancouver General Hospital
Vancouver, British Columbia, Canada

Bruno Scheller, MD (Chapter 32)
Klinische und Experimentelle Interventionelle Kardiologie
Universität des Saarlandes
Homburg, Germany

Mikkel Malby Schoos, MD (Chapter 59)
Rigshospitalet
University of Copenhagen
Copenhagen, Denmark

Robert S. Schwartz, MD (Chapter 67)
Medical Director
Minnesota Cardiovascular Research Institute
Minneapolis, Minnesota

Rohan Shah, MD (Chapter 70)
PGY-1, Department of Internal Medicine
Johns Hopkins Hospital
Baltimore, Maryland

Rahul Sharma, MD (Chapter 37)
Cedars-Sinai Heart Institute
Los Angeles, California

Rahul Sharma, MD (Chapter 46)
Interventional Cardiologist
Winston-Salem, North Carolina

Jia Shen, MD, MPH (Chapter 68)
Emory Clinical Cardiovascular Research Institute
Emory University School of Medicine
Atlanta, Georgia

Jose A. Silva, MD (Chapter 23)
Department of Cardiology
Ochsner Clinic Foundation
New Orleans, Louisiana

Frank E. Silvestry, MD (Chapter 13)
Director, Penn Cardiovascular Disease Fellowship
Associate Professor of Medicine
Hospital of the University of Pennsylvania
Philadelphia, Pennsylvania
Penn Cardiology/Penn Medicine Radnor
Radnor, Pennsylvania

It is with great pleasure that I introduce a superb addition to the “modern era” cardiovascular educational literature, the Second Edition of Interventional Cardiology, co-edited by Drs. Samady, Fearon, Yeung, and King. This updated and comprehensive textbook brings to life the full breadth of interventional cardiovascular medicine. It will become a mandatory resource for the broad community of healthcare professionals in this expanding and evolving subspecialty.

During the 40th year anniversary of the first PCTA and the 15th year anniversary of the first TAVR, it is timely to reflect on the dramatic changes that have shaped interventional cardiology over time. The original dream of Andreas Gruentzig in 1977 was to achieve catheter-based percutaneous treatment of vascular disease in alert, awake patients, a dream that was considered heresy by some and fanciful by most cogent observers. Over four decades of determined iteration, refinement, and innovation, the use of less invasive, transcatheter (non-surgical) diagnosis, and therapy has transformed medicine. To extend Gruentzig’s dream to widespread clinical practice required: (1) an evolution in technologies (from balloons to stents with local drug delivery); (2) the development of clinical research methodologies (evidence-based clinical trials and resulting society guidelines); (3) improvements in operator skills with a focus on life-long training; (4) the adoption of new practice management strategies (including optimal use of adjunctive pharmacotherapy and the application of diagnostic intravascular imaging and physiology to direct therapy decisions); (5) an expansion of interventional concepts to new nonvascular clinical targets such as structural heart disease (best embodied by the TAVR breakthrough technology); and (6) acceptance that a multi-disciplinary Heart Team approach should become the standard for optimal diagnosis and treatment of patients with complex cardiovascular disease.

This revised textbook Interventional Cardiology captures the aforementioned evolutionary journey with carefully organized content that is well illustrated and referenced and emphasizes practical aspects of
procedures, techniques, therapies, and clinical care pathways. The 9 sections and 78 chapters provide a remarkable in-depth compendium of the essential body of knowledge in interventional cardiology through 2017. Moreover, important ancillary topics such as medical management of risk factors, an understanding of evidence-based clinical trials, reimbursement and socioeconomic issues, and the principles of interventional device innovation are thoughtfully addressed. The co-editors of this impressive Second Edition of *Interventional Cardiology* should be congratulated for amassing a landmark reference that represents the most up-to-date, all-inclusive, and practical resource of its kind, which undoubtedly will be embraced by interventionalists around the world.

Martin B. Leon, MD
Professor of Medicine, Columbia University/New York Presbyterian Hospital
Director, Center for Interventional Vascular Therapy
Founder, Cardiovascular Research Foundation and Transcatheter Cardiovascular Therapeutics
New York, New York
The first edition of this textbook was published 10 years ago because Alan Yeung and I recognized that the field of interventional cardiology had matured enough to warrant a comprehensive exploration of the discipline. I was serving as chair of the writing group for the American Board of Internal Medicine Interventional Cardiology board at the time and was aware that the questions that we were asking needed a text that could provide answers from experts who were generating those answers. Alan succeeded me as chair of the board test writing group, and the job has increased greatly because of the expansion of the discipline.

To collate much of the current knowledge pertinent to interventional cardiology, we now have enlisted two of our colleagues, Habib Samady and Bill Fearon, who have become leaders in the specialty, to join us in updating or, more appropriately, redoing *Interventional Cardiology*. Of course, no textbook can provide the latest trial results, and in the age of information technology, some even question the value of textbooks. As an editor of *JACC: Cardiovascular Interventions*, I have often said that review papers should be different from book chapters. This is true but should not denigrate book chapters. A book chapter on a targeted subject forces authors to concisely focus attention to what they perceive to be the pertinent knowledge base about that subject. That base of knowledge is necessary if results of new findings are to be correctly interpreted and their influence on practice properly evaluated. History teaches us that we must know what went on before if we are to understand the present. This is the purpose of this book: to provide the current base of knowledge that is necessary but not completely sufficient to become an expert in interventional cardiovascular medicine. To become and remain an expert requires not only the current knowledge but also the continued learning from new evidence. To that end, this book will be accompanied by periodic updates that will be available electronically. We believe that new evidence in isolation, without the background, may often be misleading.

The book is organized into nine sections with chapters geared to the
current needs thoughtfully chosen by the chapter authors. Each chapter is followed by a set of questions that focus on the main points of the topic addressed by the chapter. These questions are not intended to replace courses specifically targeted to the objective of preparing for examinations. Nonetheless, we believe that this method of asking what we have learned from a discussion is a helpful tool. Growth in interventional cardiology training and practice is perhaps best reflected in the largest section of the book, which deals with interventional procedures. In this section, 29 chapters in the first edition have increased to 38 chapters with expanded coverage of radial approach, chronic total occlusion intervention methods, and structural heart disease interventions. New chapters on the MitraClip procedure and atrial appendage occlusion, and three chapters covering patient selection and procedural techniques for transcatheter aortic valve implantation headline all the amazing advances that have occurred in the treatment of structural heart disease. Likewise, important advances in peripheral vascular interventions are emphasized. More than other digestible sources, this book also provides concise explanations of evolving concepts in intravascular physiology and imaging that inform current practice and underlie research and development efforts in stenting and bioabsorbable scaffold technology, as well as evolving pharmacological approaches to control thrombosis, restenosis, and neoatherosclerosis. There are other expanded chapters on healthcare economics and methods for achieving innovation.

This book is intended for all who are being trained in the discipline of interventional cardiology as well as those who practice this specialty and have trouble remembering all the background that relates to the patient whom they are currently treating. (Certainly true for many of us.) The perspectives of the carefully selected authors of these chapters will frequently be of value in making current judgments. In addition, any physician who wants to know the astonishing possibilities of, as well as the limitations of, interventional cardiology will benefit by referring to this volume for guidance.

INTRODUCTION

Surveying the landscape of interventional cardiology today, one sees a mature discipline using sophisticated technology and techniques that are backed by the findings of rigorous clinical trials. Many advancements have occurred in the field since the first angioplasty performed by Andreas Gruentzig in 1977. What began as a technique to treat a focal stenosis in patients with stable angina by physicians who performed diagnostic cardiac catheterizations has progressed to complex percutaneous interventions in unstable patients by highly trained and experienced operators. The work in coronary interventions also served as a catalyst for the development of therapies and technology to treat valvular heart disease with percutaneous valve replacement and repair. Understanding the history and development of interventional cardiology provides important insight and perspective to appreciate current practices as well as provide inspiration for future advancement of the field.

EARLY DEVELOPMENTS IN INVASIVE CARDIOLOGY
Many individual achievements provided the foundation for the development of interventional cardiology (Fig. 1-1). Werner Forssmann is credited as performing the first human cardiac catheterization in 1929 while working in Eberswalde, Germany.\(^1\) He was inspired by the works of French physiologists Bernard, Chauveau, and Marey, who measured the intracardiac pressures in horses by directly inserting catheters into the heart. He hypothesized that accessing the heart directly with a catheter would provide a safer mechanism to deliver therapeutic drugs. Unfortunately, he did not have the support of his department chief, who thought such a procedure was reckless and likely fatal. Despite his chief’s disapproval, he was unrelenting in his pursuit and decided to perform the procedure on himself. With the help of an unsuspecting nurse, he cut down to his left brachial vein and inserted a urinary catheter as far as it would go.
He then traveled with the nurse to the basement where the x-ray machine was located and documented the catheter location in the right atrium. His self-experimentation resulted in disciplinary action, and as a result, Forssmann was not able to pursue any further study on the subject.²

Much of the development of right heart catheterization and hemodynamic assessment is credited to the work of Andre Cournand and Dickinson Richards at Bellevue Hospital in New York, which resulted in a 1956 Nobel Prize in Medicine that was shared with Forssmann.

Refinements in right heart catheterization over the next 2 decades eventually led to the desire to better understand left heart hemodynamics and
valvular function through catheterization. After working out much of the
details of accessing the left ventricle in a canine model, Henry Zimmerman
performed the first left heart catheterization on a human in 1950 via a radial
artery approach in Cleveland, Ohio. Early left heart catheterizations
consisted of hemodynamic assessments and injection of contrast into the
ventricle and aorta to assess left ventricular function and valvular disease.
The coronary arteries were indirectly assessed by these methods but were not
adequate for diagnostic quality. The concern was that the contrast media
would cause ischemia and ventricular fibrillation. The need to obtain
diagnostic assessment of coronary blockages, however, was becoming more
important with the advent of coronary artery bypass surgery.

Interestingly, the first direct coronary angiography occurred by mistake in
1958. While performing a routine left heart catheterization at the Cleveland
Clinic, Mason Sones pulled back across the aortic valve and prepared for an
aortogram. As the injection started, Dr. Sones noted the catheter tip was
directly engaged in the right coronary artery and filled the vessel with viscous
diatrizoic acid (Hypaque) contrast media before the catheter was able to be
removed. Fortunately, the patient did not develop ventricular fibrillation but
rather asystole, which was converted to sinus rhythm by having the patient
cough 3 or 4 times. Despite this near-fatal complication, Dr. Sones saw the
potential need for diagnostic angiography and was instrumental in developing
techniques to access and visualize coronary arteries.5,6

DEVELOPMENT OF ANGIOPLASTY

Up to this point in the mid-20th century, advancements in invasive
cardiology had been diagnostic, which still left therapies for coronary artery
and valvular disease in the hands of the surgeons while cardiologists
watched. This relationship, however, would soon change thanks to a
determined and somewhat controversial figure, Charles Dotter. A radiologist
by training, Dotter was well published in the field of angiocardiography and,
by age 32, was professor and chairman of the radiology department at
University of Oregon Medical School. He entered into the field of
interventional radiology by coincidence while attempting an abdominal
aortogram for an assessment of renal artery stenosis in 1963. Dotter advanced
his catheter through a stenotic right iliac artery in order to reach the aorta and,
in the process, recanalized the artery. He presented his findings at the Czechoslovak Radiologic Conference in June 1963 to a very receptive audience, where he concluded “the angiographic catheter can be more than a tool for passive means for diagnostic observation.”

He would return to the United States to further refine his technique of “Dottering” stenotic vessels with Melvin Judkins by designing specialized catheters to serially dilate stenotic lesions. His methods were not well received by surgeons in the United States despite successfully treating many patients and saving them from limb amputation. Even though Dotter had little support back home, his techniques were championed by Werner Porstmann in Berlin and Eberhard Zeitler in Engelskirchen, Germany. Zeitler would later teach Andreas Gruentzig this technique, who would go on to adapt the concept to coronary arteries.

Andreas Gruentzig’s initial training after medical school was in the field of epidemiology, but he soon became interested in peripheral vascular disease while studying at the Ratchow Clinic in Darmstadt, Germany. During his training, he became interested in Dotter’s technique in treating stenotic vessels. Gruentzig then moved to Zurich, Switzerland, to accept a position in the angiology department at the University Hospital. He quickly set out to begin the Dotter technique and invited Zeitler to Zurich to help perform his first dilation.

Despite embolizing plaque to the distal leg and obstructing flow, Gruentzig remained convinced of the promise of the procedure to treat atherosclerosis not only in the peripheral arteries but also in the heart. He recognized that the coronary arteries posed a much different challenge than the large and relatively straight peripheral vessels and that another technique besides serially dilating with a catheter was needed. Gruentzig’s answer to this challenge was a slender, steerable balloon-tipped catheter that could be inflated to expand the lesion.

He set out to design his catheter with his assistant Maria Schlumpf. Early attempts to construct the catheter took place at his kitchen table with the help of Maria’s husband, Walter, and Gruentzig’s wife, Michaela. He soon consulted with Dr. Hoph, a professor of chemistry at University of Zurich, who advised Gruentzig to use polyvinyl chloride to construct his balloon in order to maintain its desired shape and size. After some initial homemade prototypes, Gruentzig partnered with Schneider Needle Company to manufacture his balloon catheter. He tested his catheter in a dog model where
the discrete stenosis in the artery was created with silk ligature. Gruentzig was able to use his catheter to cross the stenosis and perform a balloon dilation to successfully treat the stenosis. He presented this proof of concept at the 1976 American Heart Association meeting to a lackluster response\(^{10}\) (Fig. 1-2).
Undeterred, Gruentzig was determined to use his technique to treat heart disease in humans and tried unsuccessfully to convince surgeons in Zurich to allow him to try his balloon angioplasty technique on patients undergoing bypass surgery. He eventually partnered with a cardiologist, Richard Myler, in San Francisco at St. Mary’s Hospital, who persuaded the cardiac surgeon, Elias Hanna, to test his procedure. After successfully performing the procedure in humans, Gruentzig returned to Zurich to treat patients in hopes of avoiding bypass surgery. His initial attempt was on a patient with complex disease, as well as severe peripheral vascular disease, which his catheter was not able to navigate, and the procedure was aborted. This setback illustrated the need for better lesion and patient selection to ensure success of this new procedure, and thus, Gruentzig started looking for lower risk patients without complex disease.

He soon found his next patient—a 38-year-old man with severe angina and a proximal discrete lesion. After discussing the experimental nature of the procedure with the patient and getting his consent, Gruentzig successfully performed his first balloon angioplasty procedure on September 16, 1977. The patient’s angina was successfully treated, and the patient did well after his procedure. The patient even underwent a follow-up heart catheterization in 1987 that demonstrated a patent vessel free of residual stenosis. Gruentzig successfully performed 4 more balloon angioplasties and presented his case series at the 1977 American Heart Association meeting. This meeting was a much different experience than the 1976 meeting; he presented to packed house and received a standing ovation. He would publish his early findings in *The Lancet* as a Letter to the Editor in February 1978.11

**EARLY ADOPTION OF BALLOON ANGIOPLASTY**

The success of Gruentzig’s balloon angioplasty technique ushered in a paradigm shift in approaching coronary disease, and cardiologists and
radiologists from around the world came to Zurich to learn the technique. Gruentzig knew that in order for his idea to remain successful that his technique must be properly taught to skilled operators rather than disseminated to the masses. He was worried that if careless physicians performed his procedure then fatal outcomes would doom his idea. Thus, Gruentzig established his first teaching course in 1978, where 28 physicians traveled to Zurich to watch him perform cases. While at the course, physicians learned how to perform the procedure, but just as important, they also were educated on the complications, pitfalls, and tricks to rescue a procedure. Gruentzig continued his teaching courses in Zurich, until he was recruited to come to Emory University, where his courses were continued until his untimely death in 1985 and beyond. Many other courses were also created to train the early adaptors of angioplasty. The first balloon angioplasties in the United States occurred simultaneously in San Francisco by Richard Myler and in New York by Simon Stertzer, so that neither individual would be the first to perform the procedure.12

As more physicians were taught balloon angioplasty and brought the technique to their practice, the equipment and techniques began to evolve to overcome some of the limitations of the procedure. Tortuous vessels and the inability to recross a lesion that had shut down during inflation led to the development of over-the-wire systems. John Simpson took this idea further by first crossing the lesion with a wire and then advancing the balloon over the wire. This allowed for the development of lower profile balloons and expanded the technique to stenosis in distal segments. As the technology and operator experience advanced, so did the success of the procedure as well as its ability to challenge bypass surgery. However, there had not been any definitive evidence to compare angioplasty to bypass surgery, a proven therapy. All the evidence for angioplasty consisted of an international registry established by the National Heart, Lung, and Blood Institute (NHLBI). To better understand the optimal treatment of coronary disease, the NHLBI awarded the first randomized controlled trial comparing angioplasty to bypass surgery in 1987.13

The Emory Angioplasty Versus Surgery Trial (EAST) demonstrated equivalent survival rates at 3 and 8 years.14 The EAST trial was followed by the Bypass Angioplasty Revascularization Investigation (BARI) trial, which also demonstrated no significant difference in mortality between the 2 procedures at 5 and 10 years.15-17 The only clinical difference was in the
revascularization rate after intervention, which was high for angioplasty. Despite this difference, these trials suggested that angioplasty was a safe and effective treatment for stable coronary disease.

As a result of the building evidence for balloon angioplasty in stable disease, Jurgen Meyer began investigating its use in acute coronary syndromes. Initially, it was used as an elective procedure performed to treat angina resulting from a residual stenosis after a myocardial infarction or as a rescue therapy for patients who failed thrombolysis. Geoffrey Hartzler then went on to use balloon angioplasty as an alternative to thrombolytic therapy, setting up later trials such as Primary Angioplasty in Myocardial Infarction (PAMI) and Global Use of Strategies to Open Occluded Coronary Arteries in Acute Coronary Syndromes (GUSTO IIb), which demonstrated a mortality improvement with angioplasty.\textsuperscript{19,20}

**TECHNOLOGICAL ADVANCEMENTS**

Although the concept of percutaneous intervention with balloon angioplasty was being expanded to more complex lesions, multivessel disease, and acute coronary syndrome, the procedure was not without limitations. Acute complications during the procedure such as vessel dissection and acute closure could occasionally be treated percutaneously with long balloon inflations; however, up to 12% of patients required urgent bypass surgery to rescue the vessel.\textsuperscript{21} Additionally, residual vessel stenosis and restenosis often required repeat interventions and prevented long-term success. These issues drove the need for an adjunctive therapy to help keep the vessel open. Although many new devices were developed for opening coronary obstructions, including atherectomy devices and lasers, they did not materially improve on the balloon. The idea of an endovascular scaffold or stent to maintain vessel patency was thought to be the best solution. Thus, multiple groups concurrently pursued the development of first-generation stent design across the world.

In the United States, an Argentinian-trained radiologist, Julio Palmaz, was inspired to develop a solution to the procedural failures of balloon angioplasty after attending a talk given by Gruentzig at the Society of Interventional Radiology meeting in New Orleans in 1978. He was further exposed to the balloon angioplasty equipment while training at University of
California at Davis, where he would wash the balloons after the procedures. After training, he took a position in San Antonio, Texas, where he had dedicated research time to further develop his stent idea. There, he was introduced to interventional cardiologist Richard Schatz, who helped refine his idea by suggesting an articulation connection of 2 stents to make the device more flexible. The first human implant of the Palmaz-Schatz stent occurred in Brazil in 1986. The stent was further studied in Europe in the BENESTENT and STRESS trials, which demonstrated a reduction of restenosis from 42% to 32%.\textsuperscript{22,23} The US Food and Drug Administration (FDA) gave initial approval to the Palmaz-Schatz stent in 1994 for short lesions in large-caliber vessels >3 mm, but its indications were eventually expanded to smaller vessels, vein grafts, and longer lesions.

In Europe, while working at the Centre Hospitalier Universitaire Vaudois in Lausanne, Switzerland, Ulrich Sigwart developed a woven self-expanding helical stent inspired by Chinese finger traps.\textsuperscript{24} This stent was eventually implanted in a patient in 1986 by Dr. Sigwart and Jacques Puel. Further use and development of this stent was put on hold, as Sigwart partnered with MedInvent, a subsidiary of Pfizer, which was currently dealing with ongoing valve failures with their Bjork-Shiley valve. This issue led Sigwart to partner with another company, ACS, and eventually develop a balloon-expandable stent, Multilink, which was more deliverable and steerable. The first human implant of the Multilink stent occurred in London in 1993; the Multilink was approved by the FDA in 1997 and, with slight modifications, is still in use today.

In the United States, Cesare Gianturco, an interventional radiologist, had already worked with Cook Inc. to develop a balloon-expandable coil stent to be used in peripheral arteries. He was interested in applying his coil stent design technology to coronary arteries. In our experimental lab, Gary Roubin and Keith Robinson at the Gruentzig Center tested his stent design in porcine coronary arteries.\textsuperscript{25} The first implant of his stent occurred at Emory Hospital in 1987 as part of a proposal submitted to the FDA for early feasibility. The proposal was designed for the coil stent to be used to treat patients with acute vessel closure during balloon angioplasty rather than sending to emergent bypass surgery. Based on the results of this proposal as well as other studies, the FDA approved commercial use of the stent in 1993.

Despite the success of stents to improve restenosis rate and treat acute closure of the arteries to avoid emergent bypass surgery, the early use of
stents, regardless of design, was plagued by acute stent thrombosis, which limited the widespread adaptation this new technology. To combat this issue, patients were maintained on heparin infusion and transitioned to aspirin and warfarin therapy, which often led to patients having a prolonged hospital course after stenting. Eventually, the strategy of dual antiplatelet therapy was established as the preferred method to prevent stent thrombosis in the mid-1990s.

Ticlopidine was initially used with aspirin, but hematologic disorders such as thrombotic thrombocytopenia purpura and neutropenia limited its use. Fortunately, clopidogrel was approved in 1997 and largely replaced ticlopidine.

In addition to better medical therapy, better procedural techniques and technology resulted in the understanding that stent underexpansion and malapposition were also key factors leading to stent thrombosis. Work by Antonio Colombo of Milan, Italy, and Jonathan Tobis from the University of California demonstrated that high-pressure poststent dilations led to better expansion and less malapposition within the vessel and reduced stent thrombosis risk. The development of intravascular ultrasound allowed for a better assessment of stent expansion and also helped reduce the risk of stent thrombosis.

Vessel restenosis due to intimal hyperplasia still remained a problem, even with properly deployed stents. Initial attempts to combat this process involved the use of radiation in the form of brachytherapy. This technique worked but was cumbersome due to the difficulty of handling radioactive materials in the catheterization lab. The concept then shifted to antiproliferative drugs applied to the stent itself. Many agents were tried to inhibit cell growth but failed to prevent restenosis. These included coating the stent with gold, silicon carbide, and hormone receptor blockers.

Eventually, sirolimus and paclitaxel were found to be effective agents to be applied to stents. The first drug-eluting stent, which was coated with sirolimus, was implanted in 1987. This stent would be further developed into the Cypher Stent (Cordis, San Francisco, CA) and gained approval for clinical use in 2002. Along with the Taxus Stent (Boston Scientific, Marlborough, MA), first-generation drug-eluting stents were compared to bare metal stents and were found to have a decreased rate of in-stent restenosis as well as need for revascularization.
Further advancements in stent technology resulted in more effective agents, such as everolimus and zotarolimus, as well as better techniques in applying the drug to further improve long-term outcomes. Stent technology continues to progress with development of fully resorbable stents called bioresorbable scaffolds.\textsuperscript{33}

**EVOLUTION OF STRUCTURAL CARDIOLOGY**

As the discipline of coronary intervention evolved so did the explorations into transcatheter approaches to valvular diseases. Rubio-Alvares and Limon-Lason performed the first valve intervention in 1952 in Mexico at the Instituto de Cardiologia using a ureteral catheter and a guitar string to slice open a stenosed pulmonary valve.\textsuperscript{34} The idea of catheter-based therapy remained dormant until 1979 when Dr. Semb used a balloon-tipped catheter to perform a balloon valvulotomy of the pulmonic valve.\textsuperscript{35} The concept of balloon angioplasty was later used by Jean Kan at Johns Hopkins University to further refine and develop a dedicated catheter to dilate the valve. Bulldogs served as an animal model due to the breed-specific high rate of congenital pulmonic stenosis. The first human valvuloplasty occurred in 1982, and valvuloplasty has since gone on to be the preferred initial treatment of isolated pulmonic stenosis. Based on the success of pulmonary valvuloplasty, the concept of balloon valvuloplasty was quickly adapted to other stenotic valves.\textsuperscript{36}

Approaching the mitral valve was more challenging due to lack of a direct route like the pulmonary valve. Initially, in 1984, Kanji Inoue used a surgical approach to dilate a stenotic mitral valve with good results. Percutaneous access to the left atrium was first developed by Constantine Cope in 1959 at the New Jersey Veterans Affairs Hospital and was later refined to treat transposition of the great arteries by William Rashkind and William Miller at Children’s Hospital of Philadelphia.\textsuperscript{37} James Lock adapted these techniques to perform the first mitral valvuloplasty procedure in 1984.\textsuperscript{38} Similar to pulmonary valvuloplasty, mitral valvuloplasty has become the preferred initial treatment for rheumatic mitral stenosis over surgery.

Unfortunately, the success of valvuloplasty experienced in the pulmonary
and mitral valves did not translate to treating degenerative calcific aortic valve stenosis. Alain Cribier at the Charles Nicole University in Rouen, France, performed the first aortic balloon valvuloplasty in 1985. 39 Although there was initial improvement in patients, the longevity of the result was impaired by early restenosis and poor long-term survival if surgery was not performed. To effectively treat this disease, more advanced technology would need to be developed. 40

Just as early angioplasty spurred the development of new technology, valvuloplasty has led to new technology to replace and repair dysfunctional valves. Again, the pulmonary valve led a new wave of innovating transcatheter valve replacement therapy. Philipp Bonhoeffer performed the first pulmonary valve replacement in 2000 using a large bovine jugular vein sutured to a platinum stent frame, a precursor to the Medtronic Melody Valve (Medtronic, Edgewater, MD). 41 In a similar fashion, Cribier used his experience in aortic valvuloplasty to develop a balloon-expandable stented valve as a more definitive therapy to treat aortic stenosis. He performed the first transcatheter aortic valve replacement (TAVR) in 2002 using a valve design that would later evolve into the Edwards Sapien Valve (Edwards Lifesciences, Irvine, CA). 42 Based on the PARTNER trial, the Sapien valve achieved commercial use for inoperable patients in 2011 and for high-risk patients in 2012. 43 Currently, the Edwards Sapien Valve and Medtronic CoreValve are among those commercially available for TAVR, with many more valve designs being studied in clinical trials.

Although rheumatic mitral stenosis could be treated with balloon valvuloplasty, mitral regurgitation presented a much more complex pathology to treat. Because the mitral valve has a more complex saddle-shaped anatomy, initial attempts to treat mitral regurgitation investigated methods to repair the valve. Despite many different attempts to percutaneously repair the mitral valve since the 1990s, there remains only 1 commercially available device. The MitraClip (Abbott Vascular, Santa Clara, CA) is based on a surgical edge-to-edge mitral valve repair technique known as the Alfieri stitch. The device approaches the mitral valve from a transseptal puncture and attaches a clip to the anterior and posterior valve leaflets to secure a prolapsed or failed valve segment, thus reducing regurgitation. 44 The MitraClip became commercially available to treat surgically high-risk patients with degenerative mitral valve regurgitation in 2013 after
demonstrating reduction in mitral regurgitation and equivalent survival to surgical repair in the EVEREST and EVEREST II trials.\textsuperscript{45,46} There are no transcatheter mitral valve replacement therapies commercially available; however, there are currently many devices undergoing early feasibility trials in humans.

**INTERVENTIONAL CARDIOLOGY AS A DISCIPLINE**

Initially, the field of interventional cardiology was self-regulated and available only to those who went to one of Gruentzig’s training courses and acquired an angioplasty balloon catheter. As new technology developed outside the control of Gruentzig, the procedure became available to all cardiologists. In 1988 and 1993, the American College of Cardiology issued the first set of guidelines, including indications for balloon angioplasty as well as approximate activity levels needed to maintain competence. As the field continued to expand in the 1990s, so did the knowledge base and skill set needed to be proficient in the discipline. In response to this growth, in 1998, the American Board of Internal Medicine (ABIM) approved the Certificate of Added Qualification in Interventional Cardiology, which required completion of 1 year of additional training within an ABIM-approved fellowship program with a separate board examination.

In addition to the need for specialized training and examinations, new journals, societies, and meetings were created to be resources for continued advancement and education. Many of the first-tier journals quickly developed subspecialty journals, with the first issues of *JACC: Cardiovascular Interventions* and *Circulation: Cardiovascular Interventions* appearing in 2008. These journals, and others, continue to document the continued advancements in the field.

A thorough knowledge of normal and abnormal coronary anatomy is essential for the interventional cardiologist. The direct application of this knowledge base helps in the selection of the appropriate catheter for coronary engagement in both diagnostic and intervention procedures. Knowledge of anatomy also facilitates the selection and interpretation of angiographic views during cardiac catheterization. Finally, because interventional therapy may be needed in several unusual circumstances, a working knowledge of coronary artery anomalies is also essential. This chapter addresses coronary artery anatomy and related technical issues pertinent to the interventional cardiologist.

NORMAL CORONARY ANATOMY

The coronary arterial system can be divided into the large vessels, or the epicardial coronary arteries, and the small vessels, or the microvasculature. The microvasculature consists of arterioles, which measure less than 200 μm and are poorly visualized with routine coronary angiography. These arterioles feed a broad capillary network that delivers oxygenated blood to the myocardium. They also regulate coronary pressure and flow through their ability to vasodilate and constrict in response to a variety of stimuli. The importance of the microvasculature in determining patient outcomes in both
the acute setting, such as myocardial infarction, and the chronic setting has been highlighted.¹

**The Left Coronary Artery**

Both the right and left coronary artery ostia arise from their respective aortic sinuses. Both ostia are located more than half the distance between the sinotubular junction and aortic valve annulus (Fig. 2-1). The left main coronary artery originates with an elliptic ostium measuring approximately 3.2 ± 1.1 mm × 4.7 ± 1.2 mm.² This coronary artery continues at an acute angle and travels parallel to the aortic sinus wall, coursing between the pulmonary artery and the left atrium in the region of the left atrial appendage. The length of the left main artery ranges from 0 mm (“double-barrel ostium”) to 20 mm. However, in most cases, the length of the left main coronary artery is between 6 and 15 mm, with an average diameter ranging from 3 to 6 mm.³ In two-thirds of cases, the left main coronary artery bifurcates into the left anterior descending (LAD) and circumflex arteries (Fig. 2-2); in one-third of cases, it trifurcates into the LAD artery, the circumflex artery, and a ramus intermedius artery, which follows a course similar to either the first diagonal artery from the LAD artery or first obtuse marginal artery from the circumflex.⁴

**FIGURE 2-1** Anterior (A) and posterior (B) view of the coronary arterial and venous system. AIV, anterior interventricular vein; CFX, circumflex coronary artery; CS, coronary sinus; GCV, great cardiac vein; LAD, left anterior descending artery; MCV,
middle cardiac vein; PDA, posterior descending artery; RCA, right coronary artery; SCV, small cardiac vein.
The LAD artery follows the anterior interventricular sulcus and may pass around the cardiac apex. When it passes around the apex, the LAD travels along the posterior interventricular sulcus and can anastomose with branches from the posterior descending branch of the right coronary artery. The LAD artery has characteristic septal perforating branches that serve the anterior two-thirds and the infra-apical portions of the ventricular septum. A common anatomic variant occurs when the LAD artery terminates before reaching the cardiac apex. In these cases, a large diagonal artery or an unusually large posterior descending artery from the right coronary artery should be anticipated to be present and provide the necessary left ventricular perfusion.

In addition to septal perforators, the next major branches of the LAD artery are the diagonal arteries, which course along the anterolateral free wall of the left ventricle in a diagonal fashion, hence the name. On average, two major diagonal arteries are present, although smaller diagonal vessels can be identified. In addition, small ventricular branches from the LAD can form an anastomotic network with similar branches from the proximal right coronary artery.

The circumflex coronary artery arises at an acute angle from the left main coronary artery and travels in the epicardial fat pad beneath the left atrial appendage, coursing through the left atrioventricular (AV) sulcus. When a posterior descending artery (PDA) arises from the distal circumflex artery, the coronary circulation is defined as either left dominant or codominant. A “codominant” coronary artery system is one in which a PDA arises from both the right and circumflex coronary arteries. Codominant coronary artery systems, seen in less than 10% of patients, are usually characterized by smallish PDA branches, which perfuse the posterior interventricular sulcus toward the apex of the heart. The circumflex artery gives rise to as many as three obtuse marginal arteries that supply the left ventricular lateral wall. In more than 80% of patients, the left circumflex artery transitions to a smaller AV groove artery, which is considered the distal continuation of the true
circumflex artery. Usually, this artery does not pass the crux cordis, but in the 10% of cases with a left-dominant coronary circulation, the AV groove branch is large and of similar diameter to the main circumflex artery, giving rise to both posterolateral branches and a left posterior descending branch.\textsuperscript{8}

**The Right Coronary Artery**

The right coronary artery originates from the right sinus of Valsalva and follows the right AV sulcus around the acute margin of the heart, giving off several major branches (Fig. 2-3). The conus artery is the first major branch, with a separate ostium from the aorta in 50% of cases. The sinoatrial nodal artery is the second major branch, arising from the right coronary artery in 60% of cases and from the left circumflex artery in 40% of cases.\textsuperscript{5}
FIGURE 2-3  A. A dominant left coronary artery in the left anterior oblique and cranial projection showing the continuation of the circumflex, which then gives off posterolateral left ventricular branches and the posterior descending artery. B. A nondominant right coronary artery (RCA) in the right anterior oblique projection demonstrating a right ventricular (RV) marginal branch but no posterior descending or posterolateral left ventricular branches. LAD, left anterior descending artery.

The acute marginal branches of the right coronary artery arise from the proximal to midportion of the vessel, supply the free wall of the right ventricle, and often anastomose to smaller branches of the LAD artery. The distal right coronary artery follows the posterior interventricular sulcus where it bifurcates into the PDA (in 90% of patients) and major posterolateral branches. The PDA continues in the posterior interventricular sulcus and usually terminates in the region of the cardiac apex. The posterolateral artery, a continuation of the right coronary artery, continues in the AV sulcus to the crux of the heart, frequently giving rise to the AV nodal artery. Finally, the posterolateral artery terminates in two or three branches that course toward the cardiac apex. When the right coronary artery is nondominant, it may terminate in the region of the acute margin of the heart (see Fig. 2-3). In the situation of total LAD artery occlusion, many of the branches of the right coronary artery may give rise to LAD artery collateral vessels. The right coronary conus branch artery may become clinically significant when the LAD artery is occluded proximally. In addition, the acute marginal branches of the right coronary artery anastomose with marginal branches from the circumflex artery as well as the septal perforating branches from the LAD artery. The PDA gives rise to branches that anastomose with the distal branches of the LAD artery. This angiographic visualization of the distal LAD artery by collateral arteries is especially important when performing interventions on chronic total occlusions of that artery. Likewise, the distal segments of the right coronary artery can often be visualized by left coronary angiography via collateral filling.

Myocardial bridging is a congenital variant that can occur in all coronary vessels but is most commonly found in the LAD artery. It is defined as a segment of the major epicardial artery tunneling through the myocardium and then resurfacing. Evidence of bridging has been reported in 40% to 80% of autopsy studies, but it is noted less commonly on invasive coronary angiography. The in vivo diagnosis of bridging can be improved with the use
of intravascular ultrasound and/or coronary computed tomographic angiography. The clinical relevance of myocardial bridging is controversial. In most cases, bridges are asymptomatic, benign findings. However, in some patients, they can be responsible for chest pain, arrhythmia, and acute coronary syndromes. In these instances, it is believed that endothelial dysfunction, development of atherosclerosis just proximal to the bridge, left ventricular hypertrophy, and diastolic dysfunction exacerbate the bridge in varying degrees and contribute to the clinical presentation. Symptomatic bridges are typically treated medically. Results of treatment with percutaneous coronary intervention have been poor in general. When medical therapy fails, surgical unroofing of the bridge can be considered.9

The Coronary Venous System

Knowledge of the coronary venous system is becoming increasingly important to the interventionalist to facilitate various noncoronary and electrophysiologic cardiac interventions (Fig. 2-4). The venous circulation of the heart is divided into three systems: the anterior cardiac veins, the coronary sinus and its tributaries, and the thebesian veins. The anterior cardiac veins, which originate from the right ventricular free wall surface of the heart,3,8 drain the right ventricle and empty into the right atrium. The coronary sinus and its tributaries, which course on the surface of the left ventricle, run in parallel to the coronary arterial branches. The major tributary of the coronary sinus is the anterior interventricular branch, which parallels the LAD artery and turns into the great cardiac vein as it enters the AV groove. The coronary sinus enters the right atrium adjacent to the tricuspid valve. Finally, the thebesian veins drain directly into the underlying right-side chambers. Flow is very minimal in these vessels, but these veins could give rise to very small and usually insignificant right-to-left shunts.3,8
FIGURE 2-4 Coronary venous anatomy. The coronary sinus is cannulated with a balloon catheter, wherein contrast injection of the coronary sinus visualizes both the anterior ventricular cardiac vein as well as late-phase filling of the lateral and inferior cardiac veins.

CORONARY ARTERY ANOMALIES

Benign Anomalies

Most coronary artery anomalies are clinically benign incidental findings (Table 2-1). Separate and adjacent ostia of the LAD and left circumflex arteries are the most common anomaly, occurring in 0.41% of cases according to a large series reported from the Mayo Clinic. Separate coronary ostia constitute approximately 30% of all benign coronary anomalies. Of interest, there is an association with a bicuspid aortic valve in these patients. From a practical standpoint, catheter engagement may opacify one vessel and not the other. Occasionally, two separate diagnostic catheters
are needed to complete the angiographic study of this anomalous left coronary artery system.

The second most common coronary artery anomaly is the anomalous origin of the circumflex artery from either the right coronary artery or the right sinus of Valsalva.\textsuperscript{10,11} This anomaly, seen in 0.38% of diagnostic angiograms and making up 28% of benign coronary artery anomalies, is characterized by a retroaortic course of the circumflex, with the vessel running posterior to the aortic root. The clinical importance of identifying this anomaly is high for several reasons. First, unless the catheterizing physician has an adequate level of suspicion, this vessel may remain unvisualized. Second, for patients undergoing aortic valve replacement or mitral valve repair or replacement, this artery may be at risk for damage during surgery unless the surgeon is aware of its presence and retroaortic course.
Angiographically, one imaging hallmark is a long left main coronary artery segment, often longer than 15 mm. Also, the retroaortic course of the circumflex around the aorta produces an angiographic “dot” (the end-on view of the vessel as it courses around the aorta) seen on aortography or ventriculography in the right anterior oblique projection. This coronary anomaly is best engaged with an Amplatz or multipurpose catheter in a steep left anterior oblique view.

The third most common benign coronary anomaly is the anomalous origin of the right coronary artery from the left sinus of Valsalva, occurring in 0.15% of cases and constituting 12% of benign coronary anomalies. The remaining benign coronary anomalies include an anomalous origin of the left main coronary artery from the aorta, constituting 1% of anomalies in the benign group, and an absent circumflex artery (seen in approximately 0.03% of all cases), constituting less than 1% of benign coronary anomalies.

Coronary artery fistulas constitute a separate group of benign anomalies and occur when a coronary artery branch communicates directly with another chamber or structure, usually the right ventricle or pulmonary artery. Most fistulas, usually incidental findings during angiography, are small and clinically unimportant and rarely demonstrate the high flow and drainage into a right-side chamber that would produce a significant left-to-right shunt. Small fistulas have been noted to occur in 0.12% to 0.14% of catheterization cases, constituting approximately 10% of all benign coronary anomalies.

**Clinically Serious Anomalies**

Twenty percent of coronary artery anomalies are associated with potentially serious clinical consequences (Table 2-2). The most common anomaly in this group is the origin of the right coronary artery from the left sinus of Valsalva, which occurs in approximately 0.12% of all cases and constitutes 8% of all coronary anomalies. In this case, the right coronary artery has an interarterial course between the aorta and pulmonary artery. This anomaly may be associated with ischemic symptoms and requires surgical revascularization. The course of the vessel produces a bend point anterior to the aorta, resulting in an angiographic dot sign seen on ventriculography or aortography.

| Table 2-2 | Potentially Serious Coronary Anomalies (20% of total cases) |
Anomalous Pathways of the Left Coronary Artery Arising From the Right Aortic Sinus

Another group of coronary anomalies considered to be potentially serious involves the origin of the left main coronary artery (LMCA) from the right sinus of Valsalva (Fig. 2-5). Overall, these anomalies constitute 1.5% of all coronary anomalies and are seen in 0.2% of all catheterization cases. The LMCA from the right sinus of Valsalva has four potential pathways, with one being strongly associated with angina, syncope, or sudden death. Computed tomography coronary angiography has simplified diagnosing the course of the anomalous LMCA, but knowledge of the invasive angiographic findings remains important. The first pathway is a retroaortic course that takes the left main artery posterior to the aortic root. This pathway is characterized by a posterior angiographic dot sign and is considered benign (see Fig. 2-5C).
In the second pathway, the LMCA may cross low and anterior through a “septal” course (see Fig. 2-5A; Figs. 2-6A-C and 2-7). This anomaly is usually benign and characterized by septal perforators coming off of the LMCA, with an intramuscular course passing near the right ventricular outflow tract. As the LMCA curls downward at the bifurcation point to give rise to the circumflex artery, it creates a downward loop, or angiographic “eye” sign.
FIGURE 2-6 A. Long left main coronary artery that supplies only a left anterior descending branch and no circumflex. B. Injection of the right coronary artery with reflux into the anomalous left circumflex faintly filling this vessel. C. Selective injection of the anomalous circumflex coronary artery originating from the right sinus of Valsalva.
FIGURE 2-7 Anterior course of the left main artery originating from the right coronary sinus.

The third pathway in this group involving the LMCA coursing anteriorly over the pulmonary artery and right ventricle demonstrates an upward loop and an upgoing eye sign created by the alignment of the left main and circumflex arteries. This anomaly is also considered benign (see Fig. 2-5B).\textsuperscript{10-13}

The fourth anomalous left main pathway from the right sinus of Valsalva is considered to be serious. Originating in the right sinus, the left coronary artery following an intramural path between the pulmonary artery and aorta creates an anterior dot sign as it bends and exits its intra-arterial segment (see Figs. 2-5D and 2-8). This anomaly has been associated with angina, syncope, and sudden cardiac death. When it is found, surgery is usually required.\textsuperscript{13} The slitlike ostial orifice stretching or narrowing during activity is thought to be the mechanism producing ischemia in these patients.
The anomalous origin of the LMCA, LAD artery, or right coronary artery from the pulmonary artery is another potentially serious coronary anomaly. In these situations, coronary flow is antegrade in the normal coronary artery and retrograde in the anomalous vessel, allowing left-to-right shunting from the coronary artery bed to the pulmonary circulation. When the right coronary artery is involved, the situation is relatively benign. However, an anomalous origin of the LMCA or LAD artery from the pulmonary artery is often associated with angina and ischemic left ventricular dysfunction. Combined, anomalous origins of coronary arteries from the pulmonary artery constitute 0.8% of all coronary anomalies and are seen in 0.04% of cases. Ligation or grafting of the aberrant vessel is the treatment of choice.

Other potentially serious coronary anomalies are rare and include a single
coronary artery supplying the entire ventricle. These occur in 0.05% of catheterization cases, constitute 3.3% of all coronary anomalies, and should be considered potentially serious. There are many variations of single coronary arteries, which have been classified by Lipton et al.\textsuperscript{16}

\section*{CORONARY ARTERY COLLATERAL CIRCULATION}

The coronary collateral circulation is a potential source of blood to the myocardium that develops when blood flow via the normal route is impaired. It is believed that small anastomoses between the branches of the major epicardial coronary arteries exist in a dormant fashion. With the appropriate stimuli, these anastomoses can enlarge and allow adequate blood flow to otherwise ischemic myocardium.

Myocardial ischemia and/or development of a pressure gradient appear to be the most important stimuli to the development or maturation of coronary collateral circulation. The exact mechanism by which this is achieved remains an intense area of investigation. It appears that the increased production of growth factors induced by ischemia results in angiogenesis and/or vasculogenesis.\textsuperscript{17} Others have proposed that the physical forces as a result of a pressure gradient might induce endothelial cells to proliferate.\textsuperscript{17}

The presence of collateral circulation has been shown to have important clinical sequelae in both the acute and chronic settings. For example, in patients with acute myocardial infarction treated with fibrinolytic therapy, the presence of collateral circulation was associated with improved ventricular function, less aneurysm formation, and smaller infarcts.\textsuperscript{18-20} Long-term survival in patients with stable angina and coronary artery disease has been shown to be improved in those with good collateral circulation in comparison to patients with poor collateral circulation.\textsuperscript{21}

Rentrop and colleagues\textsuperscript{22} popularized a standard angiographic technique for assessing collateral circulation. The degree of contrast filling of a diseased vessel after injection of the contralateral vessel was graded on a scale of 0 to 3, where 0 equals no filling, 1 equals filling of side branches of the diseased vessel via collateral channels without visualization of the epicardial segment, 2 equals partial filling of the epicardial segment via collateral channels, and 3
equals complete filling of the epicardial segment of the diseased vessel via collateral channels. This qualitative (and rather insensitive) method for determining the degree of collateral circulation has been replaced by coronary wire-based techniques for measuring pressure- or velocity-derived collateral flow indices.\textsuperscript{23-25}

A number of common collateral connections between the major epicardial arteries have been described,\textsuperscript{7} including intracoronary collaterals or connections from the proximal portion of an occluded artery to the distal portion of the same vessel. These can exist as “bridging” collaterals, which are small channels that develop around an occlusion and allow filling of the distal vessel. Alternatively, larger channels can form from a branch proximal to an occlusion, such as an acute marginal branch off the right coronary artery, and anastomose to a branch distal to the occlusion, such as another acute marginal branch or the PDA. Another example is the Kugel artery, a branch off the proximal right coronary artery that anastomoses to the AV nodal artery, distal to a right coronary artery occlusion, and thereby fills the vessel beyond the blockage.\textsuperscript{26}

Intercoronary collaterals are connections between branches of two of the three major epicardial coronary arteries. Common examples include septal-to-septal collaterals emanating from the posterior descending coronary artery going to the LAD artery, or vice versa; the distal LAD artery and PDA often collateralize each other, as do the obtuse marginal branches of the circumflex and either the posterior left ventricular branches of the right coronary or the diagonal branches of the LAD artery. An important source of collateral flow to the LAD artery that can easily be missed at the time of angiography if not selectively injected with contrast is the conus branch of the right coronary artery.\textsuperscript{27}

**MULTIPLE CHOICE QUESTIONS**

1. The coronary microvasculature is defined as:
   A. Arterioles that measure less than 200 μm in diameter and are easily visualized on conventional coronary angiography.
   B. Arterioles that measure less than 200 μm in diameter and are not visualized on conventional coronary angiography.
   C. Arterioles that measure greater than 200 μm in diameter and are easily visualized on conventional coronary angiography.
   D. Arterioles that supply deoxygenated blood to the myocardium.
   E. Arterioles that are unable to vasodilate or vasoconstrict in response to stimuli.

2. The right coronary artery:
   A. Originates from the left sinus of Valsalva.
   B. Gives off the conus artery in 90% of cases, whereas the conus artery originates from a separate ostium in the other 10% of cases.
   C. Gives off the sinoatrial nodal artery in 90% of cases.
   D. Gives off the conus artery, which may be an important source of collaterals to an occluded left anterior descending artery.
   E. Gives off the posterior descending branch in 10% of cases.

3. Myocardial bridging:
   A. Has been reported in 40% to 80% of autopsy cases.
   B. Is an acquired variant that can develop in any coronary artery.
   C. Is best diagnosed with coronary angiography.
   D. Causes symptoms in most cases.
   E. Is most commonly treated with surgery when symptomatic.

4. Which of the following statements is true regarding benign coronary anomalies?
A. Separate ostia of the left anterior descending and left circumflex arteries (absence of a left main coronary) are the least common.
B. Many fistulas demonstrate high flow with significant left-to-right shunts.
C. A long left main coronary artery is an imaging hallmark of an anomalous circumflex coming off the right coronary artery.
D. The right coronary artery coming off the left sinus of Valsalva is the most common.
E. A bicuspid aortic valve is associated with an anomalous circumflex coming off of the right coronary artery.

5. Which of the following statements is true regarding the clinically serious coronary anomalies?
   A. These represent 80% of all coronary anomalies.
   B. The left main coronary artery coming off the right sinus of Valsalva has only one known course, which it takes to reach the left ventricle.
   C. Surgery is never required when the left main coronary artery comes off the right sinus of Valsalva.
   D. A single coronary artery supplying the entire left ventricle occurs in 5% of all coronary angiograms and represents 30% of all anomalies.
   E. An anomalous right coronary artery coursing between the pulmonary artery and the aorta may be responsible for ischemic symptoms and can require surgical revascularization.

INTRODUCTION

This chapter on cardiac anatomy takes a practical approach for operators who are going to perform various procedures associated with structural heart disease. Rather than assume the traditional approach of describing the gross anatomy of the heart in isolation from the procedures performed, this chapter will attempt to provide useful information (Tips and Tricks) of how the anatomy, as seen by the percutaneous operator, affects the procedure results. Therefore, the emphasis is not only on gross anatomy, but also the anatomy that the interventionalist perceives using different imaging modalities. Whereas a surgeon can see and touch the anatomic structures, a cardiac interventionalist has to rely on indirect methods of visualization, which include fluoroscopy, echocardiography, and intracardiac ultrasound. Magnetic resonance or computed tomography images can be useful for orientation and diagnosis before the procedure (and, more recently, can be used as an overlay on the fluoroscopy monitor in the catheterization lab). However, the focus of this chapter is what the interventionalist has at his or her disposal at the time of the procedure to understand the anatomy. Accurate use of available imaging modalities in the catheterization laboratory and appreciation of relative orientations are important for optimal device sizing.
and placement.

**ORIENTATION**

Fluoroscopy provides a familiar image with the right atrium adjacent to the spine in the anteroposterior (AP) view, to the right in left anterior oblique (LAO) angulation, and anterior to the spine in the right anterior oblique (RAO) projection. The left upper pulmonary vein is just superior to the left atrial appendage and extends outside the cardiac shadow (Fig. 3-1). Transesophageal echocardiography (TEE) provides an image with the left atrium at the top of the screen because it is the closest structure to the probe, whereas the anterior cardiac structures, including the right atrium, are at the bottom of the screen. The left side of the image represents the inferior aspect of the heart leading to the inferior vena cava (IVC), and the right represents the superior aspects, including the superior vena cava (SVC) and aorta, all of which are not presented in the same orientation as the physical anatomy (Fig. 3-2). Rotating a TEE image 90° counterclockwise will orient the image similarly to a fluoroscopic image but with the plane of the image originating posteriorly from the esophagus to the anterior chest. The intracardiac echocardiography (ICE) probe is situated typically in the right atrium facing the atrial septum. The structure closest to the probe, and therefore at the top of the screen, is the right atrium. Similarly to TEE, the IVC is to the left of the screen, and the SVC is on the right. Rotating the ICE image 90° counterclockwise will present an image in the same anatomic orientation as fluoroscopy (see Fig. 3-1). TEE provides multiple tomographic cuts of the heart from different planes and angulations, which can be confusing for the interventionalist with a catheter in hand.
FIGURE 3-1 Anteroposterior fluoroscopy of a 24-mm sizing balloon across the interatrial septum. The wire is in the left upper pulmonary vein (LUPV). LA, left atrium; ICE, intracardiac echocardiography; RA, right atrium. (From El Said HG. Patent Foramen Ovale Morphology and Impact on Percutaneous Device Closure. Pediatr Cardiol 2004;26:62-65, with permission of Springer.)
FIGURE 3-2 A. Transesophageal echocardiography images showing a horizontal and oblique orientation of the omniplane in relation to the atrium. Positioning the probe
in the mid-esophagus with the omniplane at 0° and rotating the probe shows a 4-chamber view of the septum and atria (*echo image 1*). This is a good starting position. B. The height and angle of the omniplane determine the image cut seen on the screen. *Echo image 2*: A high esophageal omniplane position at around 50° will show the ascending aorta, and high atrial septum. *Echo image 3*: A low esophageal image shows the lower atrial septum and the posterior rim. Ao, aorta; Asc, ascending; CS, coronary sinus; IVC, inferior vena cava; LA, left atrium; LV, left ventricle; RA, right atrium; RAA, right atrial appendage; RV, right ventricle; SVC, superior vena cava; TV, tricuspid valve.

**ATRIAL SEPTAL DEFECTS**

The secundum septal defect is the most common type of atrial septal defect (ASD) and involves the fossa ovalis border and the deficient edge of the ostium secundum. The defect may be circular, oval, or fenestrated, and the septum may be rigid or aneurysmal and floppy. Relative to the long axis of the body, the right atrium lays anterior to the left atrium, and the septum is oriented obliquely in the chest from the posterior right to the anterior left. The IVC enters the right atrium at an angle and is oriented roughly in a line through the inferior-posterior quadrant of the right atrium to the superior-anterior quadrant. In utero, this orientation helps direct returning placental blood from the IVC toward the foramen ovale on the septum (*Fig. 3-3*). The eustachian valve further helps to direct the oxygenated placental blood toward the still patent foramen ovale. A long residual eustachian valve can be misinterpreted as the atrial septum on TEE.
FIGURE 3-3 Pathology sample with the right atrium opened showing the atrial septum and the rims of the fossa ovale: retro-aortic (superior-anterior [SA]), superior vena cava (SVC; superior-posterior [SP]), posterior (P), inferior vena cava (IVC; inferior-posterior [IP]), and atroioventricular (inferior-anterior [IA]). An overlay provides the approximate direction of the quadrants. Asc Ao, ascending aorta; PV, pulmonary valve; TV, tricuspid valve.

The rims surrounding the defect may be deficient in any of the quadrants if they measure less than 5 mm. The retroaortic rim is in the anterior-superior quadrant. The SVC and right pulmonary veins border the posterior-superior quadrant. The posterior free right atrial wall makes up the posterior rim. The tricuspid valve borders the inferior-anterior quadrant, and the IVC is contiguous with the posterior-inferior quadrant (Fig. 3-4).
Other types of septal defects are outside the fossa ovalis and can be close to other cardiac structures. These defects, such as the ostium primum and inferior and superior sinus venosus ASDs, are not correctable by percutaneous techniques and will not be covered in this chapter.\(^1\)

In the AP projection, an ASD is oriented slightly superior to the tricuspid valve. Because the atrial septum is oblique, a guide wire from the IVC will typically pass across an ASD to the left upper pulmonary vein, appearing slightly outside the heart border on fluoroscopy. Care must be taken not to advance the wire into the left atrial appendage oriented inferior and anterior to the pulmonary veins unless the operator is performing a left atrial appendage closure procedure (see Fig. 3-1; Fig. 3-5).\(^2\) A sizing balloon should be used to obtain the stretch diameter and the Doppler stop-flow measurements in the LAO projection to minimize foreshortening. A mobile, aneurysmal septum can be difficult to assess on imaging, and balloon sizing ensures appropriate device size selection, thus reducing the risk of embolization or complications.
FIGURE 3-5 Intracardiac echocardiography (ICE) image of the wire crossing the atrium from the inferior vena cava (IVC; left upper corner). The wire was advanced from the IVC into the right atrium (RA), then across the septum into the distal portion of the left atrium. Note that the orientation of ICE images places the right atrium at the top of the screen, but anatomically on fluoroscopy, the guide wire is traveling superiorly from the IVC through the right atrium to the superior and posterior left upper pulmonary veins.

For a complete rim and defect evaluation using TEE in the midesophageal position, the omniplane transducer is rotated through approximately 0°, 45°, and 90°. Starting at 0°, the TEE shows the anterior-posterior rims including the mitral valve and posterior atrial wall. Rotating from 30° to 45° will show the anterior-superior or retroaortic rim, which is most commonly deficient in up to 42% of patients. Moving the TEE probe at this angle in and out brings into view the superior and inferior margins of the defect (see Fig. 3-2). Further rotation to 90° to 110° will show the SVC and IVC rims (bicaval view) (Fig. 3-6). Three-dimensional echocardiography can outline the defect and the rims surrounding it, making identification of deficient rims easier. This is also helpful after device deployment to judge the level of
impingement on cardiac structures. The pulmonary venous connections can be evaluated by echocardiography and a pulmonary angiogram during the venous phase using a 45° LAO and 35° cranial projection.  

**FIGURE 3-6** Transesophageal echocardiography images of the vertical orientation of the omniplane. Rotating the probe rightward (counterclockwise) and angulating the omniplane to about 110° will yield the bicaval view (top right). Rotating the probe leftward will show the anterior structures including aorta (top left). The **bottom left panel** shows color flow used in assessing flow across the septum. Ao, aorta; CS, coronary sinus; IVC, inferior vena cava; LA, left atrium; RA, right atrium; SVC, superior vena cava; TV, tricuspid valve.

To use ICE in the assessment and positioning of a closure device, begin in the right atrial home view, keeping in mind that the most proximal structure at the top of the screen is the right atrium (Fig. 3-7A). This view shows the
right atrium, right ventricle, and tricuspid valve. Placing a 20° retrograde angle on the ICE probe and rotating the probe clockwise will show the aorta in the short axis and the right ventricular outflow (Fig. 3-7B). Additional clockwise steering will also bring the foramen ovale into the field. Continuing to rotate brings the interatrial septum into view and the left atrial appendage in the right bottom of the image. The mitral valve may also be observed with slight right-left rotation of the probe (Fig. 3-7C). Further clockwise rotation will then bring the left pulmonary veins into view with the left upper pulmonary vein (LUPV) to the right of the screen and left inferior pulmonary vein to the left (Fig. 3-7D). Slight clockwise rotation will bring the guide wire into view traversing the septum and along its path in the left atrium. Additional clockwise rotation will then bring the right pulmonary veins into view in the short axis (Fig. 3-7E). Withdrawing the probe to the inferior right atrium and with additional posterior tilt will show the SVC and superior-posterior rim (Fig. 3-7F). Once the device is deployed, moving the probe in and out in the neutral position with slight right-left angulation is done to demonstrate capture of the rims by the occluder.
FIGURE 3-7 A-F. Intracardiac echocardiography images. The most proximal structure at the top of the screen is the right atrium (RA). A. This image shows the RA, right ventricle (RV), and tricuspid valve (TV). B. Placing a 20° retrograde angle and rotating clockwise will show the top right panel and the aorta (AO) in the short axis with the right ventricular outflow. C. This panel shows that turning the probe more clockwise will visualize the foramen ovale. D. Continuing to rotate clockwise brings the pulmonary veins into view as this panel shows. The mitral valve may also be observed with slight right-left rotation of the probe. E. This panel shows that additional clockwise rotation will then bring the right pulmonary veins into view in the short axis. E. Withdrawing the probe to the inferior right atrium and with additional posterior tilt will show the superior vena cava (SVC) and superior-
The orientation of the IVC relative to the atrial septum causes the device delivery sheath to place traction on the occluder inferiorly toward the IVC. During deployment of an Amplatzer septal occluder (St. Jude Medical, Saint Paul, MN), care must be taken to orient the left atrial disk parallel to the septum before pulling it against the septum. If the device is angulated perpendicular to the defect, the left atrial disk may prolapse across the septum and into the right atrium. This is of greater concern with the Amplatzer septal occluder, especially in cases of a deficient retroaortic rim. The TorqueView sheath (St. Jude Medical) typically used with the Amplatzer device may not orient in the ideal plane in horizontal or rotated hearts. The Hausdorf sheath (Cook Medical, Bloomington, IN) has 2 posterior curves and an angled tip designed to maintain the distal part of the sheath and the device parallel to the septum so the disk is less likely to prolapse into the right atrium when there is a large ASD. Once the sheath and left atrial disk are pulled as a unit against the septum, the right atrial disk is deployed. Until the device is released, the deployment cable places traction on the device and angulates the occluder. The tension placed on the device by the cable will press the right disk into the IVC rim and possibly push it across the septum. Conversely, the torque on the superior-anterior aspect of the device with a deficient retroaortic rim may prolapse the device into the right atrium. A clockwise rotation on the delivery sheath for deficient IVC rims and counterclockwise for deficient retroaortic rims may orient the deployed, but unreleased, device more parallel to the septum and capture the rims (Fig. 3-8).
FIGURE 3-8 Transesophageal echocardiography images. On the left is the Amplatzer septal occluder oriented perpendicular to the septum due to the traction on it toward the inferior vena cava (IVC). On the right is the result of clockwise rotation of the delivery sheath, and releasing some of the traction orients the occluder more parallel to the septum. LA, left atrium; RA, right atrium.

Larger closure devices in small or geometrically unfavorable left atria can also make deployment of the left atrial disk challenging. With the delivery sheath in the LUPV, it is possible to deploy the left disk in the proximal pulmonary vein, then gently retract the disk out and oppose it to the defect ensuring the rims are captured. Finally, a deficient retroaortic rim should prompt some caution because it is associated with device-related complications including erosions, arrhythmias, and malposition. A large defect and aneurysmal septum are also risk factors because both of these issues require larger devices to be placed. The risk of erosion is rare, at 0.1% to 0.2%, but should be considered if the patient complains of chest pain, numbness, sudden weakness, dizziness, syncope, shortness of breath, or tachycardia (Fig. 3-9).
FIGURE 3-9 Amplatzer occluder compression superiorly into the aortic root during aortic root injection of contrast. This threatens possible erosion, which has not occurred yet.

PATENT FORAMEN OVALE

Patent foramen ovale (PFO) is present in 20% to 30% of the general population. In utero, the septum primum develops to pass to the left and under the septum secundum, creating a conduit shunting blood in the fetal circulation from the IVC across the interatrial septum into the left heart. The
oxygen saturation of placental blood is only 67%. If the blood were to follow the usual pathway through the right heart and the unaerated fetal lung, the oxygen content would continue to fall and would not be able to sustain organogenesis. This mechanism is so important that it is preserved throughout evolution in all mammals. At birth, the drop in pulmonary pressure closes the tunnel as the left atrial pressure exceeds right atrial pressure, and in most people, the septum primum and septum secundum fuse. PFOs vary in shape, configuration, mobility, and size. An understanding of PFO anatomy is important for device closure procedures. PFO size increases with age in children until maximum growth is achieved. In the adult, there is no evidence that the PFO size changes over time. PFOs usually range in size from 3.4 to 5.8 mm but reportedly can be larger, and may be 3 to 18 mm in length. The variation depends partly on how a PFO is measured (eg, by echocardiography or by balloon sizing at cardiac catheterization).

The PFO has an oval shape and is formed by the crescent-shaped thicker (1 cm) septum secundum superiorly with the thin (1 mm) septum primum passing from the inferior aspect of the atrium, under the septum secundum, then entering the left atrium (Fig. 3-10). It extends superiorly and behind the limbus of the septum secundum (Fig. 3-11). Inferior-posterior to the PFO is the IVC, inferior-anterior is the tricuspid valve, and superior-anterior is the aortic root. The SVC enters the right atrium superior-posterior to the PFO and is about 1.2 cm away (Fig. 3-12). To cross the PFO, a multipurpose catheter and either a 0.035 J or straight-tipped wire may be advanced up the IVC. Probing the septum about 1 cm below the SVC in a line inferior-posterior to the aorta should permit crossing the PFO tunnel as is done during a trans-septal puncture when the foramen ovale is closed (Fig. 3-13).
FIGURE 3-10 A representation of a patent foramen ovale in the open (left) and closed (right) positions.

FIGURE 3-11 The fossa ovale is bordered by the septum secundum superiorly and the septum primum inferiorly. A patent foramen ovale, if present, would be in the location highlighted in blue. LV, left ventricle; RA, right atrium; RV, right ventricle.
FIGURE 3-12 Angiogram of a catheter in the right atrium tenting the septum primum. Contrast is flowing through the patent foramen ovale (PFO) and into the left atrium (seen better on cine images). ICE, intracardiac echocardiography; LA, left atrium; RA, right atrium.

FIGURE 3-13 Posteroanterior projection (left) showing a multipurpose catheter and guide wire across the patent foramen ovale (PFO) tunnel to the left upper pulmonary
Vein. Left anterior oblique cranial projection (right) during fluoroscopy shows a sizing balloon with a waist at the site of the PFO. ICE, intracardiac echocardiography; LUPV, left upper pulmonary vein.

Accurate evaluation of the PFO tunnel length and morphology requires careful echocardiographic assessment. This is needed to assess the length and height of the PFO and the presence and extent of any septal aneurysm. This in turn can influence the choice of device size and to assure there are no other findings such as a secundum ASD, fenestrated septum, septal masses, or septal hypertrophy. To obtain the width of the PFO, it would be necessary to visualize the atrial septum directly en-face. This can be obtained currently only with 3-dimensional echocardiographic imaging. Alternatively, balloon sizing of the PFO can be performed during fluoroscopy, to obtain the stretched diameter and shape of the tunnel. It is important to decrease any foreshortening of the radiographic projection, and the LAO cranial view is usually the preferred projection (Fig. 3-14). The shape and size of the PFO tunnel using a balloon will influence selection of the device and its size to close the PFO. The 2 currently available devices in the United States are the Amplatzer septal occluder, the Gore Cardioform, and the Gore Helex septal occluder (W. L. Gore & Associates, Flagstaff, AZ). These devices are approved by the US Food and Drug Administration (FDA) for closure of ASDs but are not approved for closure of PFOs. At the present time, PFO closure is performed either under an Investigational Device Exemption protocol or used off-label. The Amplatzer septal occluder is self-centering, so sizing is done 1:1 to the defect. The Gore Helex device has a narrow neck and is composed of expanded ePTFE material on a 0.012-inch nickel-titanium wire frame. For a typical small PFO less than 12 mm, we use the 25-mm Helex device because it is soft and well tolerated. Larger PFOs requiring the use of a 30- or 35-mm occluder result in the Helex device having too little compression force. This leaves a large residual shunt in 50% of people. Therefore, we prefer the newer Gore Cardioform, or the Amplatzer septal occluder for PFOs larger than 12 mm in diameter.
FIGURE 3-14 Sizing balloon in the patent foramen ovale (PFO) tunnel outlining the morphology of the tunnel and an intracardiac echocardiography (ICE) image of the PFO showing how the septum primum goes behind and to the left of the septum secundum. (Balloon markings are 15 mm inside edge to inside edge.) LA, left atrium; RA, right atrium; SPV, superior pulmonary vein.

During TEE imaging, the omniplane angle is rotated to the bicaval view (approximately 90-110°) to show the different aspects of the septum and bring the PFO tunnel into view (Figs. 3-15 and 3-16). We currently prefer using ICE for PFO closures, but some centers report using fluoroscopic guidance only, after they have assessed the anatomy with a preprocedure TEE.

FIGURE 3-15 Transesophageal echocardiography image of an atrial septal aneurysm with a patent foramen ovale (PFO; center). The image on the left shows an agitated
saline bubble study, and the image on the right demonstrates color flow across the PFO (arrow). LA, left atrium; RA, right atrium.

FIGURE 3-16 Transesophageal echocardiography image of a patent foramen ovale (PFO) in relationship with the ascending aortic root and aortic rim. This view is helpful in assessing the device position against the aorta, especially if the aortic anatomy is distorted.

A bubble study and color-flow Doppler are applied to assess the channel. The operator can also observe the wire crossing the tunnel and assess the extent of atrial septal aneurysm as well as the septal thickness and aortic morphology (Fig. 3-17).

PFO Morphology and Genetic Sequencing

A proposed classification of PFO morphology is shown in Table 3-1.15 Fenestrations and aneurysmal septal anatomy are associated with larger PFOs and are postulated to increase the risk of paradoxical emboli. In people who
develop platypnea-orthodeoxia later in life, the proposed mechanism is that the anatomy is altered, such as with an enlarged aortic root or with hemidiaphragm paralysis. This in turn deforms the septum to enlarge the PFO and prolong the PFO opening during ventricular systole. The variation in PFO anatomy should influence the choice of the device and its size.

A recent study of 48 people from 16 families who had PFO-related phenotypes (cryptogenic stroke or migraine with aura) was performed with exome sequencing to assess single nucleotide polymorphisms. There were 3 genes that were associated with the presence of a PFO and 5 genes that were more common in people with a closed foramen ovale. The inheritance suggests that PFO closure is determined by a polygenic basis, which may explain the variety of shapes and sizes of the septum primum and PFO.

**TRANSSEPTAL CATHETERIZATION**

Multiple procedures require crossing the interatrial septum including mitral
valvuloplasty, left atrial appendage procedures, mitral valve clip, closure of mitral paravalvular leaks, and electrophysiologic studies. In complex PFO procedures where the tunnel is long and angulated, a transseptal puncture may permit a more effective placement of a device. In most interventional procedures, the puncture is aimed at the fossa ovalis. This is in contrast to pulmonary venous isolation procedures where the puncture may be angulated toward the pulmonary veins and thus away from the fossa ovalis. See the prior section on ASD and PFO closure for a more detailed description of the anatomy of the fossa ovalis and septum.

The septum is angulated in an oblique fashion from posterior-medially to anterior-laterally toward the left relative to the long axis of the body and is bordered by the posterior atrium on the right, right pulmonary veins on the left, ascending aorta anterior-superiorly, tricuspid valve anterior-inferiorly, and, a few centimeters away, the IVC posterior-inferiorly. The shape of the septum is variable and can be flat in normal atria or convex if the left atrial pressure is elevated as in mitral stenosis. The septum itself may be thickened or aneurysmal, increasing the difficulty associated with transseptal puncture.18

The equipment selection is dependent on the specifics of the anatomy. The standard Brockenbrough needle (BRK) is angled at 19°. For a curved septum, a more angulated needle (BRK-1) angled at 55° may be necessary to keep traction on the septum. Depending on the procedure planned, a Mullins catheter or the Swartz SL catheters (St. Jude Medical) may be needed. The SL0 catheter has a primary curve of 50°, whereas the SL1 has an additional secondary curve of 45° and the SL2 has a primary curve of 90°.19

**The Transseptal Procedure**

A 0.032 J-wire is advanced up the IVC, and the introducer sheath and dilator are advanced over it to the SVC. The wire is removed and the selected needle is advanced up the introducer until the needle is 1 cm inside the distal end of the dilator. The operator will feel the BRK needle curve fit in the introducer sheath’s curve. The sheath is rotated posteriorly to the 4 to 6 o’clock position to avoid the aortic root as it enters the right atrium. The catheter is withdrawn slowly under fluoroscopy until medial steps are observed; these steps are often felt as well. The first step corresponds to the introducer sheath entering the right atrium from the SVC. The needle then is moved medially and
inferiorly within the right atrium. The sheath should be along the medial aspect of the right atrium and posterior to the noncoronary sinus of the aorta. On additional slow withdrawal, the sheath will drop again over the limbus of the septum secundum into the fossa ovalis. This is observed on posteroanterior fluoroscopy as a second medial step. The tip of the introducer sheath is checked in the RAO and LAO projections. In the RAO projection, the tip should be lined up parallel to the spine. In the LAO projection, the tip should point to the left and posterior. Staining of the septum can be helpful to affirm on fluoroscopy the location of the sheath tip relative to other cardiac structures in 3 dimensions. The sheath is held stable, and with a swift movement, the needle is advanced forward to cross the septum. If the septum is aneurysmal or thickened, the needle may not puncture the septum easily. Excessive pressure on the sheath may cause it to slip out of the fossa, or if too much force is applied, the needle may puncture through the septum and then proceed to the posterior wall of the left atrium. Therefore, a bovie or radiofrequency energy may be needed to burn through the septum by applying energy to the back end of the needle for a few seconds as it rests against the tented septum. Contrast may be injected through the needle to confirm crossing into the left atrium, or the needle may be connected to a pressure transducer. Once across the septum, the needle is anchored to maintain access, and the sheath and dilator are advanced slowly together to the mid-left atrium. The needle is removed several inches and the sheath is advanced over the dilator. The dilator is then removed slowly to ensure no air is sucked into the left atrium. A Toray wire (Toray International, Tokyo, Japan) may be advanced to safely maintain wire access to the left atrium. Longer sheaths with a deflecting mechanism, such as an Agilis sheath (St. Jude Medical), may be necessary to achieve the appropriate orientation once across the septum (Fig. 3-18).
FIGURE 3-18 *Left:* Left anterior oblique (LAO) angulation showing an Agilis sheath pointing to the left and posterior across the septum. *Right:* Right anterior oblique (RAO) fluoroscopy showing the transseptal sheath parallel to the spine and pointing into the septum.

TEE or ICE imaging makes transseptal access safer but does require an understanding of the anatomy. Echocardiography can be used to “find” the tip of the transseptal sheath and observe tenting of the septum prior to extending the needle. In TEE, the omniplane is angulated from 0° showing the 4-chamber views to 65° showing the aortic root. If the sheath is observed at the same plane as the aortic root, then the operator will need to rotate the BRK needle clockwise (posteriorly) away from this area or risk a puncture into the aorta. Further angulation to 110° or the bicaval view will show how high up the septum the sheath tip is and allow the operator to monitor the tip location as the catheter is pulled down the septum (Fig. 3-19). Depending on the procedure, the operator may need to position the puncture a certain distance above the mitral valve annulus.
FIGURE 3-19 Transesophageal echocardiography images of the septum showing the aortic root (left), a 4-chamber view (bottom), and a bicaval view (right). Rotating, moving the probe in and out, and angulating the omniplane will show the different parts of the septum and puncture spot. Ao, aorta; IVC, inferior vena cava; LA, left atrium; LV, left ventricle; RA, right atrium; RAA, right atrial appendage; RV, right ventricle; SVC, superior vena cava.
It is recommended that a patient undergo a full TEE evaluation prior to a transseptal puncture to assess the morphology of the septum, the possible anomalies, and for the presence of thrombus in the left atrial appendage, especially in the setting of atrial fibrillation or mitral stenosis. Once the puncture is done, the needle is connected to pressure to confirm it is not in the pericardial space or aorta before the dilator is advanced.\textsuperscript{21}

ICE may also be used to localize the transseptal puncture. It is typically positioned in the “home view.” The probe is rotated clockwise until the aorta comes into view. It is then rotated further clockwise until the left pulmonary veins come into view (Fig. 3-20). A puncture at this plane will yield a posterior transseptal puncture typical for pulmonary vein isolation procedures. To perform a puncture appropriate for left atrial appendage procedures or mitral valve procedures, the catheter is gently rotated counterclockwise to show the left atrial appendage. The transseptal sheath may need to be rotated clockwise or counterclockwise until tenting is observed in this view. It is important to position the puncture in the correct plane to facilitate the intervention. Additional devices such as a more angulated sheath or an Agilis sheath may be needed for back-up support (Fig. 3-21).

\textbf{FIGURE 3-20} Intracardiac echocardiography images of the septal puncture. A. Transseptal sheath tenting in the same plane as the left pulmonary veins (5 o’clock). B. The septum with the left atrial appendage in view (5 o’clock). LA, left atrium; LAA, left atrial appendage; LPV, left pulmonary vein; RA, right atrium.
PERCUTANEOUS TRANSVENOUS MITRAL VALVULOPLASTY

The technique of percutaneous transvenous mitral valvuloplasty (PTMV) depends on adequate fracturing of the fused, rheumatic mitral leaflets. Success is defined as a final mitral valve area greater than 1.5 cm$^2$ with moderate or less regurgitation. Understanding the anatomic changes that take place in mitral stenosis and the specific valve pathology is important for the success of the procedure and long-term outcomes, as well as for avoiding complications during the procedure. Prior to the intervention, a full evaluation is required by echocardiographic imaging to assess the valve morphology. Although a precise number on the Wilkins score alone may not determine the success or advisability of performing the valvuloplasty, it provides a rough estimate of the severity of calcification and fibrosis, which are predictors of success with the procedure. The extent of mitral regurgitation also is important since it is likely that balloon valvuloplasty will
result in some increase in the degree of regurgitation. The Wilkins score includes leaflet mobility, valve calcification, leaflet thickening, and disease of the subvalvular apparatus. It does not, however, include an important prognostic indicator, that is, commissural calcification. Valvotomy of a highly calcified leaflet and commissure increases the risk of an unsuccessful result or worse: annular tearing and mitral regurgitation (Fig. 3-22). It is also important to identify unusual insertion of the papillary muscles at the leaflet tips and areas of restriction in the valvular apparatus. Finally, mitral stenosis significantly increases the risk for atrial fibrillation and for developing left atrial thrombus. The presence of left atrial thrombus is a relative contraindication to the procedure, and if present, it is safer to postpone the procedure until adequate anticoagulation is achieved (Fig. 3-23). Mitral valvuloplasty has been performed safely in patients with thrombus in the left atrial appendage, but this should be attempted only after 3 months of adequate anticoagulation by operators who have extensive experience with the procedure. However, surgery may be the best option for these patients.

**FIGURE 3-22** “Surgical view” of the normal mitral valve. In a rheumatic valve, the commissures fuse, restricting valve opening and creating the characteristic “hockey stick” appearance on long-axis echocardiography. This view gives the best spatial orientation to perform paravalvular and mitral procedures. It also shows the relationship to the left atrial appendage (LAA) and appropriate direction for advancing the guide wires.
FIGURE 3-23 Thrombus in the left atrium with a rheumatic, restricted mitral valve (MV). This finding on echo would be a contraindication to perform a percutaneous transseptal mitral valvuloplasty (PTMV). AO, aorta; LA, left atrium; LV, left ventricle.

The percutaneous technique has 2 components. The first is a transseptal puncture in the optimal position for the intervention (see Fig. 3-18). The second part is passing the balloon through the mitral valve and performing the commissurotomy.

The presence of a PFO may obviate the need for a transseptal puncture, but due to the orientation of the PFO tunnel, it may not orient the device in the proper direction for crossing the mitral valve. The transseptal puncture should be oriented in the direction just posterior to the left atrial appendage and the inferior part of the fossa ovalis as discussed in the preceding transseptal section (Figs. 3-24 and 3-25). Achieving an appropriate position for the puncture may be more difficult in mitral stenosis patients due to increased left atrial pressures and a convex septum bulging outward into the right atrium. This pushes the interatrial septum and fossa ovalis against the transseptal sheath, making anchoring of the sheath on the septum challenging, and the sheath may slide off (Fig. 3-26). A transseptal puncture in a patient with mitral stenosis is similar to trying to puncture the convex surface of a grapefruit, which makes precise needle tenting on the septum
difficult (Fig. 3-27). Care must be taken not to allow the catheter to slip and puncture anteriorly near the ascending aorta or posteriorly into the transverse sinus and then into the left atrium. This course may be catastrophic because the needle is within the left atrium and the operator may think it is safe to advance the large dilator and sheath. A problem will only be apparent upon removing the 14-Fr commissurotomy balloon when the pericardial effusion develops.

**FIGURE 3-24** Intracardiac echocardiography images of the septum with the left atrial appendage at 5 o’clock (left). Tenting of the septum prior to extending the Brockenbrough needle (right). LA, left atrium; LAA, left atrial appendage; RA, right atrium.
FIGURE 3-25 Gross pathology image showing the position of the left atrium and mitral valve. Dotted line denotes the approximate transseptal puncture direction overlaying the mitral valve opening. The left atrial appendage (LAA) is anterior and lateral to the plane of the interatrial septum.
FIGURE 3-26 Transesophageal echocardiography: Convex septum bulging into the right atrium. The transseptal sheath (arrow) is flat or parallel against the septum in the right atrium (instead of pointing perpendicular to it for an easier puncture). AO, aorta.
FIGURE 3-27 A model of a convex septum. As the Brockenbrough needle is rotated anterior to posterior or from the 4 o’clock to the 8 o’clock position, the needle may “jump” over the bulging foramen ovale.

The most common current method to perform percutaneous mitral valvuloplasty is by use of the Inoue balloon. The balloon is self-centering and distensible, which facilitates precise volume inflation. Once the transseptal puncture is performed, a spring-coil guide wire such as the Toray wire is advanced and safely positioned in the left atrium. The sheath and introducer are then removed from the body (Fig. 3-28). A rigid 14-Fr dilator is then used to dilate both the venipuncture at the skin and the septum making sure the dilator is passed 3 or 4 times to allow smooth Inoue balloon transit. The balloon is then advanced under imaging guidance to the left atrium, and the coil guide wire is withdrawn. Due to the stenotic mitral valve, the left atrium can be quite large, and the heart position in the chest may be more horizontal. By fluoroscopy in the RAO projection, the operator would aim the balloon at an angle almost perpendicular to the long axis of body (Fig. 3-29). Care must be taken under imaging to ensure the balloon is not entangled with the subvalvular apparatus. In the RAO projection, the balloon is advanced with the stylet manipulated slightly (about 1 cm) in or out to keep the balloon horizontal and coaxial with the mitral valve. In the RAO view, the balloon is checked for freedom of movement in the left ventricle before fully inflating it. Under TEE, the angle appears to be more oblique to almost inferior, whereas under ICE, due to the orientation of the probe, it will appear to be almost parallel to the long access of the body (Fig. 3-30).²⁷,²⁸
FIGURE 3-28 Anteroposterior fluoroscopy of the Toray looped guide wire in the left atrium (LA). The procedure was performed through a patent foramen ovale (PFO), and at the conclusion of the valvuloplasty, a sizing balloon was used to evaluate the PFO channel. RA, right atrium.
**FIGURE 3-29** Right anterior oblique 30° fluoroscopy. *Top left:* Fluoroscopy of the Inoue balloon crossing the mitral valve at an angle almost perpendicular to the long axis of the body (the catheter then proceeds inferiorly as it moves to the apex of the left ventricle). *Top right:* Distal portion of the balloon is inflated and the balloon is pulled back to the mitral valve under fluoroscopic and echocardiographic guidance. *Bottom left:* The proximal component is inflated with a waist visualized at the site of the mitral valve under echocardiography. *Bottom right:* The balloon is further inflated to the volume set by the inflating syringe.
Once the distal part of the balloon is well inflated, the balloon is pulled back against the mitral valve and the proximal portion is inflated. At this point, a waist should be observable by fluoroscopy and echocardiography. Further inflation will obliterate the waist. The balloon is then deflated and pulled back into the left atrium. The mitral valve gradient and the degree of regurgitation are assessed and the procedure is repeated in a step-wise fashion at 1-mm increments of the balloon diameter until an optimal result is obtained or mitral regurgitation is increased.29

**TRANSCATHETER AORTIC VALVE REPLACEMENT**

Transcatheter aortic valve replacement (TAVR) is associated with several chronic comorbid conditions and prior interventions that may alter the native anatomy. The process of implanting a prosthetic valve in the aortic position requires a detailed understanding of the anatomy of the left ventricular outflow tract, valve, aorta and surrounding structures. In addition, the individual approach taken for the procedure (transfemoral, transapical, transaortic) requires its own considerations, as outlined below.
The aortic valve is typically tricuspid but can exist in other configurations, the most common of which is bicuspid, which occurs in 1% to 2% of the population. A bicuspid valve is the most common indication for intervention in younger patients. The most likely leaflets to fuse in bicuspid valves are the left and right coronary cusps, followed by fused right and noncoronary cusps. A bicuspid valve is often accompanied by aortopathy with subsequent aneurysm formation, so attention has to be paid to the aorta (Fig. 3-31). Rheumatic disease of the aortic valve is less common and produces both a restricted and insufficient valve. Degenerative disease of trileaflet aortic valves increases in prevalence with age, reaching about 2% after age 65 and is associated with atherosclerotic coronary and vascular disease. Aortic sclerosis is a common associated condition occurring in 20% to 30% of all patients older than age 65 years. Currently, transcatheter aortic valve implants are indicated in the United States only for calcified degenerative valves. This is partly due to the need for annular calcification to anchor the current prostheses. Balloon valvuloplasty alone has limited long-term benefit for calcification of trileaflet valves compared to rheumatic aortic stenosis where the commissures are fused and respond better to balloon dilatation. Balloon valvuloplasty in bicuspid and degenerative valves causes stretching of the aortic wall at the nonfused comissures, and much of the early restenosis is due to aortic recoiling.

![Figure 3-31](image)

**FIGURE 3-31** A normal trileaflet aortic valve (left), a bicuspid valve (center), and a degenerative trileaflet aortic valve (right).

The aortic root continues from the left ventricular outflow tract and is separated from it by the aortic valve. The aortic root is made up of the valve leaflets, the sinus, coronary ostia, and contains several anatomic and virtual annuli, which will be described later. The root occupies the center of the heart
when viewed from the short axis (see Fig. 3-25; Fig. 3-32). The most anterior part of the root, looking from the frontal plane, contains the right coronary cusp. This lays posterior-lateral and just inferior to the right ventricular outflow tract. The continuation of the aorta then travels medially along the roof of the right atrium to the arch. The posterior right aspect of the root contains the noncoronary or posterior cusp and forms the fibrous continuity with the mitral valve’s anterior leaflet (Fig. 3-33). This is important to consider when implanting the aortic prosthesis because the fibrous continuity cannot support an implant and placing the prosthesis too far into the ventricle risks displacement, disruption of the mitral valve leaflet, or damage to the chordae tendineae. The rest of the aortic root sits against the ventricular septum, which is made up mostly of the muscular septum, and forms the border against the tricuspid valve and right infundibulum. The membranous component of the ventricular septum sits just below the right and noncoronary aortic cusps and is attached to the interleaflet fibrous triangle made up of the fibrous wall between the right and noncoronary aortic cusps (Fig. 3-34). It separates superiorly the aortic vestibule, which is inferior to the aortic orifice and is composed of fibrous instead of muscular walls, from the right atrium and superior right ventricle. It is possible to injure the septum with instrumentation during a procedure in the left ventricular outflow tract. In cases of heavy subaortic and annular calcification, the septum can be punctured during balloon valvuloplasty producing a ventricular septal defect (Fig. 3-35). Care must be taken to position the percutaneous aortic valve device in patients with an existing prosthetic mitral valve. Because the prosthetic mitral annulus is not compliant and is intimately involved with the aortic annulus, forces applied to the outflow tract will be transmitted away from the aortic-mitral continuity and onto the ventricular septum (Fig. 3-36).
FIGURE 3-32 Transesophageal echocardiography image in the short axis showing the aortic root in the middle, left atrium (LA), right atrium (RA), right ventricle (RV), right ventricular outflow tract (RVOT), and pulmonary artery (Pa).
FIGURE 3-33 Gross pathology image of the left ventricle opened along the long axis. The trigon between the right and noncoronary cusp houses the central fibrous body on the ventricular septum. The anterior leaflet of the mitral valve is continuous with the noncoronary or posterior cusp of the aortic valve.
FIGURE 3-34 The base of the fibrous triangle is made up of the membranous septum and the fibrous trigone and continues on to become the fibrous continuity of the anterior leaflet of the mitral valve.
FIGURE 3-35 A percutaneous prosthetic valve was deployed in the usual position, but heavy left ventricular outflow tract (LVOT) calcification (blue arrow) was compressed against the septal wall during balloon expansion, resulting in rupture through the septum that produced a ventricular septal defect. LV, left ventricle; RA, right atrium; RV, right ventricle; VSD, ventricular septal defect.
FIGURE 3-36 Computed tomography of a patient with a prosthetic mitral valve. Forces applied to the fibrous continuity are resisted by the prosthetic mitral ring and are transferred onto the ventricular septum as well as anteriorly (red arrow).

On the aortic side of the valve, the sinus of Valsalva expands outward, forming a bulb that attaches to the ascending aorta at the sinotubular junction. Attention should be paid to the shape and height of the sinus. A flat sinus may not have enough space during deployment of a balloon-expandable percutaneous aortic valve for the native valve leaflets to be tucked inside the sinus. Instead, a heavily calcified leaflet in a small sinus of Valsalva may be pushed flat along the walls and potentially obstruct a coronary ostium (Fig. 3-37). This possibility, due to a shorter and smaller sinus, is greater in women.
FIGURE 3-37 Computed tomography of a heavily calcified aortic valve leaflet, leaflet length, and coronary ostial height.

The course of the coronary arteries may be variable, which has implications for the procedure and may lead to compression by the implant. If there is an anomalous coronary course, there is a small chance of coronary compression during device expansion. A coronary angiogram prior to the implant is also important to look for coronary artery stenosis. The principal anatomic considerations for coronary occlusion following a TAVR procedure are the height of the coronary ostia, the diameter of the annulus, the diameter and shape of the sinus of Valsalva, and the size of the calcification on the left coronary leaflet. A sinus of Valsalva diameter less than 30 mm and left main coronary ostium less than 12 mm in height measured from the nadir of the cusp are associated with an increased risk for coronary occlusion.\textsuperscript{33} While angiographically the right coronary artery ostium appears to be lower than the left due to the angulation of the heart relative to the longitudinal axis of the body, it is actually further away from the aortic valve, so right coronary artery occlusions are much less common during TAVR.\textsuperscript{34} The risk of coronary occlusion is not changed by the approach or by annular calcification.\textsuperscript{33} The presence of a bulky nodule at the edges of the native leaflets, however, may be a risk factor and requires attention. The height of each coronary ostia should be measured from the base of the virtual ring that circumscribes the nadirs of the leaflets to the ostia, keeping in mind that a long native leaflet may still present a risk despite adequate coronary height (Fig. 3-38). In most hearts, the 3 leaflets have different sizes and insertion
points along the sinus of the root.\textsuperscript{35} If there is concern, then the coronary artery may need to be prewired and an angioplasty balloon and stent placed in the left main or anterior descending artery to facilitate an intervention should one be required. Occlusions are not usually caused by the aortic valve prosthesis itself, but by the native degenerated leaflets as they are pushed up and into the coronary ostium (\textbf{Fig. 3-39}). Acute persistent hypotension is the most common early clinical indication of coronary occlusion after valve implant. Calcification of the native valve and annulus is required to anchor the prosthesis, but a large calcified nodule may cause poor apposition of the valve stent to the sinus wall and induce paravalvular leaks.\textsuperscript{36}
FIGURE 3-38 Fluoroscopy of a balloon valvuloplasty and aortic valve implant via a transapical approach. *Top left:* Heavy valvular calcification is apparent on the left coronary leaflet being pushed against a narrow sinus during balloon expansion. *Top right:* Angiogram of the aortic root during balloon expansion showing occlusion of the left main coronary artery but contrast flows down the right coronary artery. *Bottom left:* Leaflet calcification occluding the left main coronary after valve implant. An angioplasty wire and balloon were placed down the left anterior descending artery prior to valve implant in anticipation of possible compression of the left main artery. *Bottom right:* Balloon angioplasty and stent placement in the left main coronary artery.
FIGURE 3-39 Extracted prosthesis showing the deformed stent strut (arrow) due to a calcified nodule on the native leaflet (shown on computed tomography in Fig. 3-37).

Several measurements need to be made during assessment and preprocedure planning. The most important of those is a virtual ring that circumscribes the nadirs of the 3 coronary cusps (Fig. 3-40). The left ventricular outflow tract joins the aortic valve and aortic root at this level and is the annulus ring that determines the aortic valve prosthesis size. Care must be taken to measure the annulus at this level perpendicular to the 3 leaflets and during a systolic phase. The aorta changes configuration during systole from an oval to a more round shape, which conforms more to the expected prosthesis shape and becomes larger in area. Therefore, when deciding on the prosthesis size, it is more appropriate to measure the annulus during the systolic phase. A less perpendicular plane or not measuring at the virtual basal ring level may give an incorrect annular size. This is more likely with 2-dimensional (2D) imaging; 3-dimensional (3D) imaging, such as 3D TEE or multiplanar cardiac computed tomography (CT), can help avoid this error (Fig. 3-41). During angiography, the C-arm is rotated with the pigtail catheter
in the right coronary cusp until the catheter appears to be in the center of the aortic root. Adjustments are made at 10° increments until the angiogram demonstrates a coplanar view of all 3 cusps. At this angulation, the prosthesis can be centered on the annulus while observing the relative position of the aortic root and outflow tract in profile (see Fig. 3-38).\textsuperscript{38} Echocardiography may also underestimate the size of the aortic valve annulus due to measuring from the base of the commissure between 2 leaflets diagonally to the other commissure rather than to the mid-base of an opposite leaflet 180° away (Fig. 3-42). To ameliorate this, the transducer is rotated toward the left shoulder to show a more complete root and annulus and reduce foreshortening. The other important anatomic measurements include the circumference and diameter at the mid-sinus and at the sinotubular junction (STJ). The STJ is about 20% larger than the virtual basal ring.\textsuperscript{39} In cases where the STJ is smaller than the annulus, the balloon and prosthesis selected may be larger than the STJ diameter. This presents the risk of embolizing the prosthesis into the ventricle during implant or rupture of the STJ during balloon expansion. Other measurements to be done include chamber dimensions and stroke volume. Attention to the chamber size and stroke index provides insight into the etiology of the aortic gradient and identifies conditions of low-flow and low-gradient aortic stenosis as compared to pseudostenosis.

\textbf{FIGURE 3-40} \textit{Left:} The virtual basal annulus (1), mid-sinus annulus (2), and sinotubular junction diameter (3). \textit{Right:} The virtual basal ring circumscribes the nadirs of the 3 leaflets and separates the left ventricular outflow tract (LVOT) from the root of the aorta.
FIGURE 3-41 Left: On-axis annular measurement of the basal ring. Right: Off-axis measurement showing a falsely large diameter.

FIGURE 3-42 Echocardiogram (left) and cardiac computed tomography (right) of the aortic valve in the short axis. Diameter measured from the base of one commissure to the other commissure (red) yields a foreshortened width compared to the correct measurement (white) 180° opposite.

Left ventricular septal hypertrophy also presents a challenge when implanting an aortic valve prosthesis. The balloon on balloon-expandable prostheses such as the Edwards Sapien series (Edwards Lifesciences, Irvine, CA) extends distal and proximal from the valve annulus. Although a narrow STJ may embolize the valve into the ventricle, a bulging septum and hypertrophied left ventricular outflow tract may “watermelon seed” the balloon and valve proximally into the aorta during deployment (Fig. 3-43). Additionally, patients with hypertrophic cardiomyopathy are dependent on
the high afterload of the stenotic aortic valve. Relieving the obstruction and the afterload may have a catastrophic outcome in the form of severe dynamic outflow tract obstruction, which can be life threatening. Careful imaging and study of the anatomy are important before embarking on the procedure. As patients advance in age, the aorta and its root may take on a more angulated course from the left ventricular outflow tract. A horizontal aorta directs the guide wire laterally off-center toward the right of the aortic root. This may make crossing the native valve with the prosthesis difficult. To cross the valve and center the prosthesis, pulling tension on the wire lifts the device delivery catheter off the right cusp and toward the middle of the aortic root.

![FIGURE 3-43](image)

**FIGURE 3-43** Effect of left ventricular outflow tract (LVOT) septal bulge. On the left is the native aortic valve with a septal bulge prior to transcutaneous aortic valve replacement (TAVR). On the right is the outcome after prosthesis implant. The intended center of the implant was to be at the blue arrow. The septal hypertrophy displaced the valve stent toward the aorta (Ao) so that the midpoint is now at the red arrow and more aortic than intended. LA, left atrium; LV, left ventricle.

The ventricular conduction system begins in the right side of the septum and, once past the atroioventricular (AV) node, crosses the ventricular septum to emerge on the left side through the central fibrous body (CFB) connected to the tendon of Todaro in the right atrium. The CFB is a fibrous, thickened structure where the annulus of the mitral, tricuspid, and noncoronary cusps of the aortic valve meet and makes up part of the fibrous skeleton of the heart.
(see Fig. 3-33). The CFB is located along the posterior-inferior margins of the membranous ventricular septum at the nadir of the noncoronary cusp along the left ventricular outflow tract which can be imaged by either echocardiography or CT. Once the bundle of His enters the left side, it travels superficially along the edge of the septum before dividing into the anterior and posterior fascicles. An intervention that affects the left ventricular outflow tract has the potential to disrupt conduction, inducing heart block as well as causing the mechanical complications described earlier. Patients with a right bundle branch or fascicular block are at increased risk, especially with a ventricularized or long implant. This is especially a risk with prostheses that extend into the left ventricular outflow tract such as the self-expanding valves.\textsuperscript{40} In addition to the anatomic issues discussed earlier, there are specific considerations related to the approach of the aortic valve implant procedure.

**Transaortic**

The transaortic approach permits a direct and short-distance access to the aortic valve in cases where the patient may not have adequate peripheral vascular access due to severe aortoiliac disease. This approach should be avoided in patients with a brittle “porcelain” aorta, since the calcified aortic root may fracture during the procedure, making repairs difficult and potentially causing the aorta to be replaced. When deciding on the transaortic approach, the position of the aortic arch and angle between the aorta and left ventricular outflow tract need to be studied. An aorta angled behind the sternum, or to the left of it, prevents ready access to the aortic incision site and raises the risk of vascular complications. If the entry angle through the aorta to the left ventricular outflow tract is steep due to a horizontal heart, the approach will not be in a direct line and the valve may not be oriented parallel to the native valve. The access to the aorta is made from the right anterolateral side of the aorta so that the catheter is coaxial in both the coronal and axial axes. If the access is made through the anterior wall of the aorta, the catheter would be angulated posteromedially as it crosses the aortic valve (Fig. 3-44). This is more pronounced in older patients with a horizontal aorta and sharp angulation between the left ventricular outflow tract and aortic root.
FIGURE 3-44 Transaortic approach to transcutaneous aortic valve replacement. Anteroposterior (left) and lateral (right) computed tomography images of the left ventricle and aorta. The anterior approach (yellow arrow) is behind the sternum, limiting access, and directs the catheter posteriorly and behind the right cusp. A right lateral approach (white arrow) directs the catheter coaxially down the aorta and toward the center of the aortic valve.

Transapical

The transapical approach is also an option in patients with limited peripheral access. This approach has the advantage over peripheral access due to better control of the delivery catheter position, but the disadvantages of a thoracotomy and possible ventricular bleeding. Through a mini-thoracotomy, a puncture is made in the anterior-apical left ventricle, and a guide wire is advanced antegrade out the ascending aorta (see Fig. 3-38). It is necessary to angulate the needle hub posteriorly so that the tip is pointing toward the left ventricular outflow tract. If the needle is angulated posteriorly, it will preferentially direct the guide wire toward the mitral valve. Before the thoracotomy is made, a review of the coronary angiograms is useful to avoid puncturing a coronary artery or bypass graft. The goal is to puncture the apical left ventricle between the left anterior descending artery and a diagonal where there is a paucity of coronary arteries. If the left anterior descending artery does not reach the apex and the right coronary artery instead wraps
around the apex, then care should be taken to avoid the concealed coronary in the area of planned catheter introduction.

Transfemoral

Transfemoral access is the most common entry approach to the procedure. It is associated with lower morbidity and shorter hospital stays. Vascular complications still constitute the most common procedural problem in TAVR and worsen the 30-day outcomes. A thorough understanding of peripheral anatomy is required, but a brief outline is described here. The delivery system size has decreased over time, but with the early generation devices, vascular disruption was not uncommon. Accommodating the larger sheaths becomes challenging in tortuous or highly diseased vessels. Severely tortuous iliac arteries may be straightened by a stiff guide wire provided they are not rigid with calcification. Calcified nodules in the iliac arteries may produce scoring on the sheath as it is forced past the narrowed segment of the artery (Fig. 3-45).
Other concerning signs include circumferential calcification and calcification at the edges of iliac bifurcations. Circumferential calcification prevents vessel expansion and reduces the precision of CT measurements due to blooming artifact. Heavy calcification at the retroperitoneal iliac bifurcation poses a risk for tears in a region difficult to reach and repair surgically (Fig. 3-46). The internal vessel diameters are best assessed using...
imaging such as CT or magnetic resonance imaging. When using angiography, a centimeter-graduated catheter and digital subtraction should be used. Angiography is not as ideal in providing diameter measurements due to eccentric lesions and limitations on resolution. If there is concern and a lack of adequate imaging, then peripheral intravascular ultrasound may also be used to better assess arterial diameters and disease burden prior to sheath introduction. Narrowed areas of the aorta may cause the pigtail or other catheters to become trapped by the valve sheath. In these cases, the pigtail catheter would be better placed from a radial access site.

**FIGURE 3-46** Bleeding at the site of a left iliac tear with extravasation of contrast dye. Note the operator’s hands compressing the iliac artery while preparations are made to bypass the iliac rupture.
LEFT ATRIAL APPENDAGE EXCLUSION

Atrial fibrillation is the most common arrhythmia and affects 0.4% of the general population. In patients older than 80 years, the prevalence is 9%. Atrial fibrillation hospital admissions have increased by 66% over the past 2 decades due to an increase in the average age of the population, a higher prevalence of hypertension, heart disease, and better diagnosis.\textsuperscript{44}

The left atrial appendage (LAA) is a small muscular outpouching of the left atrium arising anterior and lateral to the left pulmonary veins. Embryologically, the appendage is truly part of the heart, and the main left atrium is an extension of the coalescence of the pulmonary veins into the fetal heart. This explains why the endocardium of the left atrium is thick and white, without trabeculations, and also explains why there is cardiac muscle in the pulmonary veins. Normally, blood flow into and out of the LAA is sufficiently vigorous to prevent formation of thrombus. During atrial fibrillation, the blood velocity in the appendage is chronically reduced and stasis may occur. In patients with paroxysmal atrial fibrillation, even during normal sinus rhythm, the fractional shortening of the LAA remains suppressed, and blood velocity inside the appendage is reduced dramatically.\textsuperscript{45} Although thrombi can occur in the body of the left atrium during atrial fibrillation, more than 90% of thrombi develop within the LAA due to hemostasis and the presence of interstices within the muscle fibers of the LAA.\textsuperscript{46}

Anticoagulation significantly reduces the incidence of morbidity from thromboembolism in atrial fibrillation, but at the cost of increased bleeding. Closing the LAA by surgical or transcatheter techniques is an attractive alternative to anticoagulation therapy to reduce the risk of embolic injury while avoiding the risk of potential bleeding from anticoagulation therapy. Successful transcatheter LAA occlusion requires a knowledge of the anatomy, surrounding landmarks, and morphologic variants of the LAA.

The interatrial septum is obliquely angled from the posterior right to the anterior left in relation to the long axis of the body. The left atrium is posterior to the right atrium, so pulmonary veins that enter the left atrium are located posterosuperiorly and form the dome of the left atrium (Fig. 3-47).
The walls of the left atrium are nonuniform in thickness and smooth outside the LAA. The anterior wall of the left atrium is located behind the ascending aorta and the transverse sinus and can be very thin (~1-2 mm). This presents a risk of puncture when manipulating catheters in that region. The posterior wall is the thickest (6.5 mm) part of the left atrium, but it can become thinner at the pulmonary vein orifices (Fig. 3-48). The left lateral endocardial ridge protrusion marks the junction between the mouth of the appendage and the LUPV. Thus, the major part of the left atrium, including the septal component, is smooth-walled.

**FIGURE 3-47** Left: Anterior view of the open left atrium showing the pulmonary veins and blood return from the lungs into the atrium. Right: Posterior view of the left atrium and pulmonary veins. Ao, aorta; LAA, left atrial appendage; LPV, left pulmonary vein; RPV, left pulmonary vein; SVC, superior vena cava.
The LAA junction with the left atrium is narrow and usually well-defined. The relationship between the orifice of the LAA and the LUPV is important in preprocedural planning. The LAA may be superior, inferior or, in over half of patients, at the same level as the LUPV, and care must be taken during fluoroscopy to position the catheters in the appropriate structure. To minimize the risk of cardiac perforation during LAA occlusion procedures, a low posterior transseptal puncture will direct the catheter in a more direct fashion toward the LAA orifice (see Fig. 3-18). Care must be taken to avoid angulating too superiorly and puncturing the transverse sinus or posteriorly into the pulmonary veins. A PFO, when present, will direct the catheter in a superior-posterior direction, which may sometimes make access into the LAA more difficult. A more inferior puncture is typically required even in the presence of a PFO.

The LAA is on the left border of the heart between the left ventricle and pulmonary outflow tract. It lies within the pericardium next to the superior lateral aspect of the main pulmonary artery and superior to the left ventricular free wall (Fig. 3-49). There is considerable variability in LAA shape and orientation, which influences the selection of closure device used or if the anatomy is amenable to transcatheter exclusion (Fig. 3-50). The appendage has multiple lobes in over 80% of patients, with 2 lobes in 54% and 3 lobes in 23%. The body of the LAA is composed of trabeculated pectinate muscles, greater than 1 mm in size, which may be confused with thrombus during screening echocardiography. It is important to exclude the presence of thrombus prior to the procedure, as guide wires and a pigtail catheter will be introduced into the LAA in the course of the intervention.
FIGURE 3-49 Anterior view of the heart with left atrial appendage (LAA) in relationship to pulmonary valve and aortic valve. SVC, superior vena cava.
FIGURE 3-50 Lariat suture system excluding the left atrial appendage (LAA). The intracardiac magnet is placed in the LAA via a transseptal puncture. A pericardial tap delivers the extracardiac magnet, and the 2 are approximated until they attach near the apex of the appendage (dashed lines). TEE, transesophageal echocardiography.

Morphologic variations of the LAA include metaphorical descriptions such as the chicken wing (51%), windsock (29%), cactus (15%), and cauliflower (5%) shapes (Fig. 3-51). The chicken wing variant curves in the middle of the dominant lobe. The windsock form presents as 1 dominant lobe with other lobes arising from the dominant one. These 2 forms are the most amenable to extracardiac devices such as the Lariat suture delivery system (SentreHeart, Redwood, CA). The cactus variant also has a dominant lobe with secondary lobes extending from the dominant one in all directions. The cauliflower LAA is a shorter more complex form with multiple irregular
shapes making external device attachment challenging. The closure device should be positioned to occlude all lobes of the LAA. The morphology of the LAA also appears to be associated with variations in embolic risk.

FIGURE 3-51 A. A transseptal sheath is used to inject contrast into the left atrial appendage (LAA) demonstrating a chicken wing morphology. The pericardial sheath is advanced towards the LAA apex prior to passing the Lariat magnets. B. A transseptal sheath is used to inject contrast into the LAA demonstrating a “windsock” morphology. A pericardial wire is in place prior to advancing a pericardial sheath. C. A transseptal sheath is used to inject contrast into the LAA demonstrating the “cactus” morphology. A pericardial sheath is advanced over the wire prior to passing
The Lariat magnets. D. A transseptal sheath is used to inject contrast into the LAA demonstrating the “cauliflower” morphology.

The shape of the LAA ostium is usually visualized as one of several types: oval (69%), foot-like (10%), water drop–like (8%), triangular (8%), and round (5%). The outside of the tip of the appendage is oriented anteriorly and cephalad in most patients but may also be directed inferior, posterior, or, infrequently, into the transverse pericardial sinus. Again, this will influence the approach for extracardiac device exclusion or direction of the delivery sheath for intracardiac devices. The heterogeneity of LAA morphology requires careful imaging assessment prior to attempting transcatheter closure. CT is useful to study the surrounding structures as well as to identify the LAA morphology and its suitability for transcatheter closure. TEE, however, is the most commonly used modality to evaluate the LAA and left atrium before, during, and after device implantation.

To visualize the LAA thoroughly, the TEE probe is advanced from the high esophagus to the mid esophagus. Once the pulmonary veins are visualized, the probe is rotated clockwise until the LUPV comes into view at the 2 o’clock position. The omniplane device is then rotated through 0°, 45°, 90°, and 135° to completely scan through the different aspects of the LAA. This also allows identification of the coronary artery, mitral valve annulus, and LUPV to help orient the device prior to release. Three-dimensional TEE allows for better LAA length assessment by use of reconstruction as well as en-face visualization of the ostium for device sizing. If ICE is used, initial images are obtained from the home view to position the transseptal needle (see Fig. 3-20). Once the transseptal puncture is completed, the probe can be positioned in the pulmonary artery to visualize the LAA. This is performed by unlocking and flexing the catheter, then rotating and advancing it into the right ventricular outflow tract. The LAA ostial diameter may vary depending on the loading conditions, and thus, it is best to have the left atrium pressure around 10 mm Hg when making measurements. The ostial diameter is measured from the anterior rim of the appendage adjacent to the origin of the left circumflex artery to the posterior rim approximately 1 cm below the tip of the limbus of smooth muscle that separates the LUPV from the appendage. This ridge was often mistaken for possible thrombus, resulting in initiating anticoagulation, and so it has been called the “warfarin ridge” (Fig. 3-52). The typical diameter of the ostium is 17 mm in the long axis and 11 mm in the short axis. The depth is measured from the appendage apex to the line
transecting the ostial diameter. If the depth is smaller than the ostial diameter, an Amplatzer Cardiac Plug (St. Jude Medical) may be more suitable than a WATCHMAN device (Boston Scientific, Marlborough, Massachusetts), which requires an appendage depth at least as long as the device diameter.

**FIGURE 3-52** Transesophageal echocardiography of the left atrium, left atrial appendage (LAA), left upper pulmonary vein (LUPV), and “warfarin ridge.” The color-flow Doppler demonstrates blood flow into the left atrium from the pulmonary vein (red) and blood flow into the LAA (blue).

During preliminary imaging by use of TEE or ICE, it is important to evaluate the area between the muscular trabecular wall and atrial wall, which may be quite thin and prone to perforation by the device delivery catheter. The LAA ostium is situated above the left AV groove, which contains the left circumflex artery and the great cardiac vein. The distance between the left circumflex and ostium of the LAA is variable. When the distance is narrow, special care needs to be practiced to avoid excessive pressure by an oversized closure device, which may compress the coronary artery. In patients with prior coronary bypass graft surgery or patients with pericardial adhesions, the anatomic position of venous grafts targeted to the obtuse marginal or diagonal arteries can also be close to the tip of the LAA, exposing them to injury during percutaneous epicardial approaches. The sinoatrial nodal artery can originate from the circumflex artery in 40% of patients. The sinoatrial nodal artery can course between the LAA and LUPV in 14% of patients and may also be compressed during placement of a LAA exclusion device. Other important structures that can lie in the ridge between the LUPV and LAA are
the ligament of Marshall, left phrenic nerve, and a persistent left SVC. CT imaging is the preferred modality to demonstrate the relationship of these structures to the LAA ostium and body of the left atrium. After device closure, echocardiographic evaluation is used in conjunction with fluoroscopy to better direct the catheters and improve device positioning. Three-dimensional TEE is then used to ensure adequate device sealing of the LAA including all accessory lobes, and color-flow echocardiography is used to assess flow around the device to ensure that any residual opening into the LAA is less than 5 mm.

**VENTRICULAR SEPTAL DEFECTS**

Congenital ventricular septal defects (VSDs) are the most common congenital heart defect. They are usually diagnosed in childhood, and few are seen in adults. Acquired VSDs may occur due to trauma, infection, or after a myocardial infarct, and are more often the VSDs addressed in the adult population. Surgical VSD repair remains the mainstay of treatment. The principal complications in a hemodynamically stable patient include AV and bundle branch blocks requiring a pacemaker (4%) and residual leaks (8%). In patients who are poor surgical risks, however, the option of transcatheter treatment is attractive. As with surgery, the most common complication is AV block (1%-1.9%) and bundle branch block (2.8%). Heart block is usually transient and recovers soon after or with steroid therapy.

The ventricular septum is nonlinear and interacts with both the right and left ventricular chambers of the heart. (Fig. 3-53). The more basal and posterior section of the septum is composed of membranous tissue separating the left and right ventricular outflow tracts (see Figs. 3-33 and 3-34). It lies just under and between the right and noncoronary or posterior cusp of the aortic valve. Due to the proximity of the membranous septum to the AV node, repair of a defect there runs a higher risk of heart block. If the defect extends beyond the membranous region and includes the surrounding muscular septum, it is called a perimembranous defect. This is the most common type of VSD in adults, accounting for 72%. During procedures such as TAVR, this portion of the septum may be injured by the displaced calcification, producing a membranous VSD or heart block.
A muscular VSD can be divided into 3 types: trabecular, inlet, and supracristal; however, often a VSD can have components of different types. The trabecular VSD accounts for the majority of VSDs (5%-20%). This occurs as a defect more apically between the trabeculated muscular left ventricle and the right ventricle. When muscular VSDs occur in childhood, they often close spontaneously and may be managed conservatively, especially with small, restricted shunts. The defect may be challenging to see.
by echocardiography or appear as multifenestrated due to the trabeculations. It is important to obtain detailed imaging prior to attempting transcatheter closure of this defect to assess the thickness of the trabeculations and the diameter of the defect.

An inlet septal defect occurs just below the AV valves (tricuspid and mitral). This VSD can occur in association with AV septal defects involving the endocardial cushion in cases of more complex congenital anomalies. Due to its proximity to the AV valves, a transcatheter repair is usually not possible. If this defect is suspected, additional care should be taken to assess the cardiac anatomy and look for other defects.

The supracristal defect is also called an infundibular, subarterial, subpulmonary, conal, or doubly committed VSD. It lies between the left and right ventricular outflow tracts just under the aortic and pulmonic valves and is more anterior to the membranous septum. This defect, if large enough, will present with aortic regurgitation because the right aortic cusp prolapses into the defect. With time, this can produce progressive aortic valve damage. The defects that may be managed by transcatheter techniques are the perimembranous and muscular VSDs.

A myocardial infarct due typically to occlusion of the left anterior descending coronary artery can bring about a muscular VSD usually in the trabecular region. This type of VSD presents a challenge to transcatheter closure because of the necrotic and weakened margins surrounding the area of injury as well as the thick muscular ridges. It is associated with a high mortality but may be amenable to percutaneous closure in selected patients.

Echocardiography is the principal tool to evaluate VSDs. An initial assessment should include location, size, number of defects, and other associated anomalies. The 2 initial views used to assess a VSD are the parasternal long and parasternal short-axis views. The septum is perpendicular to the ultrasound beam in those views providing the best spatial resolution. The 4-chamber view is then used to assess muscular VSDs further. Table 3-2 lists the best window used for the different defect types (Fig. 3-54).

Table 3-2  The Different Echocardiographic Views That Best Show Each Ventricular Septal Defect (VSD) Type
FIGURE 3-54 Short-axis and parasternal long-axis transesophageal echocardiography views. These are the initial orientation views to assess for the most common types of ventricular septal defects (VSDs). Color-flow Doppler is then used to assess flow. The red, blue, and green lines demonstrate where the different types of VSD are located. LV, left ventricle; MV, mitral valve; RV, right ventricle.

Using TEE, a probe is placed in the high esophagus and rotated to show the aortic valve. The omniplane is then rotated to 40° to 70° to view the aortic

valve en face. The membranous septum is then viewable in the 7 to 10 o’clock position next to the valve and just medial to the tricuspid valve. A supracristal septal defect would be observed at the 4 to 7 o’clock position. Rotating the omniplane further to show the valve in the long axis will bring into view the membranous septum just below the aortic valve; the supracristal and the muscular septum are seen further apically. Advancing the probe to the mid-esophageal position and rotating the omniplane to 0° to show the 4-chamber view will yield the inlet and trabecular muscular VSDs. Use of 3D echocardiography is helpful in reviewing all margins of the defect as well as quantifying the physiologic extent of the shunt. The hemodynamic effects of a VSD, as well as anatomic structural consequences influence the decision to intervene on the VSD. A sizing balloon can also be used to better assess the appropriate size device to be used, similar to closing an ASD. Multiplanar CT reconstruction will further help quantify the location and size of the VSD in preparation for transcatheter intervention. It is especially helpful in assessing the location of the defect in relation to the surrounding structures and valves.

Different devices are available to close the different types of defects. Due to the heterogeneity of the ventricular septum, the devices have characteristics specific to each part of the septum. Options for closure include using the Amplatzer series of VSD devices (St. Jude Medical) and the Nit-Occlud device (pfm medical ag, Köln, Germany). The Amplatzer muscular VSD occluder is a double-disk nitinol wire mesh with polyester patch designed to fit the thicker muscular septum. The muscular occluder has symmetric right and left ventricular disks 8 mm wider around the circumference than the waist (Fig. 3-55A). The postinfarct version of the device has a 10-mm-long waist to accommodate infarcted myocardial tissue at the rims (Fig. 3-55B). The membranous VSD occluder is a self-centering retrievable double-disk device with a shorter waist. The device is eccentric with a left side aortic overhang of 0.5 mm and a left side ventricular overhang of 5.5 mm. The ventricular end has a radiopaque marker to help orient the longer component of the disk toward the ventricular apex. This allows the device to be implanted without impinging on the left heart valves (Fig. 3-55C).
FIGURE 3-55 A. Amplatzer muscular ventricular septal defect (VSD) occluder. B. Amplatzer muscular VSD postinfarct occluder. This device has a wider waist to anchor to the infarcted tissue. C. Amplatzer membranous VSD occluder. The device is eccentric with a shorter disk overhang on the valve side and longer ventricular side (C). The device is sized according to the waist (A). A marker at the distal left-sided disk identifies the orientation angiographically.

After closure, further assessment by TEE is important to determine the adequacy of closure and assess for residual shunting and stability of the device. This is accomplished by use of TEE and angiography. The TEE probe or C-arm is rotated to an orthogonal plane to show the device across the
septum in profile and assess for residual flow. The goal of the procedure is to place the left ventricular disk flush with the left side of the septal wall. The rest of the device can be irregularly placed within the defect and on the right side of the septum. Should heart block develop, the patient should be monitored and possibly treated with steroids. Echocardiography also helps in viewing the nearby structures, such as valves, and looking for possible device impingement prior to release.

THE MITRAL VALVE

The mitral valve is a complex structure that permits unidirectional flow of blood between the left atrium and left ventricle. The parachute-like structure of the mitral valve is a wonder of evolutionary design. It has to withstand the full force of the left ventricular pressure during every systole for 2.2 billion heartbeats in an average lifetime. It should not be surprising that mitral regurgitation is so common in the elderly. The valve was named by Andreas Vesalius in the 1500s because it reminded him of the Pope’s hat, called a mitre. An understanding of the anatomy of the valve and relative views using different modalities is important in procedures such as the Mitraclip (Abbott Vascular, Temecula, CA), annuloplasty ring placement, coronary sinus devices, and paravalvular leak closures.

The annulus of the mitral valve is made up of fibrocollagenous tissue that creates an asymmetric valve opening of 4 to 6 cm$^2$. The annulus measures 9 to 10 cm in circumference and is reinforced by the right and left fibrous trigons, which attach to the mitral-aortic fibrous continuity anteriorly. Identification of the trigons is important because the conduction tissue lies beneath it and could be injured during surgical repair or replacement of the valve. The mitral-aortic continuity attaches to the fibrous tissue just below the interleaflet triangle between the noncoronary and left coronary cusps. This anterior segment of the annulus is more rigid and less likely to deform. The posterior segment is made up of muscular tissue and is more likely to stretch, which predisposes to functional mitral regurgitation when the left ventricle dilates.

From the short axis, the mitral valve appears to curve upward, with the trigons more apical and the middle of the valve leaflets (A2, P2) more atrial. This has been described geometrically as a hyperbolic paraboloid or saddle.
shape. The coronary sinus circumferentially parallels the mitral valve annulus, anteriorly from the great cardiac vein and posteriorly where the vein of Marshall enters and empties into the posterior right atrium at the coronary sinus ostium. The ostium is partially covered by the Thebesian valve, which makes retrograde entry into the coronary sinus difficult in 3% of patients. There may be several valves of Vieussens within the coronary sinus, which may also impede retrograde passage of catheters or pacemaker wires. The coronary sinus is 0.5 to 1 cm above (atrially displaced) the annulus of the mitral valve. Devices that are placed within the coronary sinus to “cinch” the mitral valve leaflets are actually pulling together the atrial tissue above the level of the valve, but nonetheless appear capable of approximating the mitral leaflets (Fig. 3-56). The circumflex coronary artery runs a course parallel to the annulus of the mitral valve and coronary veins. When the artery courses under the vein, there is a risk of compressing or occluding the circumflex coronary artery with devices that are placed within the coronary sinus to approximate a percutaneous annuloplasty (Fig. 3-57).
FIGURE 3-56 The relative location of the coronary sinus (CS) compared to the mitral annulus. Top: There is a displacement vertically (y) as well as laterally (x) between the CS and the mitral annulus, and this relationship changes during the cardiac cycle as well as with pathology. The CS is the opening of the GCV into the RA. Below: The CS (white arrow) as it surrounds the heart externally from different views. GCV/AIV, great cardiac vein/anterior interventricular vein; LA, left atrium; LV, left ventricle; RA, right atrium.
The broader anterior leaflet extends in a crescent shape further into the opening and attaches to the anterior fibrous annulus. The leaflet is divided into 3 sections named A1, A2, and A3, with the A1 segment positioned laterally and A3 segment positioned most medial. The attachment point of the leaflet to the annulus is called the basal zone. The center of the leaflet is named the clear zone, and the outer free edge of the leaflet where the chordae attach is named the rough zone. This is the target zone for attachment of the Mitraclip or Alfieri stitch. As described in Figure 3-48, the anterior leaflet extends further into the orifice, while the posterior leaflet involves a larger part of the mitral annulus. The posterior mitral leaflet is more narrow in width but extends over two-thirds of the circumference of the annulus. The posterior leaflet does not displace as much as the anterior leaflet into the left ventricle during diastole. The scallops of the posterior leaflet are more distinct than those of the anterior leaflet and are named P1, P2, and P3. The P1 scallop opposes the A1 scallop laterally, and the P3 scallop is more medial and apposes A3. The free edge of this leaflet also contains the rough zone where chordae attach for support.
The chordae support the valve structures and prevent the leaflets from prolapsing into the atrium during systole. The chordae act as a series of anchors to hold or tether the leaflets from moving excessively. Most chordae originate from the papillary muscles and divide into a fan shape before reaching the valve edges. There are 3 types of chordae. The primary or rough zone chordae attach to the rough free edge of each leaflet. The secondary chords attach to the body of the leaflets on the ventricular side. The tertiary or basal chordae attach only to the basal segment of the posterior leaflet and are connected directly to the ventricular wall, not the papillary muscles. The chordae tend to be closer together at the edges of the valves. The lack of basal chordae on the anterior leaflet makes passing catheters into the ventricle easier when aiming at the center of the valve away from the commissures and toward the anterior leaflet.

There are 2 papillary muscles positioned anterolaterally, and posteromedially. They can have a single or multiple projections or heads, and the chordae originate along the edge of these muscles. The chordae from each papillary muscle divide and attach to both leaflets of the valve so that during systole the valve leaflets are brought together and secured against the contracting ventricle. It is important to note the anterior papillary muscle has a dual coronary blood supply, whereas the posterior muscle is supplied only by the right coronary artery or dominant circumflex artery. A large infarct can affect the posteromedial papillary muscle more often and result in ischemic mitral regurgitation or papillary rupture. Transcatheter repair using the Mitraclip requires that the regurgitation pathology be more centralized, such as in the A2-P2 area, and with a leaflet coaptation depth less than 11 mm, flail gap less than 10 mm, flail width less than 15 mm, and mobile leaflet length greater than 10 mm. This allows the clip to properly secure the leaflets and resolve the majority of the regurgitation. There should also not be significant mitral stenosis, and the final orifice area should be greater than 4 cm². Some valves are tethered by rheumatic disease or restriction due to papillary muscle dysfunction such that the leaflets are too far apart, have a large flail gap, or already exhibit stenosis. In these cases, the likelihood of procedural success is lower, and there is a possibility of mitral stenosis if a clip is implanted.

A way to orient the operator during fluoroscopy is to consider the location of the left anterior descending artery and right coronary artery. The anterior-lateral mitral commissure is close to the ostium of the left anterior descending
artery as it leaves the left main coronary artery. In the 30° RAO projection, the anterior leaflet is seen superiorly while the posterior leaflet is inferior. The anterior-lateral commissure is anterior at the junction of the 2 leaflets. From the LAO caudal projection, the anterolateral mitral commissure is on the left, and the posteromedial commissure is on the right, with the anterior leaflet above the posterior leaflet.

CT can provide useful information in terms of structure but not function. Echocardiography remains the principal modality to best evaluate the function of the mitral valve. Multiplanar views define the aspects of the valve apparatus in several planes corresponding to fluoroscopic and echocardiographic views (Fig. 3-58). The higher spatial resolution of CT provides structural information including restriction of the leaflets, tethering of the chordae, or dilation and deformation of the annulus.
Transthoracic echocardiography is the recommended first-line modality to assess the function of the mitral valve. Three-dimensional echocardiography provides further information on structure giving a more complete picture of the valve in real time. The parasternal long and short views provide good assessment of the annulus and valve as well as possible dysfunction including inadequate tethering of the leaflets. The 2- and 4-chamber views provide information on ventricular and annular dilation as well as atrial size to produce a more complete picture of the mitral valve pathology.\textsuperscript{62}

By TEE, the valve can be visualized in the short axis from the mid-esophageal position. Starting with the omniplane at 0° to show the 4-chamber view, the probe is rotated to step through the commissures of the 2 leaflets and demonstrate all coaptation points. The interatrial septum also can be visualized to guide a transseptal puncture. The TEE probe can then be advanced to obtain transgastric views and flexed to look up toward the mitral valve in the short axis. This is especially useful to review the entire annulus. In order to position the clip in the correct orientation relative to the regurgitation jet and prolapsed segment, a TEE “bicommissural” and “LVOT” views are used to ensure the appropriate trajectory. The use of 3D echocardiography provides incremental information on the geometry of the valvular apparatus. Due to the 3D shape of the annulus and leaflets, 2D imaging may miss the extent of pathology and foreshorten important structures. Three-dimensional echocardiography provides a better guide during percutaneous interventions and improves procedural outcomes.\textsuperscript{63}

The modalities described above can all be used to gain a better understanding of the entire mitral apparatus and the cardiac chambers forming a more complete global picture. Appropriate scores such as the Wilkins or Carpentier scale can then be applied to determine the suitability of transcatheter techniques and likelihood of success or complications.

MULTIPLE CHOICE QUESTIONS

1. During a mitral valve clip procedure, which of the following would be true when orienting the device?
   A. When crossing the septum, the device catheter should be pointed posteriorly to best cross the mitral valve.
   B. To clip medial or lateral parts of the valve, the clip may need to be rotated to be perpendicular to the coaptation plane.
   C. The location of the transseptal puncture is less important than the direction of the catheter.
   D. A patent foramen ovale can be used to cross the septum and deliver the device, avoiding the need for a transseptal puncture.

2. Which of the following is least likely to increase the risk of pacemaker implants during a transcatheter aortic valve replacement?
   A. A low implant position in the left ventricular outflow tract (LVOT).
   B. Dense LVOT calcification.
   C. A preexisting right bundle branch block.
   D. Transapical approach to the implant.
   E. Use of a self-expanding prosthesis instead of a balloon-expanding prosthesis.

3. When closing an atrial septal defect, which rim, when missing, is most likely to increase the risk of device embolization and why?
   A. Retroaortic rim due to motion of the aorta.
   B. Retroaortic rim due to tension on the device by the delivery cable.
   C. Posterior rim due to limited atrial space.
   D. Inferior vena cava rim due to tension on the device by the delivery cable.
   E. Inferior vena cava rim due to proximity to the tricuspid valve.

4. In which of the following interventions is there no risk of coronary artery
injury or occlusion?
A. Transcatheter aortic valve replacement (TAVR).
B. Coronary sinus annuloplasty.
C. Device closure of an atrial septal defect.
D. Transcatheter valve implantation in the pulmonic position.

5. Which of the following statements regarding echocardiographic imaging is true?
A. A patent foramen ovale always has right-to-left shunting by color at rest.
B. Transesophageal echocardiography is the principal tool to evaluate a ventricular septal defect.
C. Echocardiography measurement of the aortic annulus for TAVR is more accurate than computed tomography.
D. Transthoracic echocardiography is sufficient to describe the left atrial appendage anatomy for closure.
E. In intracardiac echocardiography imaging, the area at the top of the screen is the left atrium.

INTRODUCTION

The advent of percutaneous therapies has revolutionized our approach to treatment of valvular heart disease. The ability to perform such interventions safely and effectively relies heavily on anatomical details. Fluoroscopic anatomy alone is inadequate to guide valvular interventions due to poor visualization of the complex 3-dimensional valve unit. More advanced imaging technology is thus required to support fluoroscopy in guiding valvular interventions. Understanding valvular anatomy and correlating it real time with presented multimodality imaging is critical for procedural success in the catheterization laboratory.

In this chapter, we describe the anatomy of the 4 cardiac valves, applying it to fluoroscopic and multimodality imaging, to guide percutaneous valvular interventions for the cardiac interventionalist.

GENERAL ORIENTATION OF THE VALVES

The heart is normally situated obliquely in the chest such that the
Interventricular and interatrial septa are approximately 45° to the anteroposterior projection (Fig. 4-1). Therefore, a 45° left anterior oblique (LAO) projection will allow distinction of the left and right structures, whereas a 45° right anterior oblique (RAO) projection will discriminate anterior and posterior structures. The planes of the mitral and tricuspid valves are virtually at right angles to the septal plane with some inferior tilt with the mitral plane situated slightly posterior to the tricuspid valve plane. In other words, LAO 45° caudal 15° may visualize the mitral and tricuspid valves en face, whereas RAO 45° caudal 15° may provide one of the side views for these valves. The inflow and outflow of the left ventricle are aligned closely with an angle of 15° to 20° in a normal heart, whereas the inflow and outflow of the right ventricle are aligned almost at 90°.
FIGURE 4-1 Anatomic structures as visualized under fluoroscopy in the right anterior oblique (A), left anterior oblique (B), anteroposterior (C), and left lateral (D)
views.

The aortic valve plane is typically tilted caudally and leftward, with the end on view being either LAO 60°C caudal 35°C or RAO 30°C cranial 45°C. Side views can be obtained with either RAO 20°C caudal 20°C or LAO 40°C cranial 30°C projections. Pulmonary valve is tilted quite posteriorly and to the right, such that the end on view is RAO 10°C caudal 50°C, and the pulmonary valve plane ranges from RAO 30°C cranial 20°C to LAO 30°C caudal 20°C. The right ventricle wraps around the outflow of the left ventricle, being mostly anterior to the left ventricle with only the inferior margin to the right of the left ventricle; the outflow tract of the right ventricle is superior and to the left of the aortic valve. The left atrium forms most of the posterior aspect of the heart as appreciated on the lateral fluoroscopic views.

**FIBROUS SKELETON OF THE HEART**

The fibrous skeleton (Fig. 4-2) formed by the valve annuli and the intervening right and left fibrous trigones defines the plane of the atrioventricular groove and houses all 4 of the cardiac valves. The aortic valve has a central location in the fibrous skeleton and is closely related to the other 3 valves. The mitral valve (posterior medial commissure) and the tricuspid valve (septal leaflet) are intimately connected to the base of the noncoronary cusp of aortic orifice by a condensed mass of fibrous tissue, the central fibrous body, also referred to as the right fibrous trigone, which continues inferiorly as the membranous interventricular septum. The left fibrous trigone is another condensed mass of fibrous tissue that connects the anterolateral commissure of the mitral valve and the base of the left coronary cusp of the aortic valve. The pulmonary valve is located anterior and to the left of the aortic valve and has a separate fibrous ring that is connected to the base of the right coronary cusp of the aortic valve by a fibrous band referred to as the conus ligament.
Away from the central body, the fibrous skeleton becomes less robust with less discrete organization. The part of the fibrous skeleton bounded by the left and right trigones connects the anterior mitral leaflet with the noncoronary cusps of the aortic valve and is commonly referred to as the aorto-mitral curtain, intervalvular fibrosa, or subaortic curtain. Calcifications of the fibrous skeleton of the mitral and aortic annuli (mitral annular calcification) are of critical importance to the outcome of transcatheter aortic valve implantation (TAVI) with respect to symmetric deployment of the valve and resultant perivalvular leak.

**AORTIC VALVE**

**Gross Anatomy**

The aortic root is a complex and dynamic ensemble of the aortic annulus, aortic valve leaflets, sinuses of Valsalva, the sinotubular junction, and the interleaflet fibrous triangles that connects the left ventricle to the ascending aorta. It is often described as resembling a crown (Fig. 4-3) that is transected
by 3 horizontal planes.\(^1\)\(^-\)\(^3\) The top of the crown, represented by an imaginary plane that transects the ring-shaped sinotubular junction in a horizontal fashion, is formed by the peripheral attachments of the aortic valve leaflets near the commissures. The base of the crown is a virtual plane formed by horizontal transection of the basal attachments of the aortic valve leaflets. Between these 2 planes exists the true anatomic aortoventricular junction marked by the area over which the fibrous wall of the arterial trunk is attached to the supporting ventricular structures, forming the third imaginary horizontal plane of the aortic root. It is important to note that these planes are not necessarily parallel to each other due to the fact that there is reflection of left and right coronary cusps over the muscular septum.

**FIGURE 4-3** The aortic annulus is defined as a virtual ring (*green line*) with 3 anatomic anchor points at the nadir (*green points*) of each of the attachments of the 3 aortic leaflets. LCC, left coronary cusp; NCC, noncoronary cusp; RCC, right coronary cusp.

**Aortic Annulus**

The term *annulus* came into vogue to express a reference plane for valve sizing and deployment during surgical aortic valve replacement. However, despite the widespread use of this term, there is no distinct anatomic or histologic circular structure that defines it. Surgically, the annulus is crown shaped and is represented by the semilunar lines of attachment of the aortic valve leaflets to the aortic root.\(^1\) Echocardiographers, however, measure the annulus along the virtual basal plane of the crown in the left ventricular outflow tract at the inferior-most aspect of the aortic valve leaflet hinge points.\(^2\)
Annular measurements are routinely performed in the parasternal long-axis view obtained on 2-dimensional (2D) transthoracic echocardiography (TTE) and rarely in the apical 5-chamber view (Fig. 4-4). The aortic annulus on transesophageal echocardiography (TEE) is measured in the 125° to 140° long-axis view of the left ventricle (see Fig. 4-4). This measurement is taken from the inner edge of the septal endocardium to the inner edge of the anterior leaflet of the mitral valve at the hinge point of the aortic valve leaflets in mid-systole. More recently, multidetector computed tomography (MDCT) has become the gold standard for annular assessment. Annular measurements using MDCT can be obtained as either a hinge-to-hinge measurement on a single oblique view as measured on TTE/TEE or can be derived from the area or the circumference of the virtual basal ring (Fig. 4-5). There are several important points about the measurement of the “annulus.” The annulus is not circular but elliptical, and therefore, different modalities that measure different planes of the annulus do not necessarily yield same results. The annular size obtained by MDCT is typically larger than when measured by 2D TTE/TEE. When the diameter of the annulus is measured solely by 2D methods (typical for TEE or TTE), special care has to be taken to get the maximal diameter because symmetric opening of the leaflets (where typically the views are obtained) does not necessarily provide the largest diameter.
FIGURE 4-4 Biplane transthoracic (top row) and transesophageal (bottom row) imaging showing the long-axis and corresponding orthogonal short-axis plane of the aortic annulus. Aortic annulus measurements performed by transthoracic and transesophageal echocardiography.
FIGURE 4-5 Aortic annular measurement on cardiac computed tomography. Hinge points of all 3 cusps are identified in both the Sagittal oblique plane (top row) and Coronal oblique plane (middle row). Reconstructed double-obliqued axial plane or transverse plane (bottom row) is then used to measure the maximal, minimal, and mean annular diameter and the annular area and perimeter.

Leaflets

The aortic valve is normally comprised of 3 semilunar leaflets or cusps of nonuniform size (Fig. 4-6). The leaflets derive their name from the associated coronary artery (right coronary cusp, left coronary cusp, and noncoronary cusp) that arises near the cusp. Each leaflet has a free margin and a margin that is attached peripherally to the aortic root in a semilunar fashion. Each leaflet also has a ventricular surface that is smooth and an arterial surface that is rougher in nature. At the center of the free margin of the leaflets is a
thickened nodule called the nodule of Arantius.\textsuperscript{7} The remainder of the free margin extending from the nodule of Arantius to the aortic attachment is called the lunule. Coaptation of the leaflets occurs at the nodule of Arantius and a thicker closing surface 1 to 2 mm below the lunule. Therefore, fenestrations, although common in the lunule, are not associated with valvular insufficiency in the normal aortic valve.\textsuperscript{7} However, if dilation of the aortic root moves the line of valve closure toward the lunule, aortic insufficiency can result from these lunular fenestrations. The lunules of adjacent leaflets are attached to each other for a very short segment at their bases to form apposition lines referred to as commissures.

\textbf{FIGURE 4-6 Anatomy of the aortic valve.}

Functionally, the leaflets separate the aorta from the left ventricle during ventricular diastole and represent the hemodynamic ventriculoarterial junction.

\textbf{Sinotubular Junction}

The sinotubular junction is a circular ridge of fibroelastic tissue at the apices of leaflet attachment to the aortic wall.\textsuperscript{2} Anatomically, the sinotubular junction marks the transition point from the aortic root to the ascending aorta. Dilation of the sinotubular junction leads to aortic insufficiency. Severe
calcification of the sinotubular junction can be problematic for balloon-expandable TAVI. If the calcification is circumferential and the sinotubular junction diameter is smaller or comparable to the diameter of the annulus, there is some risk of “watermelon seeding” of the balloon in the ventricular direction at the time of valve deployment. Precariously, this can lead to severe aortic insufficiency or even valve embolization into the left ventricle.

**Sinuses of Valsalva**

The expanded portion of the aortic root on the arterial side of the aortic valve leaflets is called the sinus of Valsalva. It is bound distally by the sinotubular ridge and proximally by the lower most attachment of the aortic valve leaflets. There are 3 sinuses, each named for the coronary artery to which it is associated (right coronary, left coronary, and noncoronary). The sinuses prevent coronary obstruction by housing the valve leaflets and generating eddy currents that further hold the leaflets away from the aortic valve during systole. The eddy currents also play a role in valve closure and stress reduction of the aortic valve leaflets during diastole.

The geometry of the aortic sinus has important implications for valve choice and size during transcatheter aortic valve replacement (TAVR). Important measurements at the aortic root include height and width of the sinus of Valsalva, take off height of the coronary ostia, and ascending aortic diameter (Fig. 4-7). These measurements are crucial to prevent coronary ostial obstruction following TAVR.
FIGURE 4-7 Measurements at the aortic root that include height and width of the sinus of Valsalva (middle row), takeoff height of the coronary ostia (top row), and ascending aortic diameter (bottom row).

A unique aspect of the noncoronary sinus is that it rests on the interatrial
septum. When doing a transseptal puncture, visualization of this sinus by contrast injection or catheter placement in the sinus is critical to avoid puncturing the aorta.

**Interleaflet Fibrous Triangle**

Semilunar attachment of the aortic leaflets creates 3 triangular areas under each commissure called the interleaflet fibrous triangles.\(^9\) They are an extension of the left ventricular outflow tract to the sinotubular junction. The triangle between the left coronary sinus and noncoronary sinus is continuous with the aorto-mitral curtain. The triangle between the noncoronary and the right cusp is in continuity with the membranous septum. The third triangle between the left and right coronary cusps attaches to the muscular septum.

**Relationships of the Aortic Root**

Familiarity with anatomic relationships of the aortic valve to the 4 cardiac chambers and to the vascular and conduction system is important to the cardiac interventionalist in the current era of transcatheter therapies for structural heart interventions.

As described earlier, the noncoronary sinus rests on the interatrial septum. Visualization of this sinus by contrast injection or catheter placement in the sinus is critical to avoid puncturing the aorta during transseptal puncture. When using fluoroscopy for transseptal puncture, the location of the fossa ovalis is “guesstimated” based on the location of the posterior boundary of the aortic root as marked by a pigtail catheter positioned in the noncoronary aortic cusp combined with bony landmarks. The classic fluoroscopic landmark for the puncture site is in the center of the spine, at the level of the aortic root.\(^12\) To avoid aortic perforation during transseptal puncture, the dilator tip should be visualized below the pigtail catheter placed in the noncoronary cusp in the 30° LAO view and posterior to the pigtail catheter in the 30° RAO view.

Coronary obstruction after TAVR is a rare but serious procedural complication that is potentially avoidable with meticulous preprocedural aortic root analysis. A low coronary ostial takeoff or, more commonly, a low takeoff in combination with a narrow aortic root and bulky valve calcification predisposes to coronary ostial obstruction by displacement of the calcified
native cusp over the coronary ostium.\textsuperscript{10,11,13} In the setting of a narrow sinus of Valsalva, the bulky calcified leaflets cannot be accommodated and invariably get pushed over the ostia of the coronary arteries and have been observed to cause coronary obstruction. A displaced calcified native leaflet is more likely to close the origin of the left main coronary artery than the right coronary artery due to a normal higher right coronary artery ostia takeoff. Furthermore, aorto-mitral continuity via the intervalvular fibrous skeleton allows complete straightening of the left coronary leaflet, placing the left coronary ostium at a higher risk. The interventricular septum, however, anchors the right coronary leaflet and limits its upward movement, an important factor that reduces the risk of right coronary artery ostial occlusion.

A sinus of Valsalva width of 27 mm (for the 26-mm CoreValve) or 28 mm (for the 29-mm CoreValve) and a coronary height of 14 mm are recommended by the manufacturer for the implantation of the CoreValve system (Medtronic, Edgewater, MD).\textsuperscript{10} There are no specific manufacturer recommendations for the Edwards valve (Edwards Lifesciences, Irvine, CA), but a cutoff of 10 mm for the coronary height is widely practiced.

Careful consideration should be given prior to stenting the left main trunk in patients intended to have a TAVI. In the absence of beveled stents, the inferior aspect of the left main stent often extrudes into the aortic lumen. It is conceivable that a percutaneously placed valve may crush the native valve leaflets against a protruding left main stent. If left main percutaneous intervention is undertaken in such patients, precise stent placement to avoid “hanging out” into the aorta is paramount. Shallow LAO or anteroposterior (AP) cranial projections (instead of the typical LAO caudal or AP caudal views) may be useful to allow conservative stent positioning.

The His bundle and the fascicles of the left bundle are closely related to the aortic root. Conduction system disturbances and permanent pacemaker requirements are thus common following TAVR. The His bundle, a continuation of the atrioventricular node, penetrates the central fibrous body, runs between the membranous septum and the muscular septum, and bifurcates at the crest of the muscular ventricular septum into the left and right bundles. At this location, the left bundle is intimately related to the base of the interleaflet triangle between the right and noncoronary cusp of the aortic valve. In autopsy specimens, the exit of the left bundle has been identified to be 6.3 ± 2.4 mm from the noncoronary cusp of the aortic valve, making it particularly vulnerable to disruption with a lower placement of a
percutaneous aortic valve. The superficial course of the left bundle as it descends along the left interventricular septum further increases its susceptibility to injury with even minor trauma. Conduction disturbances are more common after the CoreValve compared to the Edwards valve and are likely related to the frame characteristics and mechanism of implantation.

**Pathologic Anatomy**

Three basic types of aortic stenosis are recognized: (1) degenerative calcific aortic stenosis; (2) congenitally bicuspid aortic stenosis; and (3) rheumatic aortic stenosis (Fig. 4-8). Degenerative calcific aortic stenosis is present in approximately 2% to 3% of the population over the age of 65 and approximately 4% of patients over the age of 85. Nearly one-third (29%) of patients have calcific aortic sclerosis without stenosis. Degenerative calcific aortic stenosis represents the majority of patients over the age of 70 undergoing traditional aortic valve replacement. Congenitally bicuspid aortic stenosis is the most common etiology of aortic stenosis in younger patients and has been reported to occur in 1% to 2% of the population. Adjacent cusps fuse to form a single aberrant cusp, larger than its counterpart yet smaller than 2 normal cusps combined. The hemodynamic perturbations associated with the bicuspid leaflets in combination with fibrillin-1–deficient microfibrils are responsible for the premature loss of the structural integrity of the valve as well as premature degeneration of the aortic media. As such, bicuspid aortic stenosis is often associated with dilatation of the aortic root and aneurysm formation. These patients typically present in their fifth and sixth decades of life with symptomatic aortic stenosis with or without a dilated aortic root and present a unique challenge for percutaneous valve therapy. Large annular diameter, dilated aortic sinuses, and eccentric leaflet calcification often translate into suboptimal candidacy for TAVI. Even crossing the bicuspid valve can be difficult in these patients; an AL-1 catheter and a straight 0.35-inch wire can be used to accomplish this occasionally arduous task. If the left coronary leaflet is involved in the fusion (left-right or left-non), an RAO projection is often helpful in crossing these valves, whereas a traditional LAO projection is most useful for crossing valves with fusion of the right and noncoronary leaflets. Classical rheumatic aortic valve stenosis is associated with an abnormal mitral valve (diffuse leaflet fibrosis, usually stenotic) and an aortic valve characterized by commissural fusion of
at least 1 and generally 2 or 3 commissures.

FIGURE 4-8 Mechanisms of aortic stenosis and aortic regurgitation.

Three basic types of aortic regurgitation have been recognized\(^\text{17}\) (see Fig. 4-8): type I, normal leaflets with aortic root dilation or leaflet perforation; type II, leaflet prolapse or fenestration; and type III, leaflet restriction or extensive leaflet calcification. Primary aortic regurgitation with noncalcified aortic root is typically considered a contraindication for TAVR due to the risk of valve dislocation as a consequence of insufficient anchoring. However, recent advances in valve technology have expanded percutaneous catheter-based therapies to pure aortic regurgitation.\(^\text{18}\)

**Fluoroscopic Anatomy**
Pivotal to performing TAVI and other structural heart interventions is a fundamental understanding of fluoroscopic anatomy. Two basic views commonly used for fluoroscopic imaging of the aortic valve are RAO 30° and LAO 60°. In the RAO view, the right coronary cusp is the most anterior located cusp (closest to the anterior wall of the left ventricle); conversely, the noncoronary cusp is the most posterior located cusp (closest to the inferior wall of the left ventricle) (Fig. 4-9). The left coronary cusp lies between the noncoronary cusp and right coronary cusp in the RAO projection. Conversely, in the LAO projection, the left coronary cusp is well visualized (closest to the lateral wall of the ventricle), whereas the noncoronary cusp and right coronary cusp are superimposed on one another, with the noncoronary cusp lying slightly below the right coronary cusp (see Fig. 4-9). A pigtail catheter in the noncoronary cusp can be clocked to enter the right coronary cusp and counterclocked to enter the left coronary cusp.
FIGURE 4-9 Fluoroscopic image of the heart and corresponding transesophageal electrocardiography images are shown. Mitral and aortic valve details are outlined. A1, first scallop of the anterior mitral leaflet; A2, second scallop of the anterior mitral leaflet; A3, third scallop of the anterior mitral leaflet; AML, anterior mitral leaflet; AO, aorta; IAS, intra-atrial septum; LA, left atrium; LAA, left atrial appendage;
Achieving a uniform alignment of the coronary cusps for TAVI typically requires slight caudal angulation for the RAO view and slight cranial angulation for the LAO view. Kasel and colleagues\(^{20}\) have proposed a rule—“follow the right cusp”—to obtain the perpendicular implantation view on fluoroscopy. After identification of the right coronary cusp, the implantation angle can be obtained by rotating the C-arm to an RAO or LAO angulation if the right cusp is placed behind the noncoronary cusp or the left cusp, respectively, and/or rotating the C-arm cranially or caudally if the right cusp appears higher or lower than the ideal plane intercepting other cusps, respectively.

Fluoroscopy is also important for recognizing other important anatomic considerations for TAVI such as curvature of the aortic arch, aortic valve calcification, calcification of the sinotubular junction, aortoiliac calcification and diameter, and movement of equipment through the aortoiliac system.

**Computed Tomography Anatomy**

At times, echocardiographic visualization of the aortic valve is difficult, and MDCT, with its higher spatial resolution, allows for detailed evaluation and recognition of the valvular architecture. Several anatomic issues can be addressed by MDCT including anatomy of the aortic valve (eg, bicuspid), aortic valve area, severity and location of aortic root calcification, annular measurements, sinus of Valsalva measurements, and location of the coronary ostia, sinotubular junction assessment, and aortic root orientation in relation to the body axis.\(^{21}\) Anatomic assessment of the aortic root and iliofemoral arteries using MDCT has thus become a standard practice prior to TAVI.\(^{5,22}\)

Bicuspid aortic valves are present in 1% to 2% of the population and are the second most common etiology of aortic stenosis. They can be congenital or acquired. In the congenital bicuspid aortic valve, unlike the acquired variant, the cusp containing the false commissure (raphe) (conjoined cusp) is
of similar length to that of the other cusp. The bicuspid aortic valve exists in 2 major forms: a right-left (fusion of the noncoronary cusp and either the left or right cusp) and an AP (fusion of the right and left cusp) orientation of the 2 cusps. These structural changes in the bicuspid aortic valve straighten the line of lateral attachment, limiting the mobility of the valve and subjecting the valve to hemodynamic perturbations that facilitate premature degeneration and calcification of the valve. Bicuspid aortic valve is generally considered a contraindication to TAVR because of the theoretical risk of poor seating, coronary ostial obstruction, or paravalvular regurgitation from the distorted geometry of the aortic root. However, clinical experience with TAVR, although limited in this group of patients, has been promising.

Using planimetry, the aortic valve area can be measured on MDCT. Aortic valve area assessment by TTE, however, uses the continuity equation. Therefore, MDCT evaluates anatomic valve area instead of the effective area, which is evaluated by TTE. Therefore, anatomic valve area measured by MDCT is larger than that measured by TTE. Incorporation of computed tomography (CT)-derived left ventricular outflow tract measurement into the continuity equation has been shown to improve TTE aortic stenosis severity assessment.

Age-related degenerative changes in the aortic valve are those of progressive calcification and fibrosis (intrinsic and extrinsic cusp calcification). Two patterns of calcification have been described: (1) the coaptation pattern, where calcification occurs along the line of cusp coaptation; and (2) the radial pattern, where calcification occurs as spokes of a wheel, spreading from the peripheral cusp attachments toward the center. However, in advanced stages, the calcification pattern becomes unidentifiable. Aortic valve calcification can be scored both qualitatively and quantitatively by cardiac CT. Aortic valve calcification is qualitatively assessed as follows: grade 1, no calcification; grade 2, mildly calcified (small isolated spots); grade 3, moderately calcified (multiple larger spots); and grade 4, heavily calcified (extensive calcifications of all cusps) (Fig. 4-10). Extensive aortic root calcium precludes optimal valve implantation and identifies patients at risk for significant paravalvular leak after TAVR.
MDCT is regarded as the gold standard for aortic annulus measurement.\textsuperscript{30-32} In the reconstructed axial images of the aortic root, the following 3 measurements are made immediately below the most caudal attachment of the 3 aortic leaflets to measure the annulus: (1) measurement of the long and short diameters of the oval aortic annulus to calculate the mean diameter; (2) area-derived diameter (planimetry of the area of the aortic annulus and calculation of the diameter that corresponds to this area under the assumption of full circularity); and (3) perimeter-derived diameter (measurement of the circumference of the aortic annulus and calculation of the diameter that corresponds to this length again under the assumption of full circularity).

In addition to evaluation of the aortic valve and annulus, many other parameters are ascertained during the acquisition of cardiac CT that are routinely used in planning of TAVR, including aortic dimensions, coronary ostial height, sinus of Valsalva, and sinotubular junction diameters.\textsuperscript{33}

**Echocardiographic Anatomy**

Echocardiography provides excellent temporal and spatial resolution for investigating not only the anatomy but also the function of the aortic valve. Identification of various anatomic relationships in different transthoracic and transesophageal views is critical for planning and guidance of structural
interventions (Fig. 4-11). Two-dimensional Doppler TTE is the most commonly used tool for assessing the severity of aortic stenosis. This can be accomplished by estimating the valve area by planimetry or using the continuity equation, measuring the peak transvalvular velocity and the peak and mean pressure gradients across the valve. Peak pressure gradient can be calculated from the peak velocity using the Bernoulli equation ($\Delta P = 4V^2$, where $\Delta P$ = pressure gradient and $V$ = flow velocity in m/s at the site of obstruction). Aortic valve area is estimated by the continuity equation using Doppler-derived transvalvular velocities (TVIs) in conjunction with anatomic measurements of the left ventricular outflow tract (LVOT; Aortic valve area = LVOT \times LVOT VTI/aortic valve VTI).

In the presence of aortic valve regurgitation or significant left ventricular (LV) dysfunction, measuring aortic valve gradient alone is inadequate to
determine the severity of aortic stenosis. In these situations, aortic valve area should also be measured because the continuity equation is reliable even in the presence of aortic and mitral insufficiency and independent from transaortic flow.36

Many indices have been investigated for determining the severity of AS, namely, dimensionless index, jet width at the aortic valve level, valve resistance, percent LV stroke work loss, and modified ventricular-vascular coupling. However, none of these adjunctive measures have proven to more reliable than transvalvular gradient, aortic valve area, and jet velocity. As such, current guidelines define the severity of aortic stenosis based on these parameters.35

Dimensionless index is the ratio of the systolic velocity flow integral in the LVOT to the systolic velocity integral in the aortic jet and may be useful in the setting of severe LV dysfunction. Dimensionless index <0.3 is consistent with severe aortic stenosis and has a high sensitivity and specificity for diagnosis of severe aortic stenosis.37 Not surprisingly, TTE has limitations; poor acoustic windows and severe calcification of mitral and aortic annulus may lead to inaccurate measurement of LVOT diameter and aortic valve gradients translating to erroneous calculations of aortic valve area.38 Nonparallel interrogations of jet velocity may lead to underestimation of the severity of stenosis, due to the higher central velocity of aortic flow through the valve.39 In the presence of mitral regurgitation, irregular heart rhythms, or subvalvular or supravalvular stenosis, transvalvular velocities can be overestimated.40 Low cardiac output or significant LV dysfunction may lead to underestimation of aortic stenosis severity.

The enhanced resolution capability of 2D TEE can provide anatomic details not obvious on TTE (see Fig. 4-11). On TEE, the short-axis view of the aortic valve can be obtained in the mid-esophageal aortic valve short-axis view (30-60°). Aortic valve planimetry can be performed on the obtained images. Long-axis images of the aortic valve are obtained from the mid-esophageal (110-140°), transgastric (approximately 120°), or deep transgastric (0°) locations. Both of the transgastric views allow Doppler interrogation of the aortic valve due to parallel alignment of the TEE transducer to the LVOT in these views. The mid-esophageal long-axis view, on the other hand, can be used to evaluate the LVOT and aortic root dimensions. Superior aortic root analysis by TEE has been associated with
improved patient selection and success of TAVR.

Recently, there has been widespread use of cross-sectional 3-dimensional (3D) TEE (Fig. 4-12) because it has several advantages over 2D TEE imaging and provides incremental value to fluoroscopy in guiding structural heart disease interventions and in identifying complications during the procedure.\textsuperscript{41,42} Three-dimensional TEE is gaining acceptance as an accurate alternative to MDCT for aortic root analysis before TAVR.\textsuperscript{41}

\section*{MITRAL VALVE}

\subsection*{Gross Anatomy}

The mitral valve gets its name from the resemblance of its leaflets to a bishop’s mitre, or headdress. It is a complex functional unit composed of the
mitral annulus, anterior and posterior leaflets, subvalvular apparatus (chordae tendineae and papillary muscles), LV myocardium (attachment of the papillary muscles), and left atrial wall (Fig. 4-13). These individual structures work synchronously to open during diastole and close during systole.

FIGURE 4-13 Mitral valve complex unit and mitral annulus.

Annulus
The mitral annulus is not a distinct anatomic entity, but a saddle-shaped fibrous tissue plane at the left atrioventricular junction that serves as an insertion site for the mitral leaflets. The part of the annulus near both commissures is more ventricular, and the part supporting the middle parts of the leaflets is more atrial, giving it the saddle-shaped appearance. The annulus can be divided into anterior and posterior parts by the commissures. Anteriorly, it is continuous and extends between the left and right fibrous trigones as the aorto-mitral curtain. Posteriorly, it is discontinuous and less well developed, making it susceptible to enlargement. The annulus is strongest near the commissures at the left and right fibrous trigones. These variations allow major changes in the shape and dimensions of the annulus at different stages of the cardiac cycle. The anterior annulus is dynamic and moves toward the posterior annulus in systole (to increase LVOT size and to enhance leaflet coaptation) and toward the septum in diastole (to increase diastolic mitral valve opening). The annulus has a shorter AP extension than sidewise. The anterior annulus is related to the left ventricle, left fibrous trigone, left coronary sinus, noncoronary sinus, right fibrous trigone, and interventricular septum, from the lateral to medial direction. The posterior annulus is related to the interventricular septum and then the free wall of the left ventricle going from medial to lateral direction.

The relationship of the annulus to the coronary sinus is of particular importance due to potential devices that can modify annular shape and size. The coronary sinus opens in the right atrium just behind and to the right of the posteromedial commissure of the mitral valve. If one traces the coronary sinus more proximally, it runs on the atrial side of the mitral annulus with 0.5 to 1 cm of distance between the two. As the mitral annulus flattens in patients with severe mitral regurgitation, this distance increases. Anterolateral commissure of the mitral valve is close to where the anterior cardiac vein becomes the coronary sinus.

**Leaflets**

The aortic/anterior leaflet of the mitral valve is dome shaped with attachment to the anterior two-fifths of the annular circumference. This leaflet lies in close relation to the left and noncoronary cusps of the aortic valve in combination with which it forms the aorto-mitral curtain (Fig. 4-14). Near the tip of the leaflet on the ventricular surface, there is a deep crescentic rough
zone on the ventricular side that provides attachment to the chordae tendineae. The ridge demarcating the proximal margin of the rough zone indicates the maximal extent of the coaptation zone. The anterior leaflet does not have a basal zone as it forms the smooth boundaries for the ventricular outlet. Segmentation of the anterior leaflet is artificial, with different parts of the leaflet demarcated as A1, A2, and A3 from lateral to medial corresponding to similar segments of the posterior leaflet.

FIGURE 4-14 Mitral valve leaflets and their relationships.

The mural/posterior leaflet is quadrangular and narrow with attachment posteriorly to three-fifths of the annular circumference. It has 2 distinct indentations along the free edge that divide the leaflet into 3 lobes or “scallops”: a relatively large middle scallop (P2) and smaller anterolateral (P1) and posteromedial scallops (P3). Each scallop has a crescentic, opaque rough zone, receiving on its ventricular aspect the attachments of the chordae. This rough area, which is larger than the comparable area on the anterior leaflet, identifies the area of apposition of the leaflets. From the rough zone to within 2 to 3 mm of its annular attachment, there is a membranous clear zone devoid of chordae. Contrary to the anterior leaflet, the basal 2 to 3 mm of the
posterior leaflet are thick and vascular and receive the basal chordae.

**Chordae Tendineae**

Two types of chordae connect the leaflets to the heads of both the anterolateral and the posteromedial papillary muscles. The primary chordae connect to the free edge of the leaflet (“fan chordae”), whereas the thicker secondary chordae (“strut” chords) connect to the rough zone of the leaflets. Functional secondary chordae are critical to preserve LV geometry and contractility. A third type of chordae, the tertiary chordae, is short and connects the basal zone of the posterior leaflet to the ventricular free wall. Commissural chordae are a subtype of primary chordae that insert into the free edge of the anterolateral and posteromedial commissures. Most chordae divide into branches from a single stem soon after their origin from the apical one-third of a papillary muscle or proceed as single chordae that divide into several branches near their attachment. In the majority of hearts, the chordal density is highest in the subcommissural area. This is important to recognize because the percutaneous clip can get tangled more easily in the commissural area than in the middle of the valve. False chordae, or chordae that are not inserted into the valve leaflet, occur in about 50% of left ventricles and often cross the subaortic outflow. Their role, if any, has yet to be determined.

**Papillary Muscles**

There are 2 papillary muscles with large variation in the size, shape, and location. The anterolateral and posteromedial papillary muscles arise from the apical one-third of the lateral and inferior LV free walls, respectively. The posteromedial muscle is frequently U shaped or with multiple heads. The anterior papillary muscle usually has 1 head. Chordae tendineae arise mostly from the tip and apical one-third of each muscle, but sometimes take origin near their base. The chordae from each papillary muscle diverge and are attached to a corresponding rough zone on both leaflets. The anterolateral papillary muscle has dual blood supply from the left anterior descending and left circumflex coronary arteries, whereas the posteromedial papillary muscle is supplied commonly by only the right coronary artery, making it vulnerable to ischemic damage and rupture. The anteropapical displacement of the papillary muscle can lead to systolic anterior motion (SAM) of the mitral
valve in the absence of hypertrophic obstructive cardiomyopathy. Anterior displacement of the papillary muscle increases anterior leaflet slack and subsequently leaflet length, factors that beget SAM.\textsuperscript{44} Similarly, anomalous insertion of the papillary muscle directly into the anterior mitral leaflet can produce SAM without hypertrophic obstructive cardiomyopathy. Global LV dilatation as seen in dilated cardiomyopathy causes an imbalance between the closing (LV contractility, LV electrical synchrony, and annular contraction) and tethering (papillary muscle displacement apically, LV remodeling, and annular dilation) forces of the functional mitral unit, causing symmetric tethering of the mitral leaflets and leading to central malapposition and central mitral regurgitation (MR). On the other hand, inferior myocardial infarction exclusively displaces the posteromedial papillary muscle, leading to increased tension in the chordae arising from the posteromedial commissure and asymmetric tethering of the leaflets with subsequent posteriorly directed MR that can originate more medially, sometimes approaching the posteromedial commissure. Posterior annuloplasty may work better for this type of situation than with apical tethering. Further, clipping may be difficult if the funnel-shaped regurgitant orifice extends up to the posteromedial commissure.

**Pathologic Anatomy**

**Mitral Stenosis**

The 2 most common forms of acquired mitral stenosis are rheumatic heart disease and calcific or degenerative mitral stenosis (Fig. 4-15). The assessment of anatomy aims to distinguish between the two and identify potential contraindications to balloon mitral commissurotomy. Rheumatic process affects the tips and commissures, causing thickening and restriction of the tips. Further, there is fibrosis and shortening of the chordae. Balloon mitral valvuloplasty works well in patients with severe symmetric commissural fusion with minimal calcification and relatively well-preserved subvalvular apparatus. On the contrary, when the subvalvular fibrosis is severe with significantly shortened chordae (anterior chordae with less than 8-mm length from the tip of the mitral valve to the papillary muscle), commissural separation with balloon commissurotomy will fail to release the
leaflets for durable success. In patients with nonrheumatic degenerative mitral stenosis caused by mitral annular calcification, there is dystrophic calcification of the posterior mitral annulus, musculature of the LV base, and ventricular surface of the posterior mitral leaflet. Sparing of the anterior mitral leaflet and commissures differentiates mitral annular calcification from rheumatic mitral disease in most cases. In mitral annular calcification, balloon valvuloplasty does not work because balloon dilatation cannot mobilize the leaflets.
Mitral Regurgitation

Abnormalities of the mitral valve complex that affect valve closure during systole cause MR that can be either degenerative or primary and functional or...
secondary. Degenerative disease includes Barlow disease (myxomatous degeneration) and fibroelastic deficiency, both of which can result in mitral valve leaflet prolapse and MR. Fibroelastic deficiency is the most common etiology to present for surgical mitral valve repair, representing approximately 70% of the US surgical population. Rheumatic heart disease is an important cause of degenerative MR in other parts of the world that causes leaflet restriction with reduced motion in both systole and diastole from leaflet fusion, calcification, and apical leaflet doming. Functional MR (FMR) occurs from geometric derangement of the mitral valve functional unit subsequent to LV remodeling in the setting of regional or global LV dysfunction from any cause. Ischemic MR results from an imbalance of closing and tethering force on the mitral leaflets. Various factors can decrease the closing force, including diminished LV contractility, LV electrical dyssynchrony, and diminished annular contraction. Similarly, many factors can increase the tethering forces, such as papillary muscle displacement, LV remodeling, and annular dilation. It is becoming increasingly clear that there is tremendous interaction of ventricular, valvular, and annular factors in generation, perpetuation, and progression of FMR.

Alain Carpentier proposed a morphologic classification based on leaflet motion to describe the pathophysiologic changes that contribute to MR from either etiology (see Fig. 4-15). Carpentier class I regurgitation occurs in the presence of normal leaflet motion and is usually caused by annular dilatation or leaflet perforation. Carpentier class II is caused by exaggerated leaflet motion as a result of leaflet prolapse, which is commonly the result of chordal/papillary muscle elongation or rupture. Carpentier class III is caused by restricted leaflet motion that is subdivided into class IIIa (restricted motion in systole and diastole) seen in rheumatic heart disease from commissural fusion and/or leaflet or chordal thickening and class IIIb (restricted motion in systole only) due to posterior wall motion abnormality or papillary muscle dysfunction seen with LV dysfunction from any cause. This simplification has utility in terms of both the surgical and percutaneous approaches, as the goal of therapy is to restore normal leaflet function but not necessarily normal valve anatomy.

**Fluoroscopic Anatomy**

Orientation of the leaflets of the mitral valve is best imagined by identifying
the commissures in every projection (Fig. 4-16). The anterolateral commissure is near the left anterior descending artery ostium, and the posteromedial commissure is close to the origin of the posterior descending artery. RAO view shows the anterolateral commissure on the top and the posteromedial commissure on the bottom; both the anterior and posterior leaflets are superimposed and lie in the middle. Anterior and posterior papillary muscles are well visualized in systole during ventriculogram. In contrast, the LAO view gives appreciation of the mitral annulus and delineates the anterior and posterior leaflets. Different segments (A1, A2, A3 and P1, P2, P3) of the leaflets are also well appreciated in this view. The relation of the papillary muscle to the leaflets is also well delineated. The LVOT is well seen in this orientation, although some cranial angulation may help to eliminate foreshortening of the outflow tract. Relation of the mitral annulus to the different structures is well appreciated in this view.
FIGURE 4-16 Line diagrams of angiographic projections for assessment of the mitral valve. bs, basal septum; L, left coronary cusp; LAO, left anterior oblique; N, non coronary cusp; R, right coronary cusp; RAO, right anterior oblique.

CT Anatomy

The poor temporal resolution of MDCT limits its role in the anatomic assessment of the mitral valve. Radiation exposure is also of concern with CT. However, CT can provide useful information in special situations.
It is easier to measure annular size with MDCT because of the possibility to reconstruct the mitral annular plane from a 3D dataset. Further, one can assess the geometry of the subvalvular mitral apparatus on MDCT, which may be critical to determine the precise mechanism of FMR and in guiding interventions. MDCT also provides a unique opportunity to study the mitral annulus and its relation to the surrounding structures. The relation of the mitral annulus to the coronary sinus and the great cardiac vein, and their relationship with the left circumflex artery, can be easily recognized on MDCT. Nevertheless, due to limited temporal resolution, the relation of the mitral annulus to the coronary sinus in different phases of the cardiac cycle can be difficult to determine. There is no standard method to measure this distance; however, 2-, 3-, or 4-chamber views can be used to determine this distance. It may be important to measure the angle between the coronary sinus plane and the mitral annulus. This angle may provide some insight into the direction of pull of the device in the coronary sinus to the mitral annulus. Despite these measurements, the success of a device can still be difficult to predict from CT prior to procedure.\cite{47} Qualitative assessment to judge the calcification of the mitral annulus is also important if placement of CS devices is planned. Typically, significant calcification can be considered a relative contraindication for this approach. MDCT may be particularly helpful in accurate identification of paravalvular leaks and in procedural planning.\cite{48}

**Echocardiographic Anatomy**

Echocardiography is the preferred imaging modality for mitral valve disease. The suitability for balloon mitral valvuloplasty can be readily established from standard TTE images of the mitral valve using one of the several anatomic scores developed to predict balloon mitral valvuloplasty outcomes.\cite{49,50} The parasternal long-axis view is used to assess valve thickening, mobility, and calcification (Fig. 4-17). Modified standard views (apical 4, 2, 5, and parasternal long axis) obtained by tilting the probe medially or laterally are used to image the long axis of the papillary muscle and its attached chordae to assess subvalvular thickening, fusion, and calcification. The presence or absence of commissural calcification outperforms any of the risk scores to predict the outcome of valvuloplasty and should be assessed on the parasternal short-axis view (see Fig. 4-17).
The proximity of the mitral valve to the posteriorly positioned TEE probe in the esophagus strikingly improves anatomic assessment of the mitral valve (Fig. 4-18). This has been successfully exploited to improve patient selection and safety of percutaneous mitral valve therapies.51 For imaging of the mitral valve on TEE, 2 important planes can be visualized at 0°, one in the mid-esophagus and the other in the transgastric location. The correlation of these views to the fluoroscopic anatomy is shown in Figure 4-19. The mid-esophageal 0° view provides a 4-chamber view of the mitral and tricuspid valves (see Fig. 4-18). The relation of the interatrial septal puncture site or septal devices to the mitral valve can be best assessed in this view. When the TEE probed is advanced to the transgastric location with flexion, a short-axis view of the left ventricle at the mitral valve level can be obtained. This view
is critical for evaluating the mitral valve in short axis, which can be helpful in several mitral interventions (e.g., commissure evaluation during mitral valvuloplasty, assessing the orientation of clip in relation to valve coaptation line during MitraClip [Abbott Vascular, Temecula, CA] procedure). The orientation of different segments of mitral leaflets is shown in Figure 4-18. When the transducer is rotated at 40° to 60° with the probe at the mid-esophageal level, mitral valve commissural view can be obtained. In this view, A2 is typically located in the middle of the LV inflow, with P1 and P3 on either side. TEE is also essential to rule out clots in the left atrium prior to valvular interventions. Biplane TEE is at times helpful when devices are being advanced into the left atrium (Fig. 4-20).
FIGURE 4-19 Correlation of fluoroscopic plane to transesophageal echocardiography. Three-dimensional TEE has significantly improved the analytical details of the mitral valve. Its ability to visualize the valve superiorly from the left
atrium, the “en-face view” or the “surgeon’s view,” is of particular interest during treatment of mitral paravalvular leaks and edge-to-edge therapy using the MitraClip procedure (Fig. 4-21). Three-dimensional TEE provides incremental imaging information compared with 2D TEE to guide in several critical steps.\textsuperscript{52} The usefulness of real-time 3D TEE has been confirmed for safe guidance of the clip delivery system through the left atrium toward the mitral valve, precise positioning of the clip delivery system in the middle of the intercommissural line as well as at the center of the regurgitant jet, accurate alignment of the clip arms perpendicular to the intercommissural line in the left atrium as well as the left ventricle, confirmation of correct grasping location in the middle of the anterior and posterior mitral leaflets resulting in a symmetric split of the mitral orifice, and adequate positioning of a second clip relative to the first clip if required. Similar value of real-time 3D TEE for critical steps in paravalvular leak closure (see Fig. 4-21), including device deployment, has been demonstrated.\textsuperscript{53}
Tricuspid Valve

The tricuspid valve, so called because of its 3 triangular or trapezoidal leaflets, is the most apically placed cardiac valve and the one with the largest orifice (Fig. 4-22). The tricuspid valve functional unit includes the fibrous annular ring, leaflet tissue, chordae tendineae, and papillary muscles.
Similar to the mitral valve, the tricuspid annulus derives its support from the fibrous skeleton of the heart (right atrioventricular ring as opposed to the left atrioventricular ring) and has an ellipsoid and nonplanar morphology, appearing somewhat “saddle shaped” in configuration (Fig. 4-23). The highest points of the annulus are in the anteroseptal segment in close proximity to the right ventricular outflow tract and the aortic valve and the posterolateral segments. The lowest points of the annulus are in the posteroseptal segment, which is closer to the right ventricular apex and the anterolateral area. This geometry changes in patients with functional tricuspid regurgitation. As the severity of tricuspid regurgitation increases, the annulus takes on a more planar and circular configuration as the anterior-posterior distance increases disproportionately to the septal-lateral distance and the vertical axis decreases. The flattening of the tricuspid valve annulus alters the normal papillary muscle-to-leaflet and annulus relationship, causing leaflet tethering and functional regurgitation. Unlike the mitral annulus, the tricuspid annulus does not contract independently, thus making it potentially more susceptible to the function of the perianular myocardium. Additionally, the fibrous skeleton supporting the annulus is not as extensively
anchored in the periphery as the mitral annulus, which in turn allows it to be more malleable in regard to remodeling. Therefore, some degree of tricuspid regurgitation coexists with right ventricular dysfunction.

FIGURE 4-23 Tricuspid annulus and tricuspid valve leaflets. A, anterior; AVN, AV node; CSO, coronary sinus ostia; L, lateral; P, posterior; S, septal; TK, triangle of Koch; TT, tendon of Todaro.

The tricuspid annulus is closely related to the right coronary artery in its entire course around the atrioventricular groove until it gives rise to the posterior descending artery. The small cardiac vein is also related the tricuspid annulus throughout its course in the right atrioventricular groove. Both structures can be potentially injured at the time of tricuspid valve surgery with deep annular suture placement. Similarly, deep suture placement can injure the atrioventricular node due to its close proximity to the tricuspid annulus in the triangle of Koch.

**Leaflets**

As implied by the name, the tricuspid valve consists of 3 leaflets, each named in reference to their location within the right ventricle: the anterior (superior), posterior (inferior), and septal leaflets (see Fig. 4-23). Typically, the anterior leaflet is the largest, extending from the septum medially along the anterior margin of the atrioventricular groove to the acute margin of the atrioventricular groove. The anterior leaflet separates the inflow and outflow portions of the right ventricle. The attachment of the septal leaflet is to the
interventricular septum (anterior to posterior) with occasional extension to the inferior wall. It is the least mobile of the 3 leaflets of the tricuspid valve. Spanning the distance between the anterior and septal leaflets is the posterior leaflet. The septal leaflet is normally attached more apically than the anterior leaflet of the mitral valve and has chordae that attach it directly to the adjacent ventricular septum. These distinctive anatomic features are helpful in differentiating the mitral and tricuspid valves in complex congenital abnormalities. Similar to the mitral valve, the leaflets of the tricuspid valve have a rough zone, clear zone, and basal zone.

**Papillary Muscles and Chordae**

The right ventricle has a variable number of papillary muscles. Most commonly, there are 3 papillary muscles, named according to their location of origin in the right ventricle. Arising from the lateral aspect of the anterior wall of the right ventricle is the anterior papillary muscle, which is the largest and most consistent in origin. Conversely, the posterior papillary muscle arises from the posterior aspect of the right ventricle and is often bifid or trifid. The septal papillary muscle is the most inconsistent in origin and often has associated chordae that arise directly from the myocardium. A unique aspect of the right ventricle is the presence of the septomarginal trabeculae muscular ridges that connect the anterior wall of the right ventricle to the interventricular septum carrying with it the right bundle branch fibers of the conduction system (moderator band).

The tendinous chordae of the tricuspid valve arise from the upper third of the papillary muscles or directly from the ventricular wall and are classified similar to those of the mitral valve by their points of insertion into primary, secondary, and tertiary chordae.

**Pathologic Anatomy**

**Tricuspid Regurgitation**

Tricuspid regurgitation is typically referred to as functional (not related to a primary valvular pathology) or valvular. Valvular tricuspid regurgitation is less common as the etiology for tricuspid regurgitation (when it is considered
the mechanism), many etiologies exist, and the 2 broad descriptive categories are rheumatic or nonrheumatic. Nonrheumatic involves a host of disease processes that affect the tricuspid valve, including infective endocarditis, Ebstein anomaly, carcinoid syndrome, connective tissue diseases such as Marfan syndrome, papillary muscle dysfunction, valvular prolapse, and other structural problems in the valve complex that are either congenital or trauma related.

Functional tricuspid regurgitation is the most frequent etiology of tricuspid regurgitation and, although oversimplified, typically results from impaired leaflet coaptation from dilation of the right ventricle and tricuspid annulus. The clinical context in which this occurs is generally related to cardiomyopathy and mitral valve disease. Severe functional tricuspid regurgitation has a negative impact on survival and quality of life. However, surgical repair is not uniformly performed even in patients undergoing mitral valve repair or replacement. Percutaneous approaches to both repair and replace the tricuspid valve are thus gaining momentum. Strategies to treat functional tricuspid regurgitation percutaneously include the following: placement of transcatheter valves in the inferior vena cava and, rarely, in the superior vena cava to reduce regurgitant volume and pressure in the inferior vena cava; valve-in-valve therapy for degenerated tricuspid bioprosthesis; and transauricular intrapericardial tricuspid annuloplasty.

**Fluoroscopic Anatomy**

Two projections that are useful to gain a fluoroscopic understanding of the anatomy of the right-sided cardiac structures are the posterior-anterior view and a lateral view. During ventricular systole, the posterior-anterior view provides excellent visualization of the right atrium, right ventricle, tricuspid valve, and pulmonary artery. Conversely, in ventricular diastole, the lateral view nicely delineates the relationships of the superior and inferior vena cava to the right atrium and ventricle. Additionally, the lateral view also provides another vantage point of the pulmonary artery, right ventricular outflow tract, and pulmonic valve.

**CT Anatomy**

The role of cardiac CT for imaging the tricuspid valve remains to be proven.
As previously described, the tricuspid valve separates the right atrium from the morphologic right ventricle and consists of the same components as the mitral valve (leaflets/cusps, commissures, chordae tendineae, and papillary muscles). Distinguishing the morphologic left and right ventricles can be difficult in patients with complex congenital heart disease. Fortunately, there are several unique characteristics that make this possible by CT: the moderator band, a heavily trabeculated apex, well-developed infundibulum, septal papillary muscles, and the lack of fibrous continuity of the aortic valve and outflow.

Cardiac CT is also useful for evaluating leaflet morphology and thickening as well as leaflet apposition, but may not add much to TEE in this regard. Leaflet nonapposition is best determined at the end of ventricular systole in an electrocardiogram gated CT. Other indirect markers of tricuspid valve disease are the presence of contrast in the hepatic veins or inferior vena cava during the first-pass phase of CT (very sensitive marker for tricuspid regurgitation), bowing of the interventricular septum into the left ventricle during systole (indicative of elevated right-sided filling pressures), and lastly, right atrial and ventricular dilatation, which may alert one to the presence of tricuspid regurgitant disease. Constrictive pericarditis and pulmonary hypertension are important etiologies to consider when evaluating the tricuspid valve by cardiac CT. In patients with tricuspid stenosis, CT imaging is good at identifying fusion of the leaflet edges and shortening of the chordae tendineae.

**Echocardiographic Anatomy**

TTE and TEE of the tricuspid valve are more challenging than with the left-sided valves due to the tricuspid valve’s unfavorable location, behind the sternum and farther from the esophagus. The anterior and posterior leaflets can be visualized in the right ventricular inflow view, while the anterior and septal leaflets are visualized in the parasternal short-axis images and the apical 4-chamber view (Fig. 4-24). TEE has some incremental value (see Fig. 4-24). The 0° mid-esophageal 4-chamber view is often a good starting point for imaging of the tricuspid valve. Often, the etiology of the tricuspid regurgitation can be identified in this view, although supplemental views are helpful. In this view, the septal leaflet and a nonseptal leaflet (anterior or posterior) are well seen, as is the degree of tricuspid regurgitation. The
nonseptal leaflet can be either anterior or posterior depending on the positioning of the probe and degree of flexion or anteflexion. The 60° mid-esophageal right ventricular inflow-outflow view is well suited for visualization of the anterior and posterior leaflets of the tricuspid valve, as well as the right ventricular inflow and pulmonic valve. Better visualization of the chordae tendineae and papillary muscles can be accomplished with rotation of the probe to 120° for a long-axis view of the right ventricular inflow. The single best view to visualize all 3 leaflets together is the transgastric short-axis view (~30°).

**FIGURE 4-24** Tricuspid valve assessment on transthoracic and transesophageal echocardiography.
PULMONIC VALVE

The pulmonary root separates the right ventricular outflow tract from the main pulmonary artery. The components of the pulmonary root include the sinotubular junction, the sinuses of Valsalva, valvular leaflets, interleaflet triangles, and pulmonary annulus. Similar to the aortic valve, the pulmonary valve is a trileaflet valve made up of 3 semilunar cusps: anterior, left, and right. The pulmonary root similarly consists of 3 imaginary “rings” described by their anatomic relationship to the pulmonary valve. Superiorly, commissural apposition occurs at the sinotubular junction of the pulmonary trunk, signifying the location of the first ring. The ventriculoatrial junction marks the location of the second ring; the third ring is the basal-most ring occurring within the ventricle at the level of the base of the sinuses.

Pathologic Anatomy

Pulmonic Stenosis

Pulmonic stenosis (PS) produces obstruction to right ventricular outflow. Mild PS is well tolerated, but moderate to severe PS leads to progressive right ventricular hypertrophy and failure from right ventricular systolic pressure overload. Three types of PS are often described: valvular PS, supravalvular PS (stenosis of the main pulmonary artery or branch pulmonary artery stenosis), and subvalvular PS. Pulmonic valve stenosis is largely a congenital defect (Noonan syndrome, congenital rubella, tetralogy of Fallot) and is rarely the result of rheumatic fever, endocarditis, or carcinoid syndrome.

PS exists in 3 varieties. Most commonly, the pulmonic valve is a fibrotic and dome-shaped valve with preserved leaflet motility. This variety is most amenable to percutaneous balloon valvuloplasty. Conversely, the dysplastic variant (thickened leaflets with poor mobility) and the unicuspid/bicuspid variants are not particularly pliable or responsive to balloon valvuloplasty.

Balloon valvotomy of the pulmonic valve is indicated for asymptomatic patients with a mean transvalvular gradient >40 mm Hg or peak instantaneous gradient of >60 mm Hg.60 For symptomatic patients, the threshold for intervention is somewhat lower (mean gradient >30 mm Hg or
Percutaneous treatment is also recommended for focal branch and/or peripheral pulmonary artery stenosis with more than 50% stenosis and an elevated right ventricular systolic pressure greater than 50 mm Hg with or without symptoms.

Surgery is the preferred treatment for patients with severe PS and associated hypoplastic pulmonary annulus, severe pulmonary regurgitation, subvalvular PS, or supravalvular PS.

**Pulmonary Regurgitation**

Pulmonary regurgitation is principally the result of long-standing pulmonary hypertension, idiopathic pulmonary artery dilation, or connective tissue disease and remains clinically silent for many decades, although it can contribute to right-sided volume overload and dysfunction. Percutaneous therapies for pulmonary regurgitation are limited, although percutaneous pulmonary valve implantation has been successfully performed in patients with congenital heart disease and conduit dysfunction (stenosis or regurgitation).  

**Fluoroscopic Anatomy**

Right ventricular angiography is performed as a routine part of pulmonic valvuloplasty in both anterior-posterior and lateral projections to precisely locate the pulmonic valve and measure the annulus (Fig. 4-25). The lateral projection is particularly helpful in delineating the anatomy of the right ventricular outflow tract, infundibular obstruction, right ventricular function, and mobility of the pulmonic valve. Systolic doming of the valve leaflets may be appreciated on angiography. Pulmonary angiography is also useful to determine the degree of pulmonary regurgitation and evaluate for other lesions such as supravalvular or peripheral PS. With a pigtail in the right ventricle, the markers on the pigtail may be used to assess the diameter of the annulus to aid in balloon sizing. Typically, the goal balloon-to-annulus ratio is 1.2 to 1.4. A successful procedure is defined as one in which the final transvalvular gradient is <20 mm Hg.)
Complete or near-complete outflow tract obstruction by ventricular angiography should alert the operator to the likelihood of “suicide ventricle” physiology that may occur immediately after balloon valvuloplasty as the result of a sudden reduction in ventricular afterload and hypertrophic obstructive cardiomyopathy–like physiology with increased outflow tract obstruction in the setting of afterload reduction. Patients exhibiting “suicide ventricle” physiology should be treated with a β-blocker and intravenous fluids but not inotropic agents because these may exacerbate the outflow tract obstruction and hypotension. In the ensuing days to weeks, the outflow hypertrophy will regress in size and the subvalvular gradient will diminish.
CT Anatomy

Cardiac CT is useful in planning pulmonary valve procedures because these patients commonly have congenital heart disease and complex anatomy. Right ventricular outflow tract obstruction has many potential etiologies as previously outlined, and therein lies the utility of cardiac CT in planning the appropriate treatment approach. Appropriate preprocedural imaging with cardiac CT or magnetic resonance imaging may also tip off the operator to potentially poor candidates for percutaneous valvuloplasty (ie, those with bicuspid or unicuspid valves [<20% incidence] or myxomatous dysplastic valves).

Because of the ordinarily slender and delicate appearance of the pulmonic valve, it may not always be readily seen. If it is easily visible by CT, it is likely to be thickened. Like the tricuspid valve, the morphology of the pulmonic valve can be directly assessed by CT. In contradistinction to the tricuspid valve, the pulmonic leaflet apposition is best appreciated at end diastole, and the extent of leaflet excursion is better viewed in end systole. Moderate to severe PS is typically associated with poststenotic dilatation of the pulmonary artery and right ventricular hypertrophy (Fig. 4-26). Pulmonary regurgitation occurs as the result of dilatation of the pulmonic annulus, usually in the presence of pulmonary hypertension or dilatation of the pulmonary artery, either idiopathic or secondary to another disease process.
FIGURE 4-26 Sagittal computed tomography images of the right ventricular outflow tract show a dilated pulmonary root in a patient with pulmonic stenosis.

Similar to CT evaluation of the tricuspid valve, examination of the chamber size and thickness of the right heart should be performed when pulmonic valve pathology is suspected. Right atrial and ventricular dilation/hypertrophy may be present, and pulmonary trunk dimensions should also be scrutinized. Bowing of the interventricular septum into the LV cavity in systole is consistent with pressure overload; however, if septal bowing is present in both systole and diastole, this is most consistent with right-sided volume and pressure overload.

Echocardiographic Anatomy

Assessment of the pulmonic valve by TTE can be done on the parasternal short axis at the level of the aortic valve (Fig. 4-27). Severe PS is suggested by a continuous wave Doppler velocity of 4 m/s or greater across the pulmonary valve. Color-flow Doppler imaging across the pulmonary valve is used to detect pulmonary regurgitation noninvasively on echocardiography. TEE imaging of the pulmonary valve is often limited in utility. However, if TEE imaging is needed, the pulmonic valve is best visualized in 60° mid-esophageal inflow-outflow view (see Fig. 4-27). In this view, doming of the leaflets, calcification, mobility, and leaflet thickening can be assessed. Supplemental mid and upper esophageal short-axis views may also be beneficial when assessing degree of mobility, valve morphology, and procedural success.

CONCLUSION
In depth understanding of anatomy and its implications in different interventions is mandatory for the success of structural heart interventions.

pulmonary artery), and future directions. Cardiol Young. 2014;24(6):1095-1100.

**MULTIPLE CHOICE QUESTIONS**

1. The most accurate estimate of the annular size for transcatheter aortic valve implantation is obtained from which imaging modality?
   A. Two-dimensional (2D) transthoracic echocardiography (TTE)
   B. 2D transesophageal echocardiography (TEE)
   C. Three-dimensional (3D) TEE
   D. Multidetector computed tomography (MDCT)

2. Which imaging modality is preferred for mitral valve disease?
   A. MDCT
   B. Fluoroscopy
   C. Cardiac magnetic resonance (CMR)
   D. Echocardiography

3. The anterior mitral leaflet is closely related to which of the following structures?
   A. Left and right coronary cusps of the aortic valve
   B. Left and noncoronary cusps of the aortic valve
   C. Right and noncoronary cusps of the aortic valve

4. Which is the single best view to visualize all 3 leaflets of the tricuspid valve on TEE?
   A. Midesophageal 4-chamber view
   B. The transgastric short-axis view
   C. 60° mid-esophageal right ventricular inflow-outflow view

5. Which of the following is an indication for pulmonary balloon valvotomy?
A. Asymptomatic individual with mean transvalvular gradient >40 mm Hg or peak instantaneous gradient of >60 mm Hg
B. Asymptomatic individual with mean transvalvular gradient <20 mm Hg or peak instantaneous gradient of <50 mm Hg
C. Asymptomatic individual with mean transvalvular gradient >25 mm Hg or peak instantaneous gradient of >40 mm Hg

**ANSWERS**

1. D
   Accurate measurement of the oval-shaped aortic annulus is crucial for precise valve sizing in patients undergoing transcatheter aortic valve implantation (TAVI). The “annulus” is not circular but elliptical, and therefore, different modalities that measure different planes of the annulus do not necessarily yield same results. The annular size obtained by MDCT is typically larger than when measured by 2D TTE/TEE. Aortic annulus measurement by 3D TEE, although better than with 2D TTE/TEE, is smaller than that obtained on MDCT. 3D TEE should be used for transcatheter aortic valve replacement (TAVR) sizing only when MDCT is not available or contraindicated. MDCT provides the most accurate measurement of the aortic annulus.

2. D
   Echocardiography is the preferred imaging modality for mitral valve disease. The proximity of the mitral valve to the posteriorly positioned TEE probe in the esophagus strikingly improves anatomic assessment of the mitral valve. This has been successfully exploited to improve patient selection and safety of percutaneous mitral valve therapies. The poor temporal resolution of MDCT limits its role in the anatomic assessment of the mitral valve. The anatomic information from CMR is not equivalent to that from echocardiography due to relatively thick imaging size.

3. B
   The aortic/anterior leaflet of the mitral valve is dome shaped with attachment to the anterior two-fifths of the annular circumference. This leaflet lies in close relation to the left and noncoronary cusps of the aortic valve in
combination with which it forms the aorto-mitral curtain.

4. B
The 0° mid-esophageal 4-chamber view is often a good starting point for imaging of the tricuspid valve. In this view, the septal leaflet and a nonseptal leaflet (anterior or posterior) are well seen. The nonseptal leaflet can be either anterior or posterior depending on the positioning of the probe and degree of flexion or anteflexion. The 60° mid-esophageal right ventricular inflow-outflow view is well suited for visualization of the anterior and posterior leaflets of the tricuspid valve, as well as the right ventricular inflow tract and pulmonic valve. The single best view to visualize all 3 leaflets together is the transgastric short axis (~30°).

5. A
Balloon valvotomy of the pulmonic valve is indicated for asymptomatic patients with a mean transvalvular gradient >40 mm Hg or peak instantaneous gradient of >60 mm Hg. For symptomatic patients, the threshold for intervention is somewhat lower (mean gradient >30 mm Hg or peak instantaneous gradient >50 mm Hg). Percutaneous treatment is also recommended for focal branch and/or peripheral pulmonary artery stenosis with more than a 50% stenosis and an elevated right ventricular systolic pressure greater than 50 mm Hg with or without symptoms.
Peripheral Anatomy for the Interventionalist

Joseph A. Walsh
Curtiss T. Stinis

INTRODUCTION

In contemporary practice, catheter-based interventions have become an increasingly important therapeutic modality for the treatment of nearly all areas of the peripheral arterial and venous system, including the head, neck, and great vessels, as well as the upper and lower extremities. A thorough understanding of the peripheral arterial and venous anatomy is the foundation for any successful peripheral vascular interventional procedure. This chapter describes the arterial and venous anatomy above and below the diaphragm, with emphasis on the pertinent anatomic variants and radiographic examinations in the catheterization laboratory.

AORTIC ARCH AND UPPER EXTREMITIES

The vascular anatomy of the aortic arch and upper extremities begins at the level of the sinus of Valsalva. From the sinotubular ridge, the ascending aorta travels anteriorly and superiorly, passing over the main pulmonary artery and left mainstem bronchus. At this level, the mean diameter of the ascending
thoracic aorta in the normal adult human is 3.5 cm.

The brachiocephalic or right innominate artery is the first major branch off the aortic arch. The next major vessel that arises from the aortic arch is the left carotid artery. The left subclavian artery is the last great artery that arises directly off the aortic arch. After the left subclavian artery arises, the aortic arch ends. This anatomic region, called the isthmus, is found between the last great vessel and the attachment of the ductus arteriosus, after which the descending aorta begins and continues down to the level of the iliac bifurcation.

In 30% of patients, the normal relationship described above is not seen. The most common variants are a shared ostium of the brachiocephalic artery and the left carotid artery (15%), or the so called “bovine arch,” where the left carotid artery arises from the proximal aspect of the brachiocephalic trunk (10%). Other common variants include the right subclavian arising from the arch distal to the left subclavian artery and the left vertebral artery arising directly from the aortic arch (5%) between the left carotid and left subclavian arteries.\textsuperscript{1,2} In healthy individuals, the great vessels arise from the horizontal portion of the aortic arch, but with increasing age, the vessels tend to shift counterclockwise toward the ascending aorta.

The right innominate or brachiocephalic artery gives rise to the right subclavian artery and right common carotid artery. After the bifurcation of the subclavian and carotid arteries on the right, the next vessels that arise off the right subclavian include the right vertebral artery and the right internal mammary artery. The right subclavian artery then gives rise to the thyrocervical trunk and the costocervical trunk. At this location, the subclavian artery becomes the axillary artery after it crosses the lateral margin of the first rib. On the left, the subclavian artery gives rise to the left vertebral artery and the left internal mammary artery. Anatomically, its course is similar to the right subclavian artery, giving rise to similar branches.

The axillary artery on both the left and the right gives rise to several small branches around the shoulder, including the superior thoracic, thoracoacromial, lateral thoracic, subscapular, and circumflex humeral artery. It then becomes the brachial artery at the lateral margin of the teres major muscle. The brachial artery divides into the radial and ulnar arteries in the antecubital fossa. In relationship to surface markers, the brachial artery bifurcates a few centimeters below the elbow joint. The ulnar artery then undergoes anastomosis with the median artery and forms the superficial
palmar arch in the hand. The radial artery forms the deep palmar arch. The remaining axial artery at the level of the radial–ulnar bifurcation is known as the interosseous artery. Because radial artery access has become increasingly popular for cardiac procedures, an understanding of radial artery anatomic variations is important to performing successful radial catheterization procedures. Radial artery variations are present in 9.1% of the population, with abnormal origin of the radial artery occurring in 5.2%, radioulnar loop in 1.5%, and significant tortuosity noted in 5.6%.

Arteriography of the aortic arch is carried out for diagnostic purposes and to plan interventions. Anteroposterior (AP) and 45° to 60° left anterior oblique (LAO) projections are initially used to image the arch and great vessels. Imaging the right brachiocephalic territory is best accomplished in a right anterior oblique (RAO) projection with caudal angulation. For selective shots of the left subclavian artery, an AP projection or steep LAO views are useful (Table 5-1).

<sup>a</sup>Ipsilateral or contralateral indicates the angulation for a left femoral artery is best obtained with the same-side (ipsilateral) angulation (ie, LAO projection) or, if contralateral, the opposite angulation (ie, RAO projection).
When performing diagnostic angiography of the aortic arch, it is important to determine the specific type of aortic arch (Fig. 5-1), identify any anatomic variation, and identify the presence of atherosclerotic disease, as these factors can determine both catheter selection as well as interventional technique. The three types of aortic arch are determined by the takeoff of the great vessels relative to the horizontal portion of the greater curvature and assist the clinician in determining the level of complexity and choice of catheters for selective engagement. For example, selective carotid angiography of a type I and most type II arches can be accomplished using a JR4 diagnostic catheter, whereas a type III arch would favor a Vitek or Simmons catheter.

![Aortic arch types](image)

**FIGURE 5-1** Aortic arch types.

**VENOUS CIRCULATION OF THE UPPER EXTREMITIES**

Because arteriovenous fistulas are prone to degeneration and may be suitable for percutaneous intervention, knowledge of the venous anatomy is useful. Furthermore, placement of devices, such as pacemakers and automatic implantable cardioverter-defibrillators, requires use and knowledge of upper extremity venous anatomy. The venous system of the upper extremity is predominantly superficial. The dorsal venous network of the hand empties into the basilic vein, the cephalic vein, and the antecubital veins. The cephalic vein originates dorsally and laterally, crossing the elbow joint and entering the superior aspect of the axillary vein just above the clavicle. The basilic vein, which originates on the ulnar side of the arm, continues medially to the brachial artery. It joins the brachial vein to become the axillary vein at the
The medial cubital veins are the veins that connect the basilic and cephalic veins in the antecubital fossa.

The deep veins in the upper arms and chest follow their respective arteries. The axillary and cephalic veins become the subclavian veins, which are continuations of the axillary veins. As the subclavian veins cross the sternum, they join with the internal jugular veins to form the brachiocephalic veins. The left brachiocephalic vein is longer than the right. The right and left brachiocephalic veins join behind the first anterior rib to form the superior vena cava. The azygous vein forms at the level of the second lumbar vertebra. It travels in the anterior aspect of the posterior mediastinum to the right of the midline and arches anteriorly to join the superior vena cava just above the entry into the pericardium.

Persistent left superior vena cava is an important anatomic variant that occurs in 0.5% to 2% of the general population. In this condition, the left brachiocephalic vein does not develop fully, and the left upper limb and head and neck drain into the right atrium via the coronary sinus. The variation, in isolation, is considered benign, but it is frequently associated with congenital heart defects.

**CAROTID AND VERTEBRAL ARTERIES**

The carotid and vertebral arteries are becoming increasingly important to the interventional cardiologist as endovascular therapy has become a more viable option for atherosclerotic disease of these vessels. The right common carotid artery arises in a reliable fashion from the right innominate artery and travels superiorly. It then bifurcates into the right internal and external carotid arteries. Anatomically, the left common carotid artery arises directly from the aortic arch and travels cephalad to bifurcate into the left internal and external carotids. As detailed earlier, however, the left common carotid has a more variable course in 30% of cases and may arise as a shared ostium or a direct branch of the right innominate. The common carotid arteries are paired vessels, located anteriorly within the neck. The bifurcation of the common carotid arteries into the internal and external arteries on both sides is generally at the level of cervical vertebra C3 to C4. In some patients, the
bifurcation is significantly higher and arises deep in the mandible, which would require dislocation for carotid endarterectomy. The proximal portion of the carotid bifurcation houses the carotid sinus, which regulates baroreceptor reflexes via the glossopharyngeal nerve and can cause bradycardia and hypotension during carotid intervention.

Both internal carotid arteries supply the anterior circulation of the brain as well as a portion of the skull base. The first segment of the internal carotid artery is the cervical segment, which has no branches. This is the only segment of the internal carotid artery that is extracranial and is the target for conventional endovascular intervention. The remaining three segments of the internal carotid artery are named in relation to their location in the skull: the petrous and cavernous portions, which lie within the petrous bone and cavernous sinus, respectively; and the supraclinoid segment, which runs above the level of the anterior clinoid process. The internal carotid artery runs posterolateral to the external carotid artery and then courses medially to enter the skull base through the carotid canal (Fig. 5-2). The area of the brain supplied by the anterior and middle cerebral arteries is termed the carotid territory.
The external carotid artery is a smaller artery in relation to the internal carotid artery. The distinguishing feature of the external carotid artery is its branches (Fig. 5-3): the superior thyroid, ascending pharyngeal, lingual, facial, occipital, and posterior auricular arteries. A general understanding of the branches originating from the external carotid artery is important as these branches are often wired during intervention. The external carotid artery then terminally bifurcates into the internal maxillary and superficial temporal arteries. Some patients develop temporary jaw claudication after carotid stenting if the ostium of the external carotid is compromised, but this is usually temporary and infrequently requires any intervention.
Arteriography of the carotid arteries is carried out primarily in two views: a lateral projection and an AP view with cranial angulation. The lateral view serves to separate the internal (posterior, no branches) from the external (anterior, with branches) carotids and to image the bifurcation and common carotid. Often, oblique views can also accomplish this. The AP view best characterizes the common carotid and the distal internal carotid arteries. As the internal carotid enters the cranium, it traverses the cavernous sinus and forms a siphon-like S curve. It is critical to maintain wire position below the level of the siphon because an intracranial perforation or dissection could occur if the wire or a distal protection device is allowed to enter the
intracranial carotid. It is also critical to image the intracranial carotid both before and after carotid stenting to define the key branches where complications can arise. Structures of key importance include the ophthalmic, anterior cerebral, and middle cerebral arteries, which should all be closely interrogated after the procedure for occlusion or compromise (see Fig. 5-2).

The vertebral arteries arise as the primary branches of the subclavian arteries, supplying the posterior circulation of the brain, spinal cord, and muscles of the neck. Vertebral arteries enter the foramina of the C6 vertebra and then run within the bony canals, exiting at the C2 foramina. These arteries then turn laterally to course around the C1 vertebra before returning medially to ascend through the foramen magnum to join and form the basilar artery. The most common views of the vertebral arteries are anteroposterior. The ostia of the vertebral arteries are best captured by contralateral oblique projection.

VENOUS ANATOMY OF THE HEAD AND NECK

The head is drained by the internal jugular veins and external jugular veins. The internal jugular vein is formed by the sigmoid and petrosal sinuses. These veins course inferiorly on both sides, running lateral to the carotid arteries and deep to the sternocleidomastoid muscle of the neck. They then join the subclavian vein on their respective sides. The external jugular vein drains portions of the face and the neck and runs superficial to the sternocleidomastoid muscle before joining the subclavian veins. Finally, the vertebral veins drain the occipital region of the brain and adjacent to the vertebral arteries, emptying into the innominate veins.

ANATOMY OF THE ABDOMINAL AORTA

The major arteries of interest to the interventionalist that arise from the abdominal aorta are the celiac artery, the superior mesenteric artery, the inferior mesenteric artery, and the renal arteries. The celiac artery arises
ventrally from the abdominal aorta at the vertebral level T12-L1. This artery is commonly called the *celiac trunk*, giving rise to the left gastric artery, common hepatic artery, and the splenic arteries. The left gastric artery branches off to the distal esophagus and stomach. The hepatic artery resides in the hepatoduodenal ligament and typically divides into the right, middle, and left branches. The cystic artery is most frequently a branch of the right hepatic artery. Further branches arising from the common hepatic artery are the gastroduodenal artery, the anterior and posterior superior pancreaticoduodenal arteries, and the right gastroepiploic artery. The splenic artery is particularly long and tortuous, supplying the spleen and pancreas. The main branches are the pancreatic, short gastric and left gastroepiploic arteries. The splenic artery then supplies the splenic parenchyma through numerous branches (Fig. 5-4).

![Fig. 5-4 Angiographic anatomy of the celiac trunk.](image)

The renal arteries arise from the aorta slightly inferior to the origin of the superior mesenteric artery, at the L1-L2 level. Seventy percent of the population has a single renal artery to each kidney, with the remaining 30% having multiple renal arteries, usually separate vessels to the upper and lower poles of the kidney. This could also be seen as an early bifurcation of a single renal artery, giving the appearance of 2 arteries. Usually, this variant consists of a primary renal artery and an accessory artery that can supply either the upper or the lower pole of the kidney.
It should be noted that the origins of the left and right renal arteries are in different locations as they arise from the aorta. The left renal artery orifice typically arises laterally, whereas the right renal artery is positioned anterolaterally. The renal arteries then divide into anterior and posterior segments at the renal hilus, continuing to divide into lobar arteries. The terminal branches are the arcuate arteries that supply the corticomedullary junction.

The superior mesenteric artery arises at the level of the L1 vertebral body. This artery supplies the midgut from the ligament of Treitz to the midtransverse colon. Its origin is caudal to the celiac artery but cephalad to the origin of the renal arteries. It takes a steep downward course as it travels toward the right, lower abdominal quadrant. The major branches of the superior mesenteric artery include the inferior pancreaticoduodenal artery, jejunal and ileal branches, and the middle colic artery, which supplies the transverse colon. The colic artery portion of the superior mesenteric artery is divided into the ileocolic, right colic, and middle colic arteries. The ileocolic artery provides the blood supply to the cecum and anastomotic branches to the right colic artery. The right colic artery arises between the middle and ileocolic arteries and supplies the right colon and proximal transverse colons. Of note, the arc of Riolan refers to a direct communication between the superior and inferior mesenteric arteries, via the left and middle colic branches that anastomose at the splenic flexure (Fig. 5-5).
FIGURE 5-5 Branches of the aorta below the diaphragm. Ca, celiac artery; IMa, inferior mesenteric artery; LRa, left renal artery; RRa, right renal artery; SMa, superior mesenteric artery.

The inferior mesenteric artery is the last major artery arising from the abdominal aorta. This artery typically arises at the level of the L3 vertebra and supplies the distal transverse colon, left colon, and rectum. Its origin is from the left anterolateral surface of the aorta, which gives it a very typically
arteriographic appearance. The main branches of the inferior mesenteric artery include the left colic artery, sigmoid arteries, superior rectal artery, and the marginal artery of Drummond.

Performing optimal arteriography of the major abdominal aortic arteries can be challenging. Engagement of the celiac trunk and superior mesenteric artery is often best performed in a lateral projection given that these vessels arise anteriorly from the abdominal aorta, and their origins can be more easily identified in the lateral projection (Fig. 5-6). Imaging of these vessels should include both AP and lateral projections, which will define the origin and proximal vessels as well as the distal branch territories. The renal arteries can easily be engaged and imaged in an AP projection. However, as a result of the slightly different takeoffs of these arteries, a shallow LAO projection, typically 10° to 20° LAO, is an excellent view for both engagement and selective and nonselective imaging. The inferior mesenteric artery is typically engaged and imaged in the AP projection (Table 5-2).

¹ Ipsilateral or contralateral indicates the angulation for a left femoral artery is best obtained with the same-side (ipsilateral) angulation (ie, LAO projection) or, if contralateral, the opposite angulation (ie, RAO projection).
THE ILIAC ARTERIES AND LOWER EXTREMITIES

The aorta bifurcates into the common iliac arteries at the level of the L4-L5 vertebrae (Fig. 5-7). The common iliac arteries divide into the internal and external iliac arteries. The internal iliac artery is commonly referred to as the hypogastric artery. The external iliac arteries then continue, giving off the inferior epigastric and deep circumflex iliac arteries. The inferior epigastric artery anastomoses with the superior epigastric artery and runs along the anterior abdominal wall. The external iliac artery turns into the common femoral artery when the deep circumflex iliac artery arises from the external iliac. It is important to recognize that there are three structures that mark the boundary between the external iliac artery and the common femoral artery: the deep circumflex iliac artery, the interior epigastric artery, and the inguinal ligament (Fig. 5-8).
RCla = Right common iliac artery
RIIa = Right internal iliac artery
REIa = Right external iliac artery
LCla = Left common iliac artery
LIIa = Left internal iliac artery
LEIa = Left external iliac artery
The internal iliac artery divides into the posterior and anterior divisions, with the posterior division giving off the superior gluteal, iliolumbar, and lateral sacral branches. The anterior division gives rise to the obturator, inferior gluteal, and internal pudendal branches. The inferior gluteal artery supplies the gluteus muscle and branches to the sacral nerve. The internal pudendal artery gives off the inferior hemorrhoidal branch before giving rise to the penile arteries, the dorsal artery of the penis, and the cavernosal artery. There is an extensive anastomotic network between the left and right internal iliac arteries, and hence, unilateral internal iliac disease may be less likely to cause symptoms. Anastomotic connections also exist between the inferior
gluteal and perforating arteries of the femoral circulation, which explains how common iliac disease can cause claudication in the buttocks and proximal thigh.

The common femoral artery divides into the superficial femoral artery and profunda femoris artery. The profunda femoris artery courses laterally and posteriorly to the superficial femoral artery and is also known as the deep femoral artery. Major branches off the profunda femoris artery include the medial and lateral femoral circumflex arteries. One or both of these branches may occasionally (15%-20%) arise directly from the common femoral artery. The common femoral artery is a key access point for endovascular procedures, and therefore, a proper understanding of the anatomic landmarks is critical to obtaining proper femoral access and closure and reducing complications. The external iliac artery becomes the common femoral artery as it passes beneath the inguinal ligament, which is demarcated angiographically by the origin of the inferior epigastric artery (as it passes beneath the inguinal ligament) and the deep circumflex iliac artery. The inferior border of the anatomic common femoral artery is the bifurcation of the superficial femoral artery and the profunda femoris. This anatomic definition of the femoral artery, however, does not define the optimal location for femoral arterial access with respect to endovascular procedures. The optimal location for common femoral artery access is that portion of the common femoral artery that is located over the anterior pelvic bony structure known as the pubis. When a femoral sheath is removed, the gold standard for obtaining hemostasis is manual compression. This can only be effectively accomplished if the access site can be adequately compressed against an underlying bony structure (the pubis). Significant variability exists in the population with respect to the relationship of the bifurcation of the superficial femoral artery and profunda femoris artery and the pubis. Thus, it is quite possible to obtain access within the common femoral artery (as defined by the anatomic definition) yet have this site be well inferior to the pubis. Although such access is technically within the anatomic common femoral artery, it does not represent an ideal access location due to the absence of an adequate posterior bony structure against which to compress the artery for purposes of obtaining adequate hemostasis. The optimal point for common femoral artery access lies within the portion of the common femoral artery that lies over the pubis. This segment of the common femoral artery represents the “functional” common femoral artery as it relates to arterial
access for endovascular procedures (Fig. 5-9). Access sites that are inferior to the pubis are associated with a higher rate of complications such as hematoma and pseudoaneurysm formation, whereas access sites located above the pubis are associated with high rates of retroperitoneal bleeding (Fig. 5-10).

FIGURE 5-9 Anatomic versus functional common femoral artery.
FIGURE 5-10 A. Lateral diagram of common femoral artery anatomy. B. Low access
site with risk for hematoma and/or pseudoaneurysm. C. High access site with risk for retroperitoneal hemorrhage.

The superficial femoral artery courses within the medial thigh until it divides posteriorly at the level of the adductor canal. Anatomically, this region is also known as the *Hunter canal*. This area is also the anatomic boundary of the superficial femoral artery and the popliteal artery. At its origin, the popliteal artery gives off the descending genicular, superior genicular, and supreme geniculate arteries, which are a rich source of collaterals in occlusive arterial disease, as is the profunda femoris artery. The popliteal artery then divides into the anterior tibial artery and the tibioperoneal trunk below the level of the knee. The anterior tibial artery courses anteriorly to supply the interosseous muscles, continuing inferiorly to terminate as the dorsalis pedis artery in the foot. The tibioperoneal trunk gives rise to the peroneal and posterior tibial arteries. The peroneal artery follows a medial course posterior to the interosseous membrane of the tibia and fibula and terminates with the posterior communicating branch and an anterior perforating branch. The posterior tibial artery continues medially to pass posterior to the medial malleolus. Together with the branches of the dorsalis pedis branch, this artery forms the pedal arch of the foot (Fig. 5-11).
SFa = superficial femoral artery
POPa = popliteal artery
Ga = geniculate arteries (superior, inferior)
TPT = tibioperitoneal trunk
ATa = anterior tibial artery
PTa = posterior tibial artery
Pa = peritoneal artery
DPa = dorsal pedal artery
Arteriography of the iliac arteries and the lower extremities involves both ipsilateral and contralateral imaging. For the aortoiliac bifurcation and common iliac arteries, an AP view is required. To image the bifurcation of the internal and external iliac arteries, a contralateral angulated view is best. For example, an LAO view would optimize imaging for the right internal and external iliac arteries. The external iliac and common femoral arteries usually require an ipsilateral angulated view, which separates out the profunda femoris artery from the superficial femoral artery since the profunda femoris follows a lateral and posterior course. The angulation is generally between 20° and 30°. Usually, AP projections suffice for the superficial femoral arteries and the vessels of the lower extremities (see Table 5-2).6,7

ACKNOWLEDGEMENTS

The authors wish to thank Richard E. Stewart, MD, for his contributions to the previous edition of this chapter

MULTIPLE CHOICE QUESTIONS

1. The most common anatomic variant in aortic arch anatomy, occurring in 15% of the population, is a common ostium of the __________ and ______________.
   A. Brachiocephalic and left common carotid arteries
   B. Left common carotid and left subclavian arteries
   C. Brachiocephalic and left subclavian arteries
   D. Brachiocephalic and left vertebral arteries

2. What is the most challenging type of aortic arch for both diagnostic imaging and therapeutic intervention?
   A. Type I
   B. Type II
   C. Type III

3. The nerve that mediates the baroreceptor reflex typically seen during carotid intervention is the __________ nerve.
   A. Trigeminal
   B. Hypoglossal
   C. Glossopharyngeal
   D. Vagus
   E. Abducens

4. During carotid intervention, it is critical to maintain wire position below the __________ to avoid intracerebral perforation or dissection.
   A. Mandible
   B. External carotid
   C. Siphon or “S” portion of the internal carotid
   D. Cavernous portion
5. What is the true anatomic landmark of the “functional” common femoral artery?
   A. Femoral head
   B. Pubis
   C. Femoral neck
   D. Anterior superior iliac spine

ANSWERS

1. A
The most common variant of the aortic arch anatomy is a shared ostium of the brachiocephalic artery and the left carotid artery, which occurs in 15% of the population.

2. C
The type III aortic arch represents the most difficult arch anatomy for both diagnostic and therapeutic interventional procedures. Because the aortic arch is highly angulated in the type III anatomy, catheter selection is key to being able to properly selectively engage the desired vessel and achieve adequate support for catheter-based intervention.

3. C
The proximal portion of the carotid bifurcation houses the carotid sinus that regulates baroreceptor reflexes via the glossopharyngeal nerve and can cause bradycardia and hypotension during carotid intervention.

4. C
It is critical to maintain wire position below the level of the siphon because an intracranial perforation or dissection could occur if the wire or a distal protection device is allowed to enter the intracranial carotid.

5. B
The optimal point for common femoral artery access lies within the portion of the common femoral artery that lies over the pubis. This segment of the
common femoral artery represents the “functional” common femoral artery as it relates to arterial access for endovascular procedures because it is the only portion of the vessel that allows the ability to adequately compress the vessel over the underlying bony structure (the pubis) when performing manual compression.
INTRODUCTION

The heart is the engine that powers life, and the coronary circulation represents the fuel pipes, providing blood with oxygen and other nutrients to keep the heart beating. Under normal physiologic circumstances, there will always be an equilibrium between oxygen demand of the myocardium and oxygen supply provided by the blood flow in the coronary arteries. There is an ingenious regulation system in the coronary circulation to maintain this equilibrium, called autoregulation. Due to the enormous reserve of the coronary circulation to provide blood to the myocardium, early stages of coronary atherosclerosis and narrowing in the coronary arteries will hardly be noticed, and if the coronary arteries become more severely narrowed, complaints will only occur in situations where the oxygen demand is increased, such as physical exercise or stress. Under those circumstances, myocardial ischemia will present itself by a characteristic pain or unpleasant sensation in the chest, arms, neck, or back, called angina pectoris. However, under resting circumstances, blood flow in the coronary circulation can be kept sufficient for a long time despite the presence of important narrowing.1

For those reasons, it is important to realize that in assessing the coronary circulation, it is not the coronary blood flow at rest that should be studied as a
measure for the severity of coronary artery disease, but the maximal achievable blood flow as can be provoked by maximum exercise or vasodilatory stimuli like adenosine. Stated in another way, the degree to which maximum blood flow in the coronary circulation is decreased determines the exercise level at which angina pectoris occurs.

Also, in case of acute coronary syndromes, fundamentally the same principles hold true. However, in those situations, a rapid and sharp decrease of coronary blood flow usually occurs due to plaque rupture and/or thrombosis, often superimposed upon preexisting lesions.

It should be realized that the severity of disease on the coronary angiogram has only a poor correlation with the degree to which coronary blood flow is decreased. In other words, it is difficult to assess the physiologic significance of a coronary artery stenosis from the coronary angiogram. Nevertheless, the angiogram is important because in performing coronary interventions, it is a road map for the interventionalist to manipulate with wires and other equipment and to place the stent(s). In this chapter, the structure of the coronary circulation is discussed, followed by the regulation of coronary blood flow. There is a brief discussion on the development of atherosclerosis and the physiologic methods to detect this in early and later stages. Some words are also spent on coronary stenoses and myocardial ischemia and the consequences of ischemia for the heart. This is followed by the paramount question why functional testing is important, leading to the concept of fractional flow reserve. Some physiologic aspects on background and features of fractional flow reserve are briefly discussed. The clinical use of fractional flow reserve is discussed later in Chapter 24. Finally, some specific manifestations of coronary artery disease and physiologic methods for how to address these are discussed.

THE CORONARY CIRCULATION

In most mammals, the coronary circulation consists of 2 blood vessels originating from the proximal aorta. In humans, these coronary arteries have a diameter of approximately 2.5 to 4.0 mm and run as a kind of corona around and across the heart. Just like all other arteries, these coronary arteries have a layered structure with an intima, media, and adventitia. It is important to realize that under normal circumstances, the resistance of the coronary
artery to blood flow is negligible, even at maximum hyperemia. From the epicardial coronary arteries, perforating branches enter the myocardium, and within the myocardium, these divide further into smaller vessels, called arterioles, with a diameter between 100 and 400 μm. Around these arterioles, smooth muscle cells are located in groups and are able to vary the resistance of the arterioles over a large domain (Fig. 6-1).

**FIGURE 6-1** Schematic representation of the coronary circulation. The coronary artery splits up into arterioles with a diameter of 100 to 400 μm, which further divide into the capillary bed. At the entrance of the arterioles, muscular sphincters are
located that can vary the resistance of the arterioles by at least 500%. Under resting conditions, the sphincters will be constricted, and if a higher blood flow is needed in response to higher oxygen demand (as in exercise), the sphincters dilate. In that way, at an equal perfusion pressure, myocardial blood flow can increase by at least 500% in healthy young individuals. In case of a moderate stenosis, an additional epicardial resistance occurs, and as a compensation, the arteriolar sphincter partially dilates even under resting conditions in order to maintain a total resistance in the bed equal to R. Consequently, during resting conditions, no noticeable effect of the epicardial stenosis is observable. However, during situations of increased demand (eg, exercise) the compensatory vasodilator reserve of the sphincters is already decreased and the maximal achievable blood flow in the coronary artery and myocardial bed is decreased accordingly. Therefore, myocardial ischemia and angina pectoris may occur during exercise. In case of a very severe stenosis in the epicardial coronary artery (lower pictograms), the epicardial stenosis can be so tight that the arteriolar sphincter needs to dilate completely to compensate the additional resistance in the coronary artery. This means that no reserve at all is left anymore. In such a case, even minimal increase in oxygen demand will result in angina pectoris. With further increase of stenosis severity, frank ischemia at rest will occur, resulting in unstable angina or an acute coronary syndrome. (From Pijls NHJ. Coronaire fysiologie en myocardischemie. In Van der Wall EE, Van de Werf F, Zijlstra F. Cardiologie. Houten, the Netherlands: Bohn Stafleu van Loghum, 2008, with permission of Springer.)

For the purpose of simplicity, these smooth muscle cells around the arterioles are indicated as a kind of sphincter. In reality, the muscle cells are more equally distributed along the arterioles. The resistance of these arterioles can vary in healthy individuals by at least 500%, which means that under normal circumstances, maximum blood flow can be at least 5 times baseline blood flow. This ratio between maximum blood flow and baseline blood flow is called coronary flow reserve (CFR), as will be discussed more extensively later. The arterioles split up into the capillaries, in analogy to any other organ in the human body. The capillary network of the heart is very dense, and every myocyte is next to a capillary. Finally, the capillaries collect into small venules and collect further into veins, which either drain directly into the heart chambers (Thebesian veins) or collect in 1 large vein, the coronary sinus, with a diameter of 5 to 10 mm and ending in the right atrium.

Coronary blood flow equals approximately 3% to 5% of total cardiac output and varies from 200 mL at rest to approximately 1 L per minute at maximum exercise in healthy young people. It is important to realize that in contrast to most other organs in the human body, oxygen extraction from the blood in the coronary circulation is very high and that oxygen saturation in
the coronary sinus is relatively low (30%-40%). This means that in the coronary circulation increase in oxygen consumption by the myocardium can only be achieved by an increase of blood flow and not by further extraction of oxygen. This issue will be discussed later in this chapter and in the other chapters.

Under baseline circumstances, the oxygen consumption of the myocardium is 0.7 to 1.3 mL O$_2$/min/g of tissue, and under maximum hyperemic circumstances, this increases to 3 to 6 mL O$_2$/min/g.

During exercise, heart rate and contractility will largely increase and lead to an increase in oxygen consumption; in addition, afterload will increase, thereby further increasing the oxygen demand and consumption of the heart. To match this tremendously increased demand, a wonderful regulation mechanism has been designed by nature, called autoregulation, which is further explained in Figure 6-1.

**Collaterals**

Collaterals are small blood vessels that can connect perfusion territories of different coronary arteries. The diameter of collaterals can vary from 10 μm to >1 mm. In the latter case, the collaterals are visible on the coronary angiogram. Collaterals can either be preexistent or develop as a response to myocardial ischemia. Repetitive ischemia is a necessary condition and the most potent stimulus to develop collaterals.

Collaterals can be either subendocardial or subepicardial. In the first case, the process underlying collateral development is often angiogenesis, and such angiogenetic collaterals only exist in a 1-layered rudimentary vessel structure. Subendocardial collaterals are often nicely observed running through the septum and connecting the septal branches of the left anterior descending artery and the posterior descending branch of the right coronary artery. In the case of subepicardial collaterals, these are often preformed (with a large variation between different individuals), have a 3-layer structure like a normal small artery, and are often very tortuous (corkscrew). This type of collaterals can often be seen across the apex connecting the distal right coronary artery and the left anterior descending artery, or running from the right ventricular branch of the right coronary artery to the left coronary artery, or even running across the atrium.
Collaterals are important because in a number of patients collaterals provide sufficient blood flow to maintain oxygen supply at rest even in case of a severe stenosis or total occlusion of the recipient coronary artery belonging to the collateral-dependent territory. The extent of collaterals and the intrinsic aptitude to develop them largely vary from one person to another and are also species dependent. In humans, in case of repetitive ischemia of the myocardium, collaterals may develop and reach a kind of maximum in most patients after approximately 3 months.

**REGULATION OF CORONARY BLOOD FLOW**

**Autoregulation**

Autoregulation is the mechanism by which oxygen supply and demand of the myocardium are matched to each other both under physiologic and pathologic circumstances (see Fig. 6-1). It is important to realize that the arteriolar sphincters can vary the resistance over a large range. If these sphincters are completely dilated, resistance in the coronary circulation decreases by roughly 500%, which means that at an equal perfusion pressure, the reserve of coronary blood flow is also 500%. Under normal circumstances, the perfusion pressure in the coronary circulation is the difference between the aortic pressure and the central venous pressure (in normal circumstances, 0-5 mm Hg). If no coronary stenosis is present, the pressure in the distal coronary artery at the entrance of the arterioles equals the aortic pressure because there is no decline of pressure in a normal coronary artery, not even during maximum hyperemia. In case of increased oxygen demand of the myocardium (exercise, stress), the arteriolar sphincters can dilate, and blood flow can increase accordingly, even if perfusion pressure remains unchanged. The mechanism by which sphincters can dilate or contract is dependent, on one hand, on mechanical factors (eg, shear stress) and, on the other hand, on humoral factors (eg, bradykinin, acetylcholine, nitric oxide). If, at exercise, arterial blood pressure further increases (and thereby also the perfusion pressure across the coronary circulation), coronary blood flow will be able to increase further and will always remain sufficient
to match the increased oxygen demand and metabolic needs of the myocardium.

The coronary autoregulation also keeps coronary flow constant despite changes in blood pressure. If, for whatever reason, blood pressure decreases, this is also accompanied by dilatation of coronary sphincters to keep coronary perfusion constant despite low blood pressure. If blood pressure increases inadvertently, contraction of sphincters prevents coronary blood flow from increasing inadvertently. In this way, coronary blood flow remains constant between mean aortic pressure from 50 to 130 mm Hg. At average blood pressures of greater than 130 mm Hg, sphincters are maximally contracted, and the further increase of blood pressure will increase coronary perfusion.

Below a mean arterial pressure of 50 mm Hg, the sphincters are maximally dilated, and a further decrease of blood pressure will lead to a pathologic decrease of coronary perfusion. As mentioned, the phenomenon whereby coronary perfusion can be maintained constant over a large range of perfusion pressures is called autoregulation of coronary blood flow.4

**Reactive Hyperemia**

Under baseline circumstances, blood flow in the left coronary artery occurs mainly during diastole. In systole, the myocardium compresses its own vasculature, and there is almost no forward blood flow in the left coronary artery. This means that blood flow in the coronary arteries is antiphasic compared to other parts of the human circulation, where blood flow mainly occurs during systole.

During maximum hyperemia of the myocardium (as present during maximum exercise but also after administration of specific vasodilatory drugs), diastolic blood flow in the coronary artery further increases, but also a systolic component in coronary blood flow occurs consisting of 15% to 25% of total coronary blood flow (Fig. 6-2).
FIGURE 6-2 A and B. Blood flow pattern in a normal left coronary artery at rest and at hyperemia. At rest, systolic blood flow is very low, and flow mainly occurs during diastole. During maximum hyperemia, a systolic component also occurs, whereas
diastolic blood flow increases even more. C. Example of reactive hyperemia after 20 seconds of occlusion of the left anterior descending artery of a dog. After relief of the occlusion, a rapid increase in blood flow occurs to 500% of resting blood flow, followed by a decrease when the oxygen debt is solved. D. Reactive hyperemia after intracoronary administration of 10 mg of papaverine in the same dog. E. Phasic and mean coronary blood flow in the left anterior descending artery of a dog after occlusions of 3, 5, 10, 20, and 30 seconds. As the time of occlusion increases, reactive hyperemia is more pronounced up to an occlusion time of approximately 20 seconds. With longer occlusions, the peak hyperemia no longer increases, but it takes longer before flow returns to baseline. (From Pijls NHJ. Coroaine fysiologie en myocardischemie. In Van der Wall EE, Van de Werf F, Zijlstra F. Cardiologie. Houten, the Netherlands: Bohn Stafleu van Loghum, 2008, with permission of Springer.22)

The blood flow pattern in the right coronary artery is more variable and more equally distributed across systole and diastole. In case of a dominant right coronary artery, it can look like a flow pattern in the left coronary artery. Normal blood flow patterns at rest and hyperemia are indicated in Figure 6-2.

If, in an experimental model (eg, a dog or a pig), the coronary artery is occluded during some time, myocardial ischemia will occur, and after release of the occlusion, a temporary increase in flow to the myocardium will occur. This is called reactive hyperemia (see Fig. 6-2). The longer the occlusion, the more pronounced and longer is the reactive hyperemia. Reactive hyperemia is maximal after occlusions of at least 20 seconds. If the occlusion lasts longer, the peak of hyperemia will not further increase but recovery of flow to baseline will take longer. Obviously, after occlusions of 20 seconds or more, the arteriolar sphincters are completely dilated. Maximum coronary hyperemia can not only be obtained by temporary occlusion of the coronary artery, but also pharmacologically by administration of specific drugs such as intracoronary papaverine or adenosine or intravenous adenosine, adenosine triphosphate, or regadenoson.5,6

Coronary Flow Reserve

The level to which coronary or myocardial blood flow can increase is indicated by CFR. The absolute CFR is defined as the ratio between hyperemic and baseline blood flow (see Fig. 6-2; Fig. 6-3).7
FIGURE 6-3 Definition and characteristics of coronary flow reserve (CFR) and fractional flow reserve (FFR). In both panels, the relationship between coronary perfusion pressure and coronary blood flow is indicated. Between an average perfusion pressure of 50 and 130 mm Hg, coronary perfusion remains constant at rest (autoregulation, horizontal lines). At maximum exercise or after administration of a vasodilatory stimulus, the arteriolar sphincters in the coronary artery are fully dilated, and a linear relation exist between perfusion pressure and blood flow (oblique lines). In case of a coronary stenosis, the slope of the oblique line will decrease. CFR is defined as maximum blood flow divided by blood flow at rest. Maximum blood flow is dependent on blood pressure, and blood flow at rest varies with heart rate and contractility. Consequently, CFR can vary over a large range for 1 specific coronary stenosis. FFR is defined as maximum blood flow in the presence of a stenosis divided by maximum blood flow in the hypothetical case where no stenosis would be present at all. This ratio is independent of changes in blood pressure, heart rate, and contractility, and under normal circumstances, FFR always has the same reference value (ie, 1.0). An FFR below 0.75 to 0.80 generally corresponds with inducible myocardial ischemia of the territory supplied by that particular coronary artery. In such cases, the stenosis is considered hemodynamically significant, and revascularization is most likely indicated.

As indicated in Figure 6-3 and as is clear from theoretical considerations, CFR correlates with blood pressure and is higher with higher blood pressure. CFR is also dependent on age and decreases with aging. In healthy young people, normal CFR is 5 to 6, but in healthy octogenarians, CFR is often hardly 1.5.

CFR is a useful theoretical parameter to understand the coronary circulation but less suitable in clinical practice to quantify the hemodynamic
significance of a coronary stenosis because of its dependency on blood pressure, age, and a number of other factors. In the practice of the interventional laboratory, apart from the lack of a normal reference value, probably the most important limitation is that to determine CFR reliably, one has to rely on resting blood flow. In the catheterization laboratory, in a patient laying on the table and undergoing an intervention, it is hard to be sure that true resting blood flow is present. As a result of these limitations of CFR in clinical studies, the threshold of CFR below which coronary ischemia is inducible varies in different studies from 1.6 to 3.3. This means that the same CFR value of, for example, 2.5 can be completely normal in one person but severely decreased in another person. Consequently, it is difficult to use CFR for decision making with respect to revascularization.

To overcome these shortcomings of CFR for clinical decision making, the concept of fractional flow reserve (FFR) has been developed. FFR is defined as maximum achievable blood flow in a stenotic coronary artery compared to maximum blood flow in that same coronary artery in the hypothetical case that the vessel would be normal. As will be explained later, FFR can be determined in the catheterization laboratory by coronary pressure measurement and is useful to characterize the hemodynamic significance of a coronary stenosis and to decide upon sense or nonsense of mechanical revascularization (stenting of bypass surgery). The concept of FFR is illustrated in Figure 6-3 and Figure 6-4 and discussed further later in this chapter.
**FIGURE 6-4** Definition of fractional flow reserve (FFR). On the left side, the epicardial coronary artery and the myocardial vascular bed are depicted. In the upper part, no stenosis is present, and normal perfusion pressure during hyperemia is 100 mm Hg. In the lower part, a stenosis is present, and distal coronary pressure at hyperemia has decreased to 70 mm Hg. Therefore, the perfusion pressure has decreased to 70 mm Hg only, whereas it should normally be 100 mm Hg. Because of the linear relationship between hyperemic perfusion pressure and hyperemic blood flow (*right part of the figure*), this means that the maximum myocardial perfusion in the presence of a stenosis has decreased to only 70% of what would be its normal value. In fact, a ratio of hyperemic blood flows is expressed as a ratio of perfusion pressures, and FFR is the hyperemic distal perfusion pressure (Pd) in the presence of the stenosis divided by the perfusion pressure in the normal case, indicated by Pa. FFR indicates the fraction of normal maximum blood flow that is still achievable in the presence of a stenosis. An FFR of 0.7 means that, as a consequence of the epicardial coronary stenosis, maximum blood flow to the supplied myocardial territory has decreased to 70% of the value it should be in a normal case. Therefore, FFR is a specific measure of the functional severity of a coronary stenosis.

**ENDOTHELIUM AND DEVELOPMENT OF ATHEROSCLEROSIS**

The early phase of atherosclerotic coronary disease is endothelial dysfunction. This is invisible by any imaging method but can be demonstrated by functional testing (*Fig. 6-5*). In reaction to a number of humoral or mechanical stimuli (eg, increased shear stress), endothelial cells produce nitric oxide (NO), leading to relaxation of underlying smooth muscle cells and vasodilation with increase of blood flow in the coronary artery. The earliest stage of (coronary) atherosclerosis is endothelial dysfunction. This can be demonstrated by intracoronary acetylcholine administration. In the presence of healthy endothelium, acetylcholine also increases NO production and, thereby, coronary blood flow. Acetylcholine also has a direct vasoconstrictive effect on the underlying smooth muscle cells, but in healthy persons, this effect is weaker than the vasodilatory NO-stimulating effect. If the endothelium is diseased, the direct vasoconstrictive effect predominates, and so-called *paradoxical vasoconstriction* occurs. This phenomenon can be used in the interventional laboratory to demonstrate endothelial dysfunction. Such a test is performed by administrating subselectively intracoronary acetylcholine under controlled conditions but is not trivial and not without
risk, and therefore, it should only be applied in specialized catheterization laboratories.

**FIGURE 6-5 Abnormal endothelial function.** The earliest stage of atherosclerosis is endothelial dysfunction, often present long before abnormalities on the angiogram can be seen. In the left panel, an apparently normal coronary angiogram is seen in a young male with many risk factors and a positive exercise test. To detect abnormal endothelial function, acetylcholine is injected into the coronary artery, resulting in severe and varying vasoconstriction in the different branches of the circumflex system. In the presence of normal endothelium, no such narrowing should be seen. In the right panel, nitroglycerin has been administered to relieve the acetylcholine effects.

The next step in the evolution of atherosclerosis is development of early plaques and often diffuse disease that is not visible on the angiogram but can be demonstrated by anatomic methods, such as intravascular ultrasound or optical coherence tomography, and by physiologic methods, such as FFR measurement. In the latter case, during hyperemia, an abnormal pressure decline will occur even in an apparently normal coronary artery.

Finally, when macroscopic, gross atherosclerosis occurs, it can be detected easily on the coronary angiogram, but physiologic measurements remain generally necessary to define the extent and physiologic significance of disease.

For the interventional cardiologist, this is important because in case of diffuse decline of coronary pressure along a coronary artery and a focal decline at 1 particular spot or a severe stenosis, stenting of the severe stenosis will not result in a restoration to normal because the diffuse gradient will persist within the artery and even increase after stenting the focal stenosis. It
is important to quantify this because, in some cases, this diffuse disease as detected by the pressure pullback recording can be responsible for residual inducible ischemia, even after successful stenting of focal spots. Similarly, by such hyperemic pressure pullback recording, patients with diffuse disease can be distinguished who cannot be treated with mechanical techniques of revascularization even though ischemia may be present. This issue will be further discussed in Chapter 24.

CORONARY STENOSIS AND MYOCARDIAL ISCHEMIA

Atherosclerosis of the coronary arteries is common in the Western world and increases with age. Approximately half of asymptomatic and apparently healthy persons between ages 50 and 65 years have visible atherosclerotic abnormalities in the coronary arteries. It is important to note that, in many of these patients, such narrowing will never cause significant problems. Therefore, the anatomic presence of a coronary stenosis does not indicate per se that revascularization is indicated. However, in case of visible atherosclerosis, preventive lifestyle management and medical treatment using aspirin, statins, angiotensin-converting enzyme inhibitors, or β-blockers might be indicated and useful.

In case of a developing stenosis in the coronary artery, an additional resistance in the coronary circulation occurs. At rest, this can be easily compensated by compensatory dilatation of the arteriolar sphincters, as can be easily understood from Figure 6-1. If at baseline, sphincter resistance is called R, minimal resistance (in this example) will be 1/5 R. A moderate stenosis in the supplying coronary artery with a resistance equaling 2/5 R can be easily compensated by a decrease of arteriolar resistance to 3/5 R.

In other words, there are now 2 resistances in series, but at rest, the total resistance remains constant assuming unchanged perfusion pressure. Therefore, coronary flow at rest will also remain constant. However, this is at the cost of CFR, which is decreased because at maximum exercise the remaining vasodilatory capacity of the sphincters has been decreased.

If the coronary narrowing becomes more severe, the situation can occur that the full vasodilatory capacity of the distal sphincters is mandatory to
compensate the increased resistance in the coronary artery and no further reserve is left. As will be clear, this is the situation with stable angina pectoris, which increases over time. With further increase of stenosis severity, even ischemia at rest may occur. Acute coronary syndromes often occur from a sudden increase of resistance in the coronary artery by plaque complication, rupture, or thrombosis. Although it is often believed that plaque rupture occurs in previously minor plaques, recent studies have indicated that the hemodynamic significance of such underlying plaques is often significant and the resultant repetitive ischemia is a potent stimulus to make a plaque vulnerable. In any case, there is a strong relationship between repetitive ischemia and vulnerability.

Whatever the relationship between vulnerability and ischemia may be, it is clear that inducible ischemia of the myocardium is the most important prognostic factor for patients with coronary artery disease. If a coronary stenosis causes no inducible ischemia, its prognosis is generally favorable, and medical treatment is the best way to continue. If a coronary stenosis is hemodynamically significant, outcome in terms of prognosis is much worse and a coronary intervention (either stenting or bypass surgery) is generally indicated. In addition, hemodynamically significant stenoses often cause complaints (angina pectoris), and mechanical intervention is the most efficient way to treat such complaints.

Consequently, one of the most important issues in interventional cardiology is to make correct decisions about which coronary stenoses should and should not be revascularized. Beyond doubt, the functional significance of a stenosis is much more important in this respect than its appearance on the angiogram. The gold standard used in the catheterization laboratory to assess the hemodynamic significance of a coronary stenosis is FFR. The physiologic background of FFR and some specific features of it will be discussed in the next section, whereas a more extensive discussion about its practicalities and clinical application will be outlined in Chapter 24.

**FRACTIONAL FLOW RESERVE**

The concept of FFR is based on 2 important principles. First, it is not resting blood flow but maximal achievable blood flow that determines the functional capacity of a patient and is decisive regarding whether myocardium will
become ischemic. Second, at maximum vasodilatation (corresponding with maximum hyperemia or maximum exercise), blood flow to the myocardium is proportional to myocardial perfusion pressure, as outlined earlier.

With those principles in mind, FFR is easy to understand from Figure 6-4. In the left upper part of the figure, a normal coronary artery and its myocardial perfusion territory are represented. If maximum vasodilation in the coronary circulation is present (all vessels and sphincters dilated), blood flow will be proportional to aortic pressure (Pa) minus central venous pressure (Pv), which is put at 0 for case of simplicity. In the left lower part of the figure, a coronary stenosis is present, resulting in a particular pressure drop at hyperemia within the coronary artery. To understand the functional significance of that stenosis for the patient, it is not the gradient across that stenosis that is important, but the degree to which the distal perfusion pressure has decreased. In our example, perfusion pressure has decreased to 70 mm Hg, whereas it should be 100 mm Hg in a normal case. Because of the proportionality between perfusion pressure and coronary blood flow at maximum hyperemia (assuming that minimal resistance is constant), maximum achievable blood flow in the diseased situation has decreased to 70% of its normal value (right part of the figure). In other words, a ratio of maximum blood flows is expressed as a ratio of perfusion pressures. In contrast to flow (which is difficult to measure directly in human coronary arteries), pressure can be measured easily by a 0.014-inch pressure wire. For that reason, FFR can be easily assessed in the practice of the catheterization laboratory by a pressure wire that measures distal coronary pressure (Pd) after administration of a maximum hyperemic stimulus and by comparing this distal coronary pressure at hyperemia to aortic pressure. Or simply stated:

$$\text{FFR} = \frac{(P_d - P_v)}{(P_a - P_v)} \approx \frac{P_d}{P_a}$$

In clinical practice, measurement of FFR is easy, as illustrated in Figure 6-6. In fact, the concept of FFR encompasses much more than only the effect of a coronary stenosis on myocardial blood flow. It is also possible to express maximum coronary artery blood flow, myocardial blood flow, and collateral blood flow quantitatively as a percentage of normal maximum myocardial blood flow. To measure the separate contributions of coronary artery and collateral blood flow to myocardial flow, however, knowledge of coronary
wedge pressure is mandatory (as can be measured during balloon occlusion). In fact, FFR gives a complete description of the coronary circulation and all components of it in terms of pressure measurement. In-depth discussion about the concept of FFR is beyond the scope of this chapter, and for that purpose, we refer the reader to the initial publication defining FFR in *Circulation* in 1993\textsuperscript{8} and a myriad of review publications.\textsuperscript{14-16}

**FIGURE 6-6**

A. Measurement of fractional flow reserve (FFR) in clinical practice in a patient with angina pectoris, a positive exercise test, and a suspected lesion in the proximal left anterior descending artery (arrow). B. A pressure wire is introduced into the coronary artery. Aortic pressure measured by the guiding catheter is indicated by the red signal, and the coronary pressure measured by the pressure sensor is indicated by the green signal. When the sensor is proximal to the suspected lesion, pressures are equal. When the pressure sensor crosses the lesion, a sudden drop in distal pressure occurs, and when inducing maximum hyperemia by IV administration of adenosine 140 μg/kg/min, distal pressure further decreases, reflecting increase of blood flow. C. At steady-state maximum hyperemia, distal coronary pressure is 52 mm Hg compared to 91 mm Hg in the aorta. FFR is easily calculated as 52/91 = 0.57. In other words, as a consequence of the visible plaque in the proximal LAD on the angiogram, maximal achievable blood flow to the anterior wall of the heart in this patient has decreased to only 57% of its normal value.

**PHYSIOLOGIC FEATURES OF FRACTIONAL FLOW RESERVE**

FFR has a number of specific advantages over other physiologic indexes that make it an easy index to assess coronary artery disease and to make decisions about the necessity of interventions. These physiologic features will be
discussed in the following section. For more practical discussion, see Chapter 24.

**Uniform Normal Value and Discrimination of Inducible Ischemia**

As discussed earlier, in a completely normal coronary artery, there is no decline of pressure, not even during maximum hyperemia. Consequently, the normal reference value of FFR is 1.0 irrespective of the patient, hemodynamic conditions, age, or any other variable. Having an uniform normal value is important, because without that, it will be impossible to define a reliable threshold value for ischemia. The threshold value of ischemia for FFR is generally taken as 0.80. In fact, it is somewhere between 0.75 and 0.80 with a small gray zone in between, as will be discussed later. In clinical practice, it is generally felt justified to revascularize a stenotic coronary artery if FFR is $\leq 0.80$ and to give medical treatment if FFR is $>0.80$.

**Relationship Between Vessel Size and Perfusion Territory**

In contrast to any anatomic method, FFR accounts for the relationship between the severity of the epicardial coronary stenosis and the size of the perfusion territory. This is especially important in assessing stenoses severity after previous myocardial infarction. Two coronary arteries might have an exactly identical stenosis with exactly identical morphologic features, but the functional severity will vary if the perfusion territory has a different extent. Such difference cannot be detected when only looking at the morphologic features of the stenotic artery. In the case of 2 identical stenoses but a larger (viable) perfusion territory distal to 1 of these lesions, the hyperemic response will be larger and the FFR consequently lower (Fig. 6-7). This explains why, after previous myocardial infarction, an apparently severe stenosis might have a rather high FFR, whereas a similar stenosis without infarction has a much lower FFR. It also explains why a moderate lesion with a large perfusion territory, including collaterally dependent myocardium, might be significant, whereas it would not be significant without the collateral perfused territory.
**FFR accounts for the extent of the perfusion area:**

![Diagram of FFR](image)

**FIGURE 6-7** Fractional flow reserve (FFR) is not only a measure of the functional severity of the coronary artery stenosis itself, but also relates stenosis severity to the extent of the perfusion territory, as indicated in this figure. In both the upper and lower parts of this figure, a similar stenosis is present, and with anatomic methods, no difference can be observed. However, because in the upper part of the figure the perfusion territory is larger, a higher hyperemic response can be provoked and FFR will be lower than in the case of a decreased perfusion territory. In fact, FFR connects coronary stenosis severity, coronary blood flow, inducible ischemia, and extent of perfusion territory with each other. See text for further explanation.

**Independency From Blood Pressure, Heart Rate, and Contractility**

In contrast to CFR, FFR is not dependent on changes in hemodynamics such as heart rate, blood pressure, and contractility. This is due to the fact that FFR is not dependent on resting blood flow, as can be understood from Figure 6-3. True resting conditions in the catheterization laboratory are difficult to obtain, and normally, during cardiac catheterization and intervention, large variations in so-called resting blood flow occur. This explains in part the large fluctuation in CFR (and other indexes relying on resting blood flow) and the wide range of CFR values in different patients with the same FFR. As illustrated in Figure 6-3, such limitation is not present for FFR. Also, in humans, studies have been performed with large variations in heart rate, blood pressure, and contractility with no effect on FFR. In the literature, it is often suggested that different values of CFR in
different patients with the same FFR is a measure of microvascular dysfunction. However, it is likely that such a range of CFRs is due to absence of one uniform normal value (eg, age, different hemodynamic circumstances) and has little to do with abnormal microvascular status.

**Collaterals**

As mentioned earlier, FFR accounts for the effects of the collateral circulation. In fact, the separate contribution of collateral and coronary artery blood flow to myocardial perfusion can be calculated by the pressure measurements, provided that wedge pressure is known.\(^8\)

In case of extensive collaterals, a stenosis might have a high FFR value, whereas in the absence of collaterals, the FFR might be low. Conversely, as mentioned earlier, a similar stenosis may have a lower FFR value if the respective artery gives collaterals to another territory.

**Issue of Maximum Hyperemia**

As discussed earlier, one of the fundamental requirements to calculate FFR is the presence of maximum coronary and myocardial hyperemia. In the catheterization laboratory, this can be achieved pharmacologically in a number of ways, as summarized in Table 6-1. When using maximum hyperemia, FFR is an extremely reliable index of ischemia and has been validated versus a true gold standard using a so-called prospective multitesting Bayesian approach.\(^{19}\)

<table>
<thead>
<tr>
<th>Table 6-1</th>
<th>Effects of Different Vasodilatory Stimuli on the Epicardial Coronary Artery and the Microvascular Bed</th>
</tr>
</thead>
</table>

---
Although a number of ways for inducing hyperemia are available in the catheterization laboratory and not difficult with a good logistic setup, because of simplicity, it has been proposed recently to leave hyperemia out and to perform resting measurements only. Several resting indexes have been proposed, such as the Pd/Pa at rest and the so-called iFR (instantaneous wave-free ratio).\(^{20}\) Unfortunately, the physiologic basis for using resting indexes is poor and not supported by experimental studies in animals. Generally, according to Poiseuille’s law and as validated in animals and humans, a small baseline pressure gradient across the stenosis can be accompanied by a large hyperemic gradient, especially in young patients, patients with a short severe stenosis, and patients with proximal lesions or a large perfusion territory, whereas a moderate gradient with only moderate hyperemic increase can be observed in older patients, patients with distal lesions, and patients with small coronary arteries (Figs. 6-8 and 6-9).
\[ \Delta P = f \cdot Q + s \cdot Q^2 \]

FIGURE 6-8 Explanation of why resting pressure indexes are not sufficient to predict true stenosis severity. According to Poiseuille’s law, the pressure gradient across a stenosis is related to blood flow by a linear and quadratic component, representing friction \((f)\) and separation \((s)\) coefficients, respectively. In some lesions, friction is the predominant factor, which means that a moderate resting gradient will moderately increase at hyperemia. At the other end of the spectrum, where separation is predominant, a minimal resting gradient can be accompanied by a very large hyperemic gradient. The latter is especially the case in younger patients with short lesions in the proximal part of a large coronary artery with a large perfusion territory. See also Figure 6-9. LAD, left anterior descending artery.
Therefore, in clinical practice, it is generally unpredictable to what extent a baseline gradient will increase with hyperemia. Nevertheless, if a resting gradient is large and already below the ischemic threshold of FFR, just for the mere purpose of making the decision about whether or not to revascularize, no additional hyperemia will be necessary, whereas in the case of very small resting gradients, often (but not always) no inducible ischemia will be present. In addition, as mentioned earlier, it is often not possible to achieve true resting conditions in a human catheterization laboratory. When using resting indexes in the best possible way, agreement with FFR with respect to presence of ischemia is achieved in approximately 80% of cases. FFR in itself has an accuracy of approximately 95% compared to the true gold standard.\textsuperscript{19,21}

There is another reason why true hyperemia is desirable. In the current population of patients in the catheterization laboratory, who often have complex coronary artery disease, predicting whether a stenosis is causing ischemia is only 1 piece of information. The other piece is making a hyperemic pullback recording to assess abnormalities along the complete course of the coronary artery to understand the nature of the disease and to predict whether stenting will be effective. For such pullback recording, resting conditions lack sufficient spatial resolution (poor signal-to-noise ratio), and maximum hyperemia is mandatory.
A compromise between resting indexes and hyperemia might be achieved by contrast FFR (cFFR; defined as Pd/Pa after a single regular bolus of 10 mL of contrast agent). An injection of contrast agent into a coronary artery generally increases blood flow very shortly up to a level of at least 80% of maximum hyperemia. Therefore, it has been suggested to use a contrast injection to discriminate whether FFR is abnormal. Although suboptimal, cFFR is more reliable than using resting indexes only, and it is easy to obtain. In addition, lesions with a small resting gradient but large hyperemic gradient, which would be completely overlooked by resting indexes, will be easily discovered by contrast. Agreement between cFFR and true FFR is achieved in approximately 85% of patients (Fig. 6-10). Further investigation of these resting indexes and cFFR is mandatory.

**FIGURE 6-10** The pyramid of diagnostic accuracy of functional indexes to correctly predict ischemia: Accuracy of the standard angiogram, resting pressure indexes, contrast FFR and true FFR to predict coronary ischemia and to facilitate decision making with respect to revascularization. For further explanation, see text. iFR, instantaneous wave-free ratio.

**SOME SPECIFIC MANIFESTATIONS OF CORONARY ARTERY DISEASE**
**Diffuse Coronary and Microvascular Disease**

When discussing CFR and FFR, for simplicity, it is often assumed that there is 1 (or several) focal narrowing in a coronary artery. However, atherosclerosis is a diffuse disease process, and often, abnormalities will be present along the complete course of the coronary artery, as can be noticed by intravascular ultrasound or optical coherence tomography. This diffuse disease can be so severe that focal stenting or bypass surgery does not make sense. Similarly, a lot of attention is paid to microvascular disease affecting the invisible part of the coronary angiogram. It might be clear that microvascular disease will affect both CFR and FFR. Several indexes have been developed to quantify microvascular disease (eg, index of microvascular resistance and absolute coronary blood flow). The practical consequences are 2-fold; first is the understanding that sometimes angina pectoris can occur without focal epicardial disease, and second is the necessity of aggressive medical treatment in such patients. However, the importance and prevalence of microvascular disease should not be overestimated; in the majority of patients with angina pectoris, inducible ischemia, and a focal lesion, stenting or bypass surgery results in disappearance of complaints and disappearance of inducible ischemia, indicating that the epicardial disease was the predominant factor.

**Myocardial Bridging**

When performing a coronary angiogram, sometimes bridging of the left arterial descending artery is observed during systole, due to a partly intramyocardial course of the artery or to a muscle bridge across the blood vessel. Bridging increases during adrenergic stimulation and may lead to complete occlusion during systole. However, its clinical meaning is mostly minimal. It is often unclear how this bridging should be interpreted and if it can be held responsible for complaints. In the literature and in clinical practice, many confounding points of view exist.

In our view, complaints due to bridging can only be present during adrenergic stimulation. This means that complaints at rest should never be ascribed to myocardial bridging, simply because coronary blood flow at rest is predominantly diastolic. As discussed earlier in this chapter, at maximum hyperemia, the systolic component in left coronary artery blood flow equals
15% to 25% of total flow (see Fig. 6-2). If that systolic component is 20% to 25%, one can imagine that by losing 20% to 25% of flow during occlusion of the bridge at maximum exercise, a theoretical FFR value of less than 0.75 to 0.80 occurs and could be responsible for ischemia. FFR in itself is not a good method to assess bridging because, at occlusion, there is no blood flow and consequently no gradient. Therefore, in those rare cases in which bridging is suspected to be responsible for myocardial ischemia, we use a Doppler wire to measure the coronary flow pattern in the left anterior descending artery. First, we induce maximum hyperemia using adenosine and calculate the systolic component of maximum coronary blood flow. Next, we perform flow velocity registrations at dobutamine-induced hyperemia. Only if the systolic component is more that 20% of the total velocity integral with adenosine and the systolic component disappears completely during dobutamine do we believe that it is justified to hold the bridging responsible for complaints. The approach to evaluate patients with myocardial bridging, as used in the Catharina Hospital (Eindhoven, The Netherlands), is outlined in Table 6-2.

Table 6-2 Diagnostic Approach to Patients with Chest Pain and Myocardial Bridging of the Left Anterior Descending Artery in the Catharina Hospital
CONCLUSIONS AND FINAL REMARKS

The coronary circulation is designed in such a way that there is always a match between oxygen demand and supply under a wide variety of physiologic conditions. This match is maintained by an ingenious regulation system called autoregulation.

Atherosclerosis of the coronary arteries is an insidious disease interfering
with the structure and function of the coronary circulation. Disease is mostly present long before coronary artery abnormalities can be seen. In case of a visible stenosis in a coronary artery, there is only a poor relation between anatomic severity and the functional severity, and sophisticated physiologic examination may be necessary to establish whether ischemia is present and revascularization is warranted.

The gold standard for functional assessment in coronary artery disease is FFR, which is calculated during maximum coronary hyperemia by measuring distal coronary pressure using a pressure wire and comparing it to proximal pressure measured using the guiding catheter. FFR allows functional assessment in a practical and easy way and can be measured during invasive coronary angiography. The clinical use of FFR will be discussed further in Chapter 24.

REFERENCES

**MULTIPLE CHOICE QUESTIONS**

1. Which intracoronary parameter has been shown to be the least influenced by hemodynamic changes?
   A. Coronary flow reserve (CFR)
   B. Fractional flow reserve (FFR)
   C. Instantaneous wave-free ratio (iFR)
   D. Resting distal coronary pressure/aortic pressure (Pd/Pa)

2. In the normal heart at rest, an increase in coronary perfusion pressure of 20% will result in which of the following?
   A. An increase in myocardial blood flow by about 20%
   B. An increase in myocardial blood flow by about 40%
   C. A decrease in myocardial blood flow by about 20%
D. No change in myocardial blood flow

3. In the normal heart during maximal hyperemia, an increase in coronary perfusion pressure of 20% will result in which of the following?
   A. An increase in myocardial blood flow by about 20%
   B. An increase in myocardial blood flow by about 40%
   C. A decrease in myocardial blood flow by about 20%
   D. No change in myocardial blood flow

4. What is the accuracy of the coronary angiogram to predict whether a coronary stenosis is able to induce myocardial ischemia?
   a. 70%
   b. 80%
   c. 90%
   d. 95%

5. What is the definition of fractional flow reserve (FFR)?
   A. Pressure gradient over a stenosis during maximal hyperemia
   B. Maximum blood flow over a stenosis divided by the resting blood flow over that stenosis
   C. Maximum blood flow in the presence of a stenosis divided by the maximum blood flow in the hypothetical absence of that stenosis
   D. Minimal luminal area divided by normal luminal area in case of a stenosis

**ANSWERS**

1. B

Both animal and human studies have shown that FFR is the only parameter that is highly independent of hemodynamic variations such as heart rate, blood pressure, and contractility. The reason that FFR is fundamentally different than CFR, iFR, and resting Pd/Pa is that it is the only parameter that is not dependent on resting flow.

2. D
Coronary autoregulation keeps coronary flow constant despite changes in coronary perfusion pressure, between a mean aortic pressure of 50 and 130 mm Hg.

3. A
During maximal hyperemia (eg, induced by adenosine, severe ischemia, or a perfusion pressure out of the autoregulatory range), autoregulation is exhausted, and therefore, perfusion pressure is proportionally related to coronary flow.

4. A
The accuracy of the angiogram to predict functionally significant stenoses is rather poor—only 70%. Anatomy alone will never be sufficient to predict physiology because it does not incorporate several important determinants of maximal blood flow, including myocardial mass and microvascular function. FFR is the current gold standard in identifying hemodynamically significant stenoses and has an accuracy of about 95%.

5. C
During maximal hyperemia, autoregulation is exhausted and coronary perfusion pressure is proportional to coronary flow. In the normal vessel, the coronary pressure is the same throughout the vessel. Therefore, in a stenotic vessel, the proximal pressure is a reflection of what the distal pressure would have been in the absence of that stenosis. Consequently, by dividing distal pressure by the proximal pressure, one can determine the maximum blood flow in the presence of a stenosis divided by the maximum blood flow in the hypothetical absence of that stenosis.
INTRODUCTION

Renal artery stenosis (RAS) is the main cause of “secondary” arterial hypertension. RAS is found in 0.5% to 5% of hypertensive patients. RAS is most often atherosclerotic in nature and less frequent due to fibromuscular hyperplasia.\(^1\) The prevalence of RAS is approximately 2% in unselected patients but reaches 40% in older patients or in patients with multiple risk factors for atherosclerosis or with documented atherosclerosis in other vascular territories.\(^2,3\) Due to improvements in vascular imaging by ultrasound, magnetic resonance imaging, computed tomography, and angiography and due to the larger proportion of elderly patients undergoing coronary angiography, the finding of a RAS on angiography is a frequent occurrence. “Drive-by” renal angiograms are frequently performed during coronary angiography procedures. However, as is the case in the coronary arteries, the relationship between anatomic findings and the functional repercussion of a given stenosis is poor.\(^4\)

Thus, stenoses of the main trunk of the renal arteries are frequent and easy to identify, but their causative role in clinical manifestations is difficult to evaluate, and it is difficult to predict the effect of renal stenting.
PATHOPHYSIOLOGY OF RENAL ARTERY STENOSIS

Renal artery stenoses contribute to arterial hypertension and/or to ischemic nephropathy.

Arterial Hypertension

Much modern thinking about the physiopathology of renovascular hypertension is influenced by the classical 1-kidney-1-clip animal model (analogous to a bilateral RAS) and the 2-kidneys-1-clip model (analogous to the unilateral RAS). A simplified scheme illustrating the pathophysiology of renovascular hypertension is shown in Figure 7-1. When the perfusion pressure decreases in the renal artery, especially in the afferent renal artery, an upregulation of renin production takes place in the juxtaglomerular apparatus. The decrease in glomerular filtration pressure will be partially counteracted by a constriction of the efferent artery. The activation of the renin-angiotensin system resulting in angiotensin II–mediated vasoconstriction is a central component to this process. In contrast, the nonstenotic kidney, subjected to higher perfusion pressure, responds by an increase in the excretion of sodium (“pressure natriuresis”) that will tend to lower the pressure. This decrease in systemic pressure will in turn decrease the perfusion pressure in the stenotic kidney and further stimulate the release of renin. Elevated levels of angiotensin II induce vasoconstriction and trigger the secretion of aldosterone. The latter enhances sodium reabsorption in proximal and distal tubules. Thus, renovascular hypertension is mediated initially by elevated plasma renin, although in case of sustained hypertension, plasma renin activity will tend to decrease. Renovascular hypertension fundamentally depends on the presence and magnitude of a pressure drop due to the stenosis.
Ischemic Nephropathy

The most common cause of renal insufficiency in patients with RAS is the association of the RAS to parenchymal disease. In contrast, the occurrence of renal failure solely due to a stenosis in the trunk of the renal artery is exceptional in unilateral RAS and rare in bilateral RAS in the absence of parenchymal disease or nephrotoxic medications. In rare cases, when bilateral stenoses are critical, the perfusion pressure may become so low that the renal tissue becomes ischemic, which in turn might lead to necrosis and fibrosis. In addition, in patients with bilateral RAS or RAS in a solitary kidney, the maintenance of a sufficient glomerular filtration pressure by vasoconstriction of the efferent artery is highly dependent on angiotensin II. When angiotensin-converting enzyme inhibitors are given, the efferent arteriolar
tone is no longer maintained, and glomerular filtration rate decreases, as in patients with cardiac failure who are sodium depleted.

SIMILARITIES AND DIFFERENCES BETWEEN MYOCARDIAL AND RENAL FLOW AND PRESSURE

Like most organs, the myocardium and the renal parenchyma are perfused by large arteries opposing no or very little resistance to flow. These arteries are often the seat of atherosclerotic narrowing. Smaller arteries and arterioles penetrate the tissue, are the site of the largest resistance, and give rise to feeding vessels, the capillaries. Due to their fundamentally different functions (pump function for the myocardium and filter function for the kidney), the consequences of a narrowing on the main arteries are almost opposite of the consequences on pressure and blood flow.

The main “goal” of the myocardium is to maintain constant blood flow to allow enough oxygen and nutrients to be supplied to the contracting myofilaments. Cardiac oxygen requirements are met thanks to a high level of oxygen extraction by the myocardium. This explains the low oxygen saturation in the coronary sinus (20%). The main mechanism to increase oxygen supply is to increase absolute myocardial flow. Therefore, a gradually increasing stenosis in the epicardial arteries induces a decrease in coronary driving pressure and will be compensated by a vasodilation of the microvasculature. This mechanism, often referred to as autoregulation, maintains a constant total resistance to flow, thus allowing a normal myocardial flow ("perfusion"). This vasodilation is mainly mediated by adenosine A2\textsubscript{1} receptors. The regulation is mainly based on a local mechanism.

In contrast, renal arteries deliver more oxygenated blood to the kidney than needed for metabolic demands. Renal metabolic requirements are met with 10% of normal blood flow. This translates into a high renal venous oxygen saturation (80%). The main “goal” of the kidney is to maintain glomerular filtration constant. A decrease in the pressure in the main trunk of the renal artery, and thus in the afferent renal artery, will be compensated by
an increase in the tone of the efferent renal artery, thus maintaining glomerular filtration pressure constant. This vasoconstriction is the result of an immediate local myogenic reflex and a delayed systemic activation of the renin-angiotensin system. The vasoconstriction is largely based on the activation of adenosine A₁ receptors. The administration of adenosine in the coronary artery leads to vasodilation, whereas adenosine induces a potent vasoconstriction in the renal circulation (Fig. 7-2).

![FIGURE 7-2](image)

In this teleologic view of physiology, one might consider that the myocardium tends to preserve flow at the cost of pressure, whereas the kidney tends to maintain pressure at the cost of flow.

**INVASIVE ASSESSMENT OF RENAL ARTERY STENOSIS**

Invasive assessment of RAS mainly encompasses angiography, Doppler flow velocity, and pressure measurements.

**Renal Angiography**

Recognition of the frequent association of atherosclerosis in the coronary and renal arteries has led to an increase in “drive-by” renal angiograms performed
by cardiologists “on their way to work.” The additional contrast burden can be limited to 10 to 20 mL, the image quality is pristine, and the specificity is higher than that with duplex echocardiography or magnetic resonance angiography. As a result, the number of RASs detected in patients with arterial hypertension has increased, leaving unanswered the conundrum of the causality of these findings. Drive-by angiograms have brought more questions than answers. It is now well recognized that the relation between percent diameter stenosis and functional assessment of these lesions is poor, even for stenoses of more than 50% of diameter reduction (Fig. 7-3). Thus, invasive angiography is the most precise tool for the identification of RAS but does not give any clue about the potential renal angioplasty to reverse the hypertension or the loss of kidney function. Intravascular ultrasound–derived assessment of the luminal dimension does not seem to add to the utility of a morphologic approach (Fig. 7-4).

**FIGURE 7-3** Plot of individual values of distal coronary pressure to aortic pressure (Pd/Pa) ratio versus percent diameter stenosis. The vertical line indicates the cut-off value for hemodynamic significance based on invasive pressure gradient measurement. The horizontal line corresponds with the cut-off value based on renal angiography (50% diameter stenosis).
Doppler Flow Velocity Measurements

By noninvasive Doppler ultrasonography, it is possible to derive the renal resistance index, which is defined as follows: 

\[1 - \frac{\text{end-diastolic velocity}}{\text{peak systolic velocity}}\] \times 100.

Structural alterations in smaller renal arteries or arterioles distal to the stenosis induced by longstanding hypertension may be one possible reason for the poor response to renal angioplasty. Such hypertension may cause nephrosclerosis and glomerulosclerosis and lead to increased vascular resistance in both the stenotic and nonstenotic kidney. It was shown that when the value of the renal resistance index exceeds 80, renal angioplasty is unlikely to improve renal function or arterial hypertension. Similarly, the reactivity of the distal renal arterial bed was tested with invasive intra-arterial Doppler wires in patients with essential hypertension but no RAS. These authors showed that nitrates induced a significant dilatation of the main renal artery and an increase in blood flow velocities, resulting in a 44% increase in absolute renal blood flow. Papaverine was shown to have no effects on the main renal artery but increased renal blood flow by 60% by vasodilation of the parenchymal arteries. More importantly, there were marked interpatient differences in the response to papaverine, suggesting that in some patients with essential hypertension a functional abnormality exists in the renal microcirculation. To
the best of our knowledge, the usefulness of invasive renal flow velocity measurements has not been studied in the setting of RAS.

**Transstenotic Pressure Measurements**

The fundamental mechanism responsible for renovascular hypertension is the presence of a decrease in renal perfusion pressure related to the presence of a stenosis in the main renal artery. If there is no or hardly any gradient across an angiographically visible stenosis in the main renal artery, then angioplasty of this stenosis does not make any pathophysiologic sense.

**How to Measure the Gradient**

The pressure gradient measured by a catheter is overestimated because the presence of the catheter partially obstructs flow. The degree of overestimation is difficult to evaluate. Figure 7-5 shows an example of the overestimation provoked by the presence of a 6-Fr guide catheter through a renal stenosis. Therefore, the gradient should be measured with pressure-measuring guide wires advanced through guide catheters. The additional advantage of using pressure wires is that the aortic pressure and the distal renal pressure can be recorded simultaneously.

**FIGURE 7-5** Example of the overestimation provoked by the presence of a 6-Fr guide catheter through a renal stenosis. When the guide catheter is pulled back while leaving the pressure sensor distal to the stenosis, the true severity of renal artery stenosis becomes apparent.
Systolic Gradient, Mean Gradient, or Pd/Pa?

In contrast to the left coronary flow where the flow is mainly diastolic, the flow in the main renal artery is mainly systolic. The maximum gradient therefore occurs in mid-systole, whereas the diastolic gradient is often very modest. The mean gradient better reflects renal physiology, as it will be determined by, and thus better account for, the renal microvascular resistance (Fig. 7-6). Yet, it is important to remember that any pressure gradient depends on the level of aortic pressure. Therefore, it is more appropriate to use the ratio of distal coronary pressure to aortic pressure (Pd/Pa), which corrects the pressure distal to the RAS for the prevailing aortic pressure.

**FIGURE 7-6** Pressure difference between renal artery and coronary stenosis (distal coronary pressure [Pd], green) with equivalent Pd/Pa ratio (aortic pressure [Pa], red; expressed in mm Hg). A. Renal artery stenosis with a predominant pressure gradient during systole. B. Coronary stenosis with a predominant pressure gradient during diastole.

Resting or Hyperemic Measurements?

In the coronary arteries, the resistance reserve is large (4-6) because the myocardium aims at preserving flow rather than perfusion pressure. In contrast, in the kidney, no significant increase in flow should not be expected because the kidney aims at preserving (glomerular filtration) pressure, at the cost of flow. In a systematic study of renal vasodilatory reserve, Manoharan et al\(^ {17} \) found a maximal increase in renal blood flow by a factor 1.8. The maximal hyperemic effect was observed after intrarenal bolus administration of dopamine (50 μg/kg). This effect was significantly larger than after
papaverine. Fenoldopam, a more specific agonist of the dopamine A₁ receptors, did not produce a more potent hyperemic response. Therefore, we suggest that dopamine is the ideal renal vasodilator because it is cheaper and more widely available than fenoldopam. An example of this renal hyperemic effect is shown in Figure 7-7. It is important to realize that, even during renal hyperemia, the Pd/Pa ratio should not be called renal fractional flow reserve (FFR).[^18] FFR has been defined for the myocardium and is only valid when there is a strict proportionality between flow and driving pressure. The relationship between renal flow and pressure has not been investigated, and a strict proportionality is unlikely to occur.

**FIGURE 7-7** Example of simultaneous pressure and velocity pressure tracings before, during, and after intrarenal administration of a bolus of 50 μg/kg of dopamine (DOPA). Immediately after administration of the bolus, a marked decrease in renal artery average peak velocity is observed, followed by an almost 2-fold increase in flow velocities without changes in blood pressure or heart rate.

**What Is a Significant Pd/Pa Value?**

Because the stimulation of the renin-angiotensin system is central to the physiology of renovascular hypertension, it is reasonable to consider a stenosis as significant when severe enough to trigger the production of renin. Therefore, in patients after uncomplicated renal stenting, we induced a
unilateral, controlled, graded RAS and correlated the magnitude of the pressure gradients and of the Pd/Pa ratios to the production of renin by both kidneys. The stenosis was induced by inflation of a balloon of increasing diameters over 10 minutes. At the end of each degree of stenosis, plasma renin concentration was measured. An example of a pressure tracing is shown in Figure 7-8. For a Pd/Pa ratio >0.90, no change in renin was observed. When Pd/Pa became <0.90, a significant increase in renin concentration was observed in the vein of the stenotic kidney, finally reaching a 3- to 4-fold increase above the baseline values. In addition, a small but consistent increase in renin concentration was observed in the renal vein of the nonstenotic kidney (Fig. 7-9).

![FIGURE 7-8](image)

**FIGURE 7-8** Example of mean pressure tracings obtained simultaneously in the aorta and distal to the artificial renal stenosis induced by incremental balloon inflations. Each degree of stenosis severity was maintained for 10 minutes. The arrows indicate the timing of sampling in the aorta and in both renal veins.
FIGURE 7-9 Effects of a balloon-induced, unilateral, controlled, graded stenosis (expressed as ratio of distal coronary pressure to aortic pressure \([Pd/Pa]\)) on plasma renin concentration in the aorta (squares), in the vein of the stenotic kidney (closed circles), and in the vein of the nonstenotic kidney (open circles). BL 1, baseline before stenting; BL 2, baseline after stenting.

**Hemodynamic Predictors of Improvement After Angioplasty in RAS**

To evaluate the usefulness of renal pressure measurements to identify patients who might benefit from angioplasty in RAS, we studied 53 patients scheduled for renal angioplasty as a result of resistant arterial hypertension and the presence of a unilateral RAS. In all patients, resting and hyperemic pressure measurements were obtained, and ambulatory blood pressure
monitoring was performed before and 3 months after the intervention. The patients were considered as “responders” when a decline in systolic blood pressure ≥20 mm Hg was observed. It was shown that a hyperemic mean pressure gradient ≥20 mm Hg and a hyperemic renal Pd/Pa <0.79 were optimal criteria to predict the success of renal stenting. These data were similar to those reported by Leesar et al. 7 Both studies confirmed that hyperemic measurements perform slightly better than resting measurements and emphasize the very low predictive value of the mere angiographic criteria.

**DISCUSSION**

Two recent, large, randomized trials20,21 and a meta-analysis aggregating data from smaller trials22 all come to similar conclusions: Renal angioplasty does not improve outcome compared to medical treatment in patients with RAS. However, in none of these studies was patient selection based on a physiologic approach. As described earlier, renal artery stenoses associated with small pressure gradients and/or associated with high intraparenchymal vascular resistances cannot be improved by renal stenting regardless of the angiographic grade of severity. Randomizing such patients dilutes the potential benefit of any treatment. Further trials should only randomize patients in whom documented invasive renal hemodynamics suggests a causative relation between the stenosis and the clinical syndrome. It is likely that the latter represents only a small percentage of all angiographically documented stenoses. Drive-by angiograms might even be justified if they are associated with wire-based pressure measurements. In the meantime, it seems appropriate to suggest renal stenting in hypertensive patients, especially when they are young and presenting with flush pulmonary edema and provided they have a large pressure gradient.

**MULTIPLE CHOICE QUESTIONS**

1. The administration of adenosine:
   A. Induces vasodilatation in coronary and renal arteries
   B. Induces vasoconstriction in coronary arteries, especially in case of mild stenosis, and vasodilatation of renal arteries
   C. Induces vasodilatation in coronary arteries and vasoconstriction in renal arteries
2. What is a central component of arterial hypertension in case of renal stenosis?
   A. The activation of the renin-angiotensin system, resulting in angiotensin II–mediated vasoconstriction
   B. An increase in the excretion of sodium, namely “pressure natriuresis”
   C. The increasing levels of angiotensin II that induce vasodilatation
   D. The decrease in glomerular filtration

3. Ischemic nephropathy:
   A. Is mostly caused by the presence of renal artery stenosis (RAS)
   B. Is mostly caused by the presence the parenchymal disease
   C. Is mostly caused by the association of RAS and parenchymal disease
   D. Is independent from renal anatomic modification

4. The renal resistance index is defined as:
   a. \( (2 - \frac{\text{end-diastolic velocity}}{\text{minimal systolic velocity}}) \times 100 \)
   b. \( (1 - \frac{\text{end-diastolic velocity}}{\text{peak systolic velocity}}) \times 100 \)
   c. \( (1 - \frac{\text{systolic velocity}}{\text{maximal end diastolic velocity}}) \times 100 \)
   d. \( (1 - \frac{\text{end-diastolic velocity}}{\text{minimal systolic velocity}}) \times 100 \)

5. Concerning the recent randomized trials on renovascular hypertension, which of the following statements is correct?
   A. They confirm the effectiveness of angioplasty on the control of hypertension.
   B. They show the superiority of medical therapy over angioplasty in the treatment of patients.
   C. They show a good correlation between the angiographic appearance and the transstenotic pressure gradient.
   D. Patients were not included in the trials based on the renal transstenotic gradient.

**Answers**

1. C
Vasoconstriction is mediated by adenosine A<sub>1</sub> receptors, which are predominant in the renal arteries.

2. A

Renovascular hypertension fundamentally depends on the presence and magnitude of a pressure drop due to the stenosis. The activation of the renin-angiotensin system resulting in angiotensin II–mediated vasoconstriction is a central component to this process. This decrease in systemic pressure will in turn decrease the perfusion pressure in the stenotic kidney and further stimulate the release of renin. Elevated levels of angiotensin II induce vasoconstriction and trigger the secretion of aldosterone.

3. C

The most common cause of renal failure in patients with RAS is the association of the RAS with parenchymal disease. In contrast, the occurrence of renal failure solely due to a stenosis in the trunk of the renal artery is exceptional in unilateral RAS and rare in bilateral RAS in the absence of parenchymal disease or nephrotoxic medications.

4. B

By noninvasive Doppler ultrasonography, it is possible to derive the renal resistance-index defined as \((1 – \text{end-diastolic velocity/peak systolic velocity}) \times 100\).
The cardiac valves permit efficient forward blood flow while preventing backflow, in turn creating unidirectional forward cardiac output. Valve disease leads either to reduction in orifice area (stenosis), impeding forward flow, or to incompetence, permitting either regurgitant flow or a combination of these effects. Valve stenosis exerts a pressure overload on the ventricle behind the stenotic valve because that chamber must generate increased pressure to drive the bloodstream past the narrowed orifice. Valve incompetence exerts a volume overload on the affected ventricle, which must enlarge to compensate for the forward flow that is lost to regurgitation. The effects of these overloads on ventricular function and geometry are dealt with in subsequent chapters. This chapter focuses on the evaluation of valve lesion severity and the effects of valve disease on hemodynamics.

**VALVULAR STENOSIS**

**Mitral Stenosis**

Usually in early diastole, there is a small gradient across the mitral valve that initiates filling and then rapidly dissipates (Fig. 8-1A). Indeed, the normally opened mitral orifice is 4 to 5 cm², which creates a functionally single chamber of left atrium and left ventricle (LV) during diastole; thus, pressures in both chambers are equal. Mitral stenosis, which is usually caused by
rheumatic heart disease, reduces orifice area, in turn causing a gradient between left atrium and LV. Mitral stenosis eventually leads to pronounced hemodynamic effects, although little hemodynamic disturbance develops until orifice area is compromised to less than half its normal size. As stenosis worsens, the pressure gradient between left atrium and LV becomes larger and longer in duration (Fig. 8-1B). This gradient is added to normal left atrial pressure, causing left atrial hypertension, eventually leading to pulmonary congestion. As mitral stenosis worsens further, reduced valve aperture impairs LV filling, limiting cardiac output. Thus, despite usually normal LV muscle function, the hemodynamics are those of LV failure. Although left atrial contraction assists late atrial emptying, most transmirtal flow occurs early in diastole, and much of the propellant force creating the pressure driving blood across the valve ultimately is derived from the right ventricle. Therefore, it is this chamber that is pressure overloaded by the disease. Still further stenosis of the mitral valve causes secondary pulmonary vasoconstriction, reinforcing and worsening pulmonary hypertension and right ventricular pressure overload.

**FIGURE 8-1** A. Simultaneous normal left ventricular (LV), aortic (Ao), and pulmonary capillary wedge pressure (PCW) tracings are shown. DFP, diastolic filling period; ECG, electrocardiogram; SEP, systolic ejection period. B. Simultaneous LV and PCW tracings from a patient with mitral stenosis are shown. The shaded area

Assessing Stenosis Severity

Because transvalvular gradient is flow dependent, a measure of stenosis severity that incorporates both flow and gradient is helpful in assessing stenosis severity. Valve area has become the most widely used of these measures.\(^2\) Flow (F) is the product of orifice area (A) and stream velocity (V) \(F = A \times V\). Rearranging the terms, \(A = F/V\). When using Doppler echocardiography to assess orifice area, velocity is measured directly. In using invasive hemodynamics to assess stenosis severity, the transvalvular pressure gradient is measured and converted to velocity using the formula \(V = \sqrt{\frac{2g}{h}}\), where \(g\) is the acceleration as a result of gravity (980 m/s) and \(h\) is the mean pressure gradient. Thus, valve area equals \(\frac{F}{44.3\sqrt{h}}\). Because flow normally tends to stream through the center of an orifice, physiologic valve area is smaller than actual anatomic valve area. This property is corrected using a constant of orifice contraction, \(C_c\). Because not all of the pressure gradient is converted to flow (some energy is lost to friction), another constant, that of velocity loss (\(C_v\)), is used. In 1951, Richard Gorlin and his father\(^2\) proposed the following equation for calculation of valve area:

\[
A = \frac{F}{C_v \cdot C_c \cdot 44.3\sqrt{h}}
\]

Flow is expressed as cardiac output during the time in diastole that the mitral valve is open (diastolic filling period, dfp). Thus the final formula is

\[
MVA = \frac{CO}{HR \cdot dfp \cdot 44.3\sqrt{h}}
\]

where MVA, is mitral valve area, CO equals cardiac output in L/min, and HR is heart rate.

The Gorlins were unable to develop the constants for the equation. Instead, they compared their calculated results to actual valve areas from autopsy and surgical specimens and applied an empiric constant of 0.85 to the denominator. By doing so, the recalculated valve areas came to within 0.2
cm\(^2\) of the actual valve areas. Even as newer noninvasive methods have become available for quantifying mitral valve area, the Gorlin formula has remained a gold standard for valve area determination.

WHEN INVASIVE DETERMINATION OF MITRAL VALVE AREA IS DESIRABLE

As noted previously, several noninvasive methods have been developed for the determination of mitral valve area. The two most commonly used are the pressure–half time method and direct planimetry.\(^3,4\) In general, these methods are adequate for clinical decision making. However, in some cases, there is a discrepancy between clinical and laboratory assessment of stenosis severity; in such cases, the additional information from invasive evaluation is helpful in making a final decision regarding the severity of a given patient’s mitral stenosis and its management. The usual cause of discordance between clinical and noninvasive assessment of the severity of mitral stenosis occurs in the patient who manifests ambiguous symptoms of heart failure while valve area is calculated to be in the mild to moderate range. Here, an invasive evaluation of hemodynamics can settle the issue. Evaluation of left atrial pressure (pulmonary capillary wedge pressure [PCWP]), cardiac output, and pulmonary artery pressure at rest and during exercise is usually very illuminating. Regardless of calculated valve area, if wedge pressure and transvalvular gradient are either significantly increased at rest or more likely provoked to increase with exercise, the hemodynamics explain the patient’s symptoms and suggest that mechanical relief of obstruction will lead to clinical improvement. If exercise does not provoke significant hemodynamic abnormalities, causes other than the patient’s mitral stenosis should be sought to explain the patient’s symptoms. Unfortunately, in today’s busy interventional catheter laboratories, careful assessment of hemodynamics, especially with exercise, has become a rarity.\(^5\)

PITFALLS IN THE INVASIVE
ASSESSMENT OF MITRAL STENOSIS

Measuring the Gradient

In the absence of transseptal puncture, left atrial pressure is estimated from the PCWP. There is much debate concerning whether this is a reliable left atrial pressure surrogate. In fact, the PCWP is or is not reliable, depending on the technique used to measure it. Apart from noting that the catheter appears to be wedged and has (in sinus rhythm) typical a and v waves, it is crucial to confirm that the catheter is truly wedged by removing highly oxygen-saturated (>90%) blood from the catheter while in the wedged position. Failure to perform this confirmatory step often results in recording a pressure that is hybrid between PCWP and pulmonary artery pressure, in turn overestimating both the PCWP and the transvalvular gradient, often by as much as 5 mm Hg. In addition, the transducers measuring both the LV pressure and PCWP must be properly calibrated and zeroed. Although recording device internal standards for calibration have improved over the years, there is no substitute for mercury calibration, considering that errors of just a few mm Hg may have an impact on assessment of stenosis severity of the mitral valve, where a gradient of just 5 mm Hg is often consistent with severe disease.

Assessing Mitral Flow

The transmitral flow period used in calculating the valve area is the entire time the valve is open in diastole. This period is measured (see Fig. 8-1B) from the time the LV pressure tracing falls below PCWP in early diastole (valve opening) to where LV pressure exceeds PCWP in early systole (valve closing). However, the use of the PCWP to measure left atrial pressure causes an 80-millisecond delay from the actual pressure event in the left atrium and its recording as PCWP. Because the LV pressure is recorded directly, the 2 pressures become nonsimultaneous. This problem is corrected by tracing the PCWP recording on paper or electronically reimposing it on the LV tracing using the correct timing of the actual pressure events. Failure to make this maneuver leads to substantial overestimation of the transvalvular gradient and inaccurate measurement of the diastolic filling pressure.
Mitral regurgitation adds a second error in assessing valve area. The pressure gradient is produced by the total flow crossing the valve. The cardiac output determination measures only forward flow, thus underestimating total flow and, as a result, underestimating mitral valve area.

Finally and obviously, the cardiac output must be measured accurately. Although the gold standard for this determination is the Fick method, thermodilution is often substituted.\textsuperscript{8,9} Although this technique is usually accurate, accuracy diminishes in the presence of tricuspid regurgitation and low cardiac output, conditions commonly present in patients with mitral stenosis. In some catheterization laboratories, a “pseudo-Fick” approach is used, in which oxygen consumption is assumed from tables of normals adjusted for height and weight. Because patients with mitral stenosis are hardly normal with respect to cardiac physiology, this technique is fraught with error and should be avoided.\textsuperscript{10}

**AORTIC STENOSIS**

As with mitral stenosis, little hemodynamic disturbance occurs from aortic stenosis until the valve orifice area is reduced to less than half its normal 3.0 to 4.0 cm\textsuperscript{2}. Serious clinical consequences usually do not occur until aortic valve area is reduced to less than 1.0 cm\textsuperscript{2} when the classic symptoms of angina, syncope, and heart failure develop, presaging sudden death.\textsuperscript{11,12} As with mitral stenosis, aortic stenosis severity is usually assessed accurately noninvasively. An abundance of comparison studies show remarkable concordance between gradient measured invasively and gradient measured using Doppler echocardiography. Likewise, there is excellent concordance between invasively derived valve areas and those derived noninvasively using the continuity equation.\textsuperscript{13,14} Thus, in many catheterization laboratories, only coronary arteriography is performed prior to contemplated aortic valve replacement with stenosis severity assessed noninvasively prior to catheterization.

**Invasive Assessment of Aortic Stenosis**

Invasive assessment of aortic stenosis, like that of mitral stenosis, uses the Gorlin formula. Systolic ejection period is substituted for diastolic filling.
period (see Fig. 8-1A). However, unlike mitral stenosis, the Gorlins had no data to compare calculated to actual valve area because, at the time, it was considered malpractice to cross the aortic valve with a catheter. Thus, an empiric constant was never developed for the aortic valve area calculation. Both the invasively derived and the noninvasively derived areas for the aortic valve are flow dependent, varying directly with flow. Two explanations are usually given for this phenomenon. First, it may be that as flow through the valve is increased, the orifice truly opens wider. Second, there is speculation that the absence of knowing the discharge coefficient (or empiric constant) affects the calculation. In fact, there are data to support either point of view.

**When Invasive Determination Is Required**

The current American College of Cardiology/American Heart Association guidelines for the treatment of valvular heart disease define severe aortic stenosis as present when peak echo jet velocity is ≥4.0 m/s, when mean transvalvular gradient is ≥40 mm Hg, or when aortic valve area is ≤1.0 cm$^2$. Unfortunately, many patients show discordance among these 3 criteria and also between the clinical and objective assessment of disease severity. Invasive assessment of aortic stenosis can be helpful in resolving these discrepancies in several situations. First, invasive assessment is useful when the clinical impression of the patient’s symptoms and lesion severity does not agree with the noninvasive data; for example, in a patient with angina and a physical exam consistent with severe disease but an echocardiographic Doppler exam that shows a gradient of only 20 mm Hg, it is likely that off-axis imaging of the aortic jet velocity has caused its underestimation. Second, invasive evaluation is helpful when features of the noninvasive exam are inconsistent with one another; that is, the aortic valve opens well, yet there appears to be a large transvalvular gradient. Third, the invasive approach is often helpful in assessing the very difficult patient with low output and low gradient. Some patients in this group have impaired systolic function and reduced ejection fraction, while others have normal ejection fraction but severe concentric hypertrophy that has reduced end-diastolic volume and concomitantly reduced stroke volume. In the group with reduced ejection fraction, there is far-advanced LV dysfunction, leading to both high operative
and late mortality rates (Fig. 8-2).\textsuperscript{22,23} However, patients in this group who augment their gradient and forward output during dobutamine stress show inotropic reserve and have a relatively good outcome following aortic valve replacement, whereas patients who fail to augment their gradient and forward output during dobutamine stress have a poor prognosis (Fig. 8-3).\textsuperscript{24,25} Although dobutamine is often administered in the echo lab, administration during catheterization allows preanalysis of the coronary anatomy. This is potentially important, because patients with severe coronary disease might fail to augment during dobutamine infusion, not because they lack inotropic reserve, but because dobutamine-induced ischemia from coronary disease precludes an increase in cardiac output. In the group with low gradient and normal ejection fraction, inotropic reserve can be used to calculate gradient and valve area at a higher cardiac output, confirming that truly severe aortic stenosis is present.
FIGURE 8-2 A. Kaplan-Meier survival curve for 52 patients with aortic stenosis, decreased LV function, and low transvalvular mean gradient (MG) compared with expected survival. B. Kaplan-Meier survival curve for patients with aortic stenosis,
decreased LV function, and low MG (<30 mm Hg) compared with patients with aortic stenosis, decreased LV function, and MG ≥30 mm Hg. Operative risk was 21%.

A final vagary in managing this group of patients is a condition sometimes referred to as “pseudo-stenosis.”

In this condition, a severely stenotic orifice area is calculated at rest. However, when output is increased, gradient fails to increase very much, resulting in a much larger valve area. Presumably, in such patients, the aortic valve is only mildly or moderately stenotic but incapable of being opened by a severely diseased LV until inotropy is increased by dobutamine. Because in such cases it is primarily ventricular rather than valvular disease that is operative, it seems unlikely that such patients would improve with aortic valve replacement, although this issue has not been clearly resolved.

**Pitfalls in the Invasive Assessment of Aortic Valve Area**

**Measuring the Gradient**

The most common source of error in the invasive assessment of aortic valve area is made in measuring the transvalvular gradient. Simultaneous measurement of ventricular and aortic pressures is preferred and is necessary if the patient is in atrial fibrillation. However, a gradient measured at pullback is acceptable as long as reentering the LV is not anticipated. As with mitral stenosis, proper gradient measurement begins with 2 properly balanced and zeroed pressure transducers. Confirmation of proper transducer fidelity is made by placing both catheters side by side in the ascending aorta (fluoroscopic confirmation) or by using a double-lumen catheter and recording perfectly matched pressures. After successfully crossing the aortic valve, the ventricular catheter must be confirmed as residing in the body of the LV. This step is important because in almost all cases of aortic stenosis, there are really 2 gradients, one just beneath the valve and a second proximal to the outflow tract.\(^{28,29}\) The subvalvular gradient is not due to true subvalvular stenosis, but rather occurs as blood accelerates into the relatively (compared to the body of the LV) narrow outflow tract.

In an effort to avoid using a second arterial puncture to admit a second catheter, some laboratories use a femoral sheath to record the distal arterial pressure. This technique simply does not work.\(^ {30}\) First, there can be no simultaneous recording of LV and arterial pressure, because ventricular and femoral artery events do not occur simultaneously. Second, by the time the pressure wave reaches the femoral artery, there has been substantial pressure recovery as turbulent flow is converted back to laminar flow as velocity decreases away from the orifice narrowing. Pressure recovery can result in an extreme reduction in total gradient. Although pressure recovery is reflective of femoral hemodynamics, the same phenomenon interferes with proper measurement of the true transvalvular gradient.\(^ {31}\) Differences in pressure recording between proper and improper techniques are demonstrated in Figure 8-4.\(^ {32}\)
FIGURE 8-4 The transaortic valve gradient recorded properly with the left ventricular (LV) catheter in the body of the LV and the distal catheter in the aorta (A) is compared with the false low gradient recorded from LV outflow tract and femoral artery (B). (Reproduced with permission from Carabello BA. The timing of valve surgery. In: Colucci WS, Gotto AM, Josephson ME, Loscalzo J, Oparil S, Popma JJ, eds. Cardiovascular Therapeutics. 2nd ed. New York, NY: WB Saunders; 2002:975-993.)

VALVULAR REGURGITATION

Although both the noninvasive and invasive assessments of valvular stenosis are quite accurate using modern technology, the assessment or valvular regurgitation as commonly practiced leaves much to be desired. In both the noninvasive and invasive arenas, excellent methods for quantifying the amount of left-side regurgitation present are available but often ignored.\(^\text{20}\) The result is that the “eyeball technique” for assessing severity is often used. Here, the visual appearance of either the regurgitant jet at echocardiography or the opacification of the receiving chamber during contrast angiography is used to estimate the severity of regurgitation. Although no hard data exist,
this method probably leads to significant errors in clinical judgment about the severity of the regurgitation present in about 20% of cases. Thus, in assessing the severity of a regurgitant lesion, all aspects of the physical examination and of echocardiographic Doppler measurements should be integrated, and no one parameter should stand alone.

**Invasive Assessment of Valvular Regurgitation**

**Waveforms**

Although rarely used definitively to assess severity of valvular regurgitation, intracardiac pressures and their waveforms may give useful clues to regurgitant severity. In both mitral and aortic regurgitation, the volume overload on the left atrium (mitral regurgitation) and LV (aortic regurgitation) leads to increased pressure in those chambers. It should be noted that chamber enlargement and enhanced chamber compliance can yield normal filling pressures even in the face of severe regurgitation. However, increased filling pressure, when present, helps support the presence of severe regurgitation. Increased left atrial pressure in mitral regurgitation is often but not always accompanied by a large v wave in the left atrial (pulmonary capillary wedge) pressure tracing.\(^{33}\) In severe aortic regurgitation, a rapid rise in the LV diastolic pressure, a femoral artery systolic pressure that is ≥40 mm Hg higher than LV systolic pressure (Hill sign), and diastasis of LV and aortic pressures add evidence that the aortic regurgitation is severe (Fig. 8-5).\(^{26}\) In tricuspid regurgitation, the right atrial pressure tracing may become ventricularized; that is, as the tricuspid valve becomes progressively less competent, the right ventricular pressure is transferred progressively more to the right atrium, so that right atrial and right ventricular pressures take on similar characteristics.
Angiography

In the noninvasive assessment of valvular regurgitation, the color Doppler image observed is that of jet velocity, not of actual flow, one of the confounders in assessing regurgitant severity from jet characteristics. Contrast angiography (although still limited in assessing regurgitation) visualizes the actual flow of contrast from the initiating chamber to the receiving chamber through the regurgitant valve. This visualization, in turn, is used to estimate the amount of regurgitant flow using a semiquantitative grading scale.

Quantitative Angiography

The best way of assessing the amount of regurgitation present would be to
know actual regurgitant flow, which then could be represented as an absolute number or as a percentage of the total flow pumped by the LV (regurgitant fraction). It is generally believed that a total regurgitant flow of more than 60 mL per beat or a regurgitant fraction exceeding 0.5 represents regurgitation severe enough to cause symptoms, ventricular damage, and death.\(^\text{20}\)

\[
RF = sv_t - fsv
\]

where RF is regurgitant flow, \(sv_t\) is total LV stroke volume, and \(fsv\) is forward stroke volume. Regurgitant fraction (RFx) is

\[
RF/sv_t
\]

Total stroke volume is determined by quantitative left ventriculography as end-diastolic volume minus end-systolic volume. These volumes are determined by the area-length or Simpson rule methods. Forward stroke volume is forward cardiac output (Fick or thermodilution method) divided by heart rate.

**When Invasive Assessment of Valvular Regurgitation Should Be Employed**

In usual practice, the estimation of regurgitant severity is made noninvasively. The validity of this assessment should be challenged when the clinical impression of lesion severity is at odds with the echocardiographic assessment. The most frequent error made is failing to take the apparent amount of regurgitation into the context of the ventricular geometry present. If severe regurgitation has been present chronically and the patient is asymptomatic, adequate forward output at noncongestive filling pressure is implied. For this to occur, the LV must enlarge in order to provide enough total stroke volume to make up for that which is lost to regurgitation.\(^\text{34}\) In addition, in mitral regurgitation, the left atrium must enlarge to accommodate the regurgitant volume at normal filling pressure. If both chambers are normal in size, it implies that the regurgitation is not severe or is acute, in which case the patient should be symptomatic. Thus, when the diagnosis of severe valvular regurgitation is made in the presence of normal LV and/or left atrial volume, severity should almost always be confirmed invasively.
Pitfalls

As with the stenotic lesions, if the pressure measurements are to be useful, they must be obtained from properly calibrated and zeroed transducers. In addition, because wave contour is also a factor to be considered, proper damping of the recording system is essential. Confirmation that proper damping is present is an assessment made from experienced observers analogous to judging that an artist used the proper shade of blue in painting the sky. This art form seems to be waning as less attention is paid to proper pressure recording.

In performing contrast angiography, the most common error is the injection of too little dye into the initiating chamber. Because contrast must fill both the initiating and receiving chambers, which are enlarged to begin with, at least 60 mL of contrast should be injected. Smaller injections may lead to poor opacification of the receiving chamber, in turn causing significant underestimation of the amount of regurgitation present. In addition, in mitral regurgitation, ventricular ectopy, which by itself may cause mitral regurgitation, must be avoided, requiring careful placement of the LV angiographic catheter and a test injection free of ectopy.

SUMMARY

Current noninvasive assessment of the severity of valvular heart disease is usually quite accurate. Further knowledge is added to noninvasive assessment by the ability of the technique to help establish valve pathoanatomy. Nonetheless, noninvasive assessment and clinical assessment are at odds with each other often enough that refined invasive assessment is necessary to arrive at a clinical decision. It is especially important in this case that attention be paid to the proper hemodynamic principles that are so crucial in making the correct clinical judgment.

MULTIPLE CHOICE QUESTIONS

1. In measuring the transvalvular gradient in aortic stenosis, which of the following is unacceptable?
   A. Recording of left ventricular (LV) and aortic (Ao) pressures using a double-lumen catheter
   B. Comparison of LV and Ao pressures from a pullback tracing in a patient in sinus rhythm
   C. Matching the 2 aortic pressures before crossing the valve and after pullback
   D. Obtaining pressures from the LV and femoral artery sheath

2. Regarding the Gorlin formula, which of the following statements is false?
   A. 44.3 in the denominator of the equation is the Gorlin constant for the aortic valve.
   B. 44.3 is the empiric constant.
   C. 44.3 is the constant of orifice contraction.
   D. All are false.

3. Invasive determination of aortic valve area is appropriate in which of the following?
   A. Echocardiographic Doppler estimate of a mean gradient of 20 mm Hg and an aortic valve area (AVA) of 0.9 cm$^2$
   B. Presence of a late-peaking systolic ejection murmur and an echocardiographic Doppler AVA of 0.8 cm$^2$
   C. A patient with syncope and an echocardiographic Doppler mean gradient of 60 mm Hg
   D. An echocardiographic Doppler exam showing a heavily calcified immobile aortic valve and a mean gradient of 15 mm Hg
   E. A and D are correct

4. A 45-year-old woman complains of dyspnea on exertion. Physical exam finds a diastolic rumble, and the echocardiographic Doppler exam finds mild to moderate mitral stenosis. How can an invasive study clarify the
5. A patient complains of dyspnea on exertion. A loud holosystolic murmur is heard. Echocardiographic Doppler exam suggests mild to moderate mitral regurgitation but with discordantly large LV and left atrial (LA) volumes. How could an invasive study be helpful?
   A. By finding a normal v wave in the PCWP tracing
   B. By performing contrast ventriculography using 30 mL of contrast
   C. By recording pressures during exercise
   D. By performing contrast ventriculography using 60 mL of contrast
   E. A, B, and D are correct.

ANSWERS

1. D

The goal is to obtain the difference in the pressures between the LV and Ao. In order to be sure there is no systematic error introduced into measurement by faulty transducer calibration or catheter lumen obstruction, identical pressures must be obtained when the catheters or both lumens of a double-lumen catheter are in the same hemodynamic location of the proximal aorta. A pullback accomplishes the same goal since it is a single catheter and is not compared to a second catheter whereby an error in either could cause a false gradient to be introduced into the system. However, using the LV and femoral artery for the recording sites automatically introduces the errors of nonsimultaneous recording and pressure recovery into the system and should be avoided.
2. D

The value of 44.3 is the square root of $2 \times$ the acceleration due to gravity (980 m/s/s; i.e., 1960). The empiric constant of 0.85 was derived only for the mitral valve. The constant of orifice contraction has not been established for either valve.

3. E

In answers A and D, there is a discordance in the findings. In answer A, the valve area is in the severe range, but the gradient is not; in answer D, the valve appears severely stenotic, but there is only a small transvalvular gradient. In both cases, an invasively measured pressure gradient could resolve the issue. In answers B and C, the data are concordant and consistent with severe aortic stenosis.

4. E

A, B, D are all standards in establishing valid hemodynamics that would help clarify the patient’s presentation. C is a distractor. Oxygen consumption index varies by as much as 30% in normal patients and by more in patients with cardiac pathophysiology. Invasive measurements must be justified by being accurate. Since cardiac output is a key element in determining mitral valve area, cardiac output determined by the Fick method must use an accurate oxygen consumption determination. Exercise performed in the cath lab might clarify her status since her symptoms are occurring with exercise. Pressures should be recorded using an oxymetrically confirmed PCWP, properly aligned with the LV pressure tracing.

5. E

Exercise while recording intracardiac pressure is almost always helpful in evaluating exercise-related dyspnea. Because the LA and LV are enlarged, an amount of contrast adequate to opacify both chambers (60 mL) can be helpful in evaluating mitral regurgitation (MR) severity. A normal v wave can be found in both mild and severe MR and is of little diagnostic help, whereas a very large v wave suggests severe MR.

ATHEROSCLEROSIS

Introduction

The complex molecular and cellular biology of the inflammatory process that promotes atherosclerosis has been elucidated through years of extensive experimental and clinical research. Vascular injury from inflammation initiates plaque formation and dictates the downstream clinical sequelae of atherosclerotic disease. It is essential that interventional cardiologists understand the natural history and pathologic processes of atherosclerosis, as well as the vascular biologic consequences of therapies employed during coronary intervention. This chapter describes (1) the pathophysiology of atherosclerosis; (2) the mechanisms responsible for an unstable plaque in acute coronary syndrome (ACS); and (3) the biology of vascular remodeling leading to restenosis, differences between balloon and stent injury, and therapies for restenosis.

A Response to Injury

Atherosclerosis is a result of risk factors and chronic arterial inflammation that promote sustained vascular injury. Several risk factors (Table 9-1) for atherosclerosis have been identified, including metabolic conditions such as
sustained exposure to low-density lipoprotein (LDL) or hyperglycemia and insulin resistance associated with diabetes mellitus or metabolic syndrome. However, additional factors, including age, family history, physical factors (eg, uncontrolled hypertension resulting in changes in shear stress), environmental factors (eg, tobacco smoke), and infectious disease, also contribute to the development of atherosclerotic plaque. Vascular injury results from an inflammatory response that involves a complex sequence of interactions between endothelial and smooth muscle cells, leukocytes, inflammatory cells (eg, macrophages) and their secreted growth factors, and cytokines, which combine with lipoproteins and components of the vascular wall to form a mature atherosclerotic plaque. Inflammation plays a central role in pathogenesis of atherosclerosis; numerous studies have demonstrated a correlation between circulating inflammatory biomarkers (eg, C-reactive protein [CRP]) and an increased risk for atherosclerosis and adverse coronary events.2-4

**Pathogenesis**

The biologic mechanisms in atherosclerotic plaque formation include intimal lipid accumulation, leukocyte recruitment, foam cell formation, neointimal growth, and vessel remodeling (Fig. 9-1).
Intimal Lipid Accumulation

A key event in the early formation of atherosclerotic lesions is the accumulation of LDL within the arterial intima, which subsequently undergoes oxidation and glycation to initiate a cascade of molecular and cellular events including growth factor and cytokine release from inflammatory, endothelial, and smooth muscle cells. It is important to recognize that dyslipidemia results in an inflammatory state and is evident in the presence of inflammatory cells within the initial lesion of atherosclerosis, the fatty streak. Foam cells are the hallmark cell of the atherosclerotic lesion and consist of macrophages that are recruited to the subintima of the vessel wall and subsequently bind and internalize oxidized lipoprotein particles via a number of scavenger receptors on the cell surface. Importantly, lipoproteins can be cytotoxic to macrophages, leading to foam cell necrosis, which, in turn, causes necrotic debris and free cholesterol esters to accumulate within the lesion to form a necrotic core. Inflammatory cells, cytokines, and proteases weaken the fibrous cap surrounding the necrotic core, which can lead to atherothrombosis in the setting of a loss of integrity of the fibrous cap barrier, allowing contact of circulating blood with the thrombotic necrotic core.

Leukocyte Recruitment

Leukocytes, predominantly macrophages, play a pivotal role in atherosclerosis. By releasing cytokines and growth factors, macrophages regulate atherogenesis, but also influence plaque destabilization leading to rupture and thrombosis. The process of leukocyte recruitment, attachment to the extracellular matrix, and migration into the plaque (ie, diapedesis) is a response to vascular injury. Chemokine-stimulated endothelial cells express leukocyte-specific cell adhesion molecules (CAMs), which loosely bind circulating mononuclear cells and allow rolling of the monocytes along the endothelial surface. Tight binding of monocytes to the endothelium is mediated by the integrin class of CAMs, which is the final step prior to diapedesis. Although their pathologic role is uncertain, plasma levels of CAMs (eg, E-selectin or intercellular adhesion molecule-1 [ICAM-1]) are associated with the development of coronary atherosclerosis.

Chemokines are an important group of cytokines produced by a number of
cells (eg, smooth muscle cells, endothelial cells, and leukocytes) that act as a chemoattractant for leukocytes to areas of vascular injury. Two important chemokines are monocyte chemoattractant protein-1 (MCP-1) and interleukin (IL)-8, which participate in the recruitment of monocytes and diapedesis of adherent cells.\textsuperscript{7-10}

Innate immunity and adaptive immunity have important roles in the development of atherosclerosis.\textsuperscript{11} Innate immunity is an immediate response to foreign material and relies on phagocytosis through neutrophils and monocytes. Monocytes are felt to be the first leukocytes recruited to the early atheromatous plaque and are differentiated into activated macrophages: type 1 induced by inflammatory cytokines (eg, interferon [IFN]-γ) or type 2 induced by IL-4, IL-13, and other anti-inflammatory cytokines. Type 1 macrophages produce large amounts of reactive oxygen species and inflammatory cytokines, which amplify the immune response to an atheroma. Type 2 macrophages express scavenger receptors and produce extracellular matrix proteins and remodeling stimuli.\textsuperscript{12-14} Other cells of the innate immune response have also been implicated in atherosclerosis, including neutrophils, mast cells, and natural killer cells.\textsuperscript{15} Adaptive immunity is an antigen-dependent response, and the CD4\textsuperscript{+} T lymphocyte is the primary cell present at atherosclerotic lesions. T cells actively secrete cytokines, which influence plaque progression and vulnerability.\textsuperscript{15} T lymphocytes secrete inflammatory cytokines such as IFN-γ, which can impair the extracellular matrix architecture and growth of smooth muscle cells, promote apoptosis, and cause plaque instability.\textsuperscript{16} CD4\textsuperscript{+} T cells also express the CD40 ligand to promote proteolysis through matrix metalloproteinases (MMPs) and stimulate cells to produce tissue factor to influence plaque rupture and thrombogenicity.\textsuperscript{17}

As lesions mature, leukocytes accumulate in the “shoulder” regions of plaques (ie, the border between the eccentric plaque and normal vessel architecture), which are more vulnerable to plaque rupture.\textsuperscript{18} In addition, atherosclerotic lesions develop preferentially at coronary bifurcations. Due to the disturbances in flow patterns at coronary bifurcations, altered shear stress may upregulate CAMs and increase leukocyte recruitment and plaque growth. Monocytes contribute to vascular calcification in response to cytokines such as monocyte colony-stimulating factor (M-CSF) and receptor activator of nuclear factor κ-B (RANKL).\textsuperscript{19} Importantly, microcalcification is
associated with plaque vulnerability.\textsuperscript{20}

**Neointimal Growth**

Smooth muscle cells and their secreted products are responsible for neointimal growth and for giving structure to the mature atherosclerotic plaque, which initially is a collection of lipids and foam cells. Growth factors and chemokines (eg, platelet-derived growth factor and thrombin) initiate smooth muscle cell migration from the media into the neointima and stimulate cell proliferation. In the neointima, smooth muscle cells expand the extracellular matrix by producing its constituent proteins including collagen, proteoglycans, elastin, fibrin(ogen), fibronectin, and vitronectin. The extracellular matrix accounts for a substantial portion of plaque volume and is vital to the structural integrity of the fibrous cap. Smooth muscle cells also express bone matrix proteins, which highlight their role in vascular calcification.\textsuperscript{21-23} Mineralization of the plaque occurs through deposition of calcium and osteopontin, but calcification does not always equate to plaque stability and is associated with higher risk in some patients (eg, elderly).\textsuperscript{24}

**Plaque Angiogenesis**

Plaque angiogenesis is important to plaque growth and the pathogenesis of atherosclerotic complications.\textsuperscript{25} Angiogenic growth factors (eg, hypoxia-inducible factor [HIF] and vascular endothelial growth factor [VEGF]) stimulate the growth of vasa vasorum from the adventitia into the plaque.\textsuperscript{26} Notably, these vessels can hemorrhage, independent of plaque rupture, and extravasation of erythrocytes provides a source of cholesterol-rich red cell membrane constituents, heme, and iron, which act as stimulants for oxidative stress and vessel growth. Neovessel density is significantly higher in nonstenotic and stenotic noncalcified plaques compared with calcified lesions or vessels without plaque.\textsuperscript{27} Neoangiogenesis is driven by hypoxia, but the latter also contributes to proteolysis through MMPs. MMPs comprise a family of interstitial collagenases that weaken the fibrous cap and gellatinases that breakdown nonfibrillar collagen and the adhesions between endothelial cells, leading to plaque vulnerability.\textsuperscript{28-30} Hypoxia also promotes proinflammatory cytokine and leukotriene release, which activates
macrophages and contributes to plaque growth.\textsuperscript{29,31}

**The Mature Atherosclerotic Plaque**

The mature atherosclerotic plaque is composed of a fibrous cap consisting of smooth muscle cells and extracellular matrix overlying a necrotic lipid core consisting of free cholesterol esters, foam cells, other leukocytes (eg, T cells), and necrotic debris from dead foam cells (see Fig. 9-1). Mature plaques are typically eccentric and heterogeneous, especially in terms of the thickness of the cap and distribution of leukocytes (highest at the shoulder regions of the plaque). These features are vitally important to plaque stability and the development of ACS.

**Vascular Remodeling**

A major limitation to coronary angiography is that it only provides information on the luminal encroachment of lesions. Intravascular imaging has provided a better understanding of atherosclerotic plaque architecture not only at sites of flow-obstructing lesions but throughout the vessel. Although the interventional cardiologist may be focused on focal obstructive lesions, it is important to realize that atherosclerosis is typically present throughout the entire coronary artery. The severity of lumen narrowing is subject to the amount of plaque growth and vascular remodeling, whereby the latter involves restructuring the cellular and noncellular components of the vessel wall under a variety of stressors (eg, smooth muscle mass increasing to normalize wall stress in hypertensive patients).\textsuperscript{32} Positive remodeling is a compensatory enlargement of the vessel to preserve the luminal area and maintain coronary blood flow (Fig. 9-2). MMPs are upregulated in areas of vessel wall remodeling and play a central role in plaque rupture.\textsuperscript{33}
Clinical Sequelae of Atherosclerosis

The clinical manifestations of coronary artery disease are often described as a spectrum, from stable angina associated with exertional angina and benign outcomes, to ST-segment elevation myocardial infarction (STEMI) associated with sudden thrombotic vessel occlusion and higher rates of morbidity and mortality. Two main mechanisms are primarily responsible for the clinical manifestations of atherosclerosis: (1) luminal narrowing that leads to a mismatch between oxygen supply and demand typically resulting in symptoms of stable angina; or (2) atheromatous plaque rupture resulting in thrombus formation and coronary occlusion. Importantly, atherosclerosis can also alter the normal endothelial vasomotor function and autoregulation of blood flow (ie, endothelial dysfunction), which can cause anginal symptoms in patients with and without epicardial coronary stenoses. Nevertheless, it is critical to recognize that thrombotic complications of atherosclerosis depend on plaque morphology and vascular biologic factors, not the severity of coronary stenosis.

Progressive Lumen Encroachment and Stable Angina
Lumen encroachment occurs from the growth and expansion of atherosclerotic lesions (see Fig. 9-2). The extent of luminal narrowing depends on the size of the atherosclerotic lesion and the amount of compensatory vascular remodeling. A coronary stenosis reduces coronary blood flow to a given vascular territory. The decrease in blood flow causes the distal microcirculation to vasodilate and increase coronary blood flow, which, in turn, reduces the ability of the coronary circulation to increase blood supply in response to demand (ie, coronary flow reserve). This process typically leads to exertional angina and is relieved by rest. Importantly, luminal encroachment does not always cause symptoms and depends on many factors including the severity of the stenosis, the oxygen carrying capacity of blood, and the supply demands of the distal myocardial bed.

A general rule is that lesions typically produce symptoms when they reach a 60% to 70% diameter stenosis. However, interrogating the intracoronary hemodynamics with flow and pressure wires has revealed that lesions with the same degree of angiographic stenosis may have very different hemodynamic and ischemic consequences. Fractional flow reserve (FFR) has become the predominant method used to assess coronary hemodynamics and is defined as the ratio of the distal pressure in the coronary artery beyond the lesion divided by the aortic pressure. Based on an association with inducible ischemia on stress testing, the initial cut-off point for not performing percutaneous coronary intervention (PCI) after FFR assessment was <0.75, as established in the FFR to Determine Appropriateness of Angioplasty in Moderate Coronary Stenoses (DEFER) study. To enhance the sensitivity and exclude ischemia using FFR, the cut-off was increased to >0.80 in the Fractional Flow Reserve Versus Angiography for Multivessel Evaluation (FAME) trial. In FAME, routine measurement of the FFR was compared with angiography alone for guiding PCI in patients with multivessel coronary artery disease (CAD). The use of FFR significantly reduced the rate of major adverse cardiac events compared with angiography alone. Importantly, a subgroup analysis of the lesions that were assessed by FFR in FAME revealed that coronary angiography could not accurately predict the hemodynamic significance of a coronary lesion. In FAME, 35% of lesions with an angiographic stenosis of 50% to 70% (ie, intermediate) were hemodynamically significant (FFR ≤0.80), whereas 20% of lesions with an angiographic stenosis of 71% to 90% were not functionally significant by
Only when lesions had an angiographic stenosis >90% was coronary angiography able to predict hemodynamic significance, where 96% of lesions with a coronary stenosis of 91% to 99% had an FFR \( \leq 0.80 \). Furthermore, 54% of patients who were classified as having multivessel CAD did not have \( \geq 2 \) lesions with an FFR \( \leq 0.80 \). The discordance between hemodynamic significance and angiographic stenosis highlights the need to use adjunctive techniques to assess the ischemic potential of coronary stenoses.

**Plaque Rupture and Thrombosis in Acute Coronary Syndromes**

The historical view held that stable angina could convert to ACS when an atherosclerotic lesion narrowed the vessel lumen to a critical point where vasospasm or thrombosis in situ could develop and cause a myocardial infarction (MI). For years, considerable debate ensued as to whether thrombus found at autopsy was a pre- or postmortem phenomenon. This widely held view continued despite James Herrick’s landmark publication of thrombus as the predominant cause of sudden coronary obstruction in 1912. The pivotal work by DeWood et al in 1980 demonstrated angiographically that ST-segment elevation and transmural MI were associated with occlusion of an epicardial coronary vessel predominantly secondary to thrombus (Fig. 9-3). Since this discovery, autopsy studies and angioscopy have confirmed the presence of visible thrombus associated with plaque rupture (Fig. 9-4) in both unstable angina and acute MI (AMI).

FIGURE 9-4 Histologic example of a ruptured plaque with subsequent thrombosis leading to a fatal myocardial infarction. (From Constantinides P. Plaque hemorrhages, their genesis and their role in supra-plaque thrombosis and atherogenesis. In: Glagov S, Newman WP III, Schaffer SA, eds. *Pathology of the Human Atherosclerotic Plaque.* New York: Springer-Verlag; 1990:393-411, with permission of Springer.)

Early thrombolytic trials were instrumental in our current understanding of ACS. As part of these trials, patients with AMI underwent serial angiography after randomization to thrombolytics or placebo, which revealed an unexpected finding, namely that the majority of the culprit lesions had <50% in diameter stenosis (Fig. 9-5). Furthermore, in some patients, mild and moderate stenoses progressed to MI within weeks. Importantly, only 15% of AMIs arose from lesions with a coronary stenosis >60% on a prior angiogram (see Fig. 9-5). These finding focused future research efforts on determining the vascular biology of a vulnerable plaque and the mechanisms responsible for conversion from a stable plaque to a thrombotic lesion.
Noncritical lesions are significantly more abundant than critical lesions, and compensatory enlargement of the vessel often accompanies atherosclerosis. Thus, mildly stenotic lesions can have an even larger plaque burden by volume, which may portend a higher risk for plaque rupture and thrombosis.

![Graph showing diameter stenosis](image)

**FIGURE 9-5** Compiled data from 4 thrombolytic trials showing that the majority of underlying lesions responsible for acute myocardial infarction involve less than 50% diameter stenosis. (Reproduced with permission from Smith SC. Risk-reduction therapy: the challenge to change. *Circulation*. 1996;93:2205-2211.)

Plaque rupture is the proximate event leading to thrombosis, which exposes the subendothelium to circulating blood. Several histologic features have been associated with plaque vulnerability, including a thin fibrous cap, a large lipid-laden necrotic core, and an accumulation of leukocytes and inflammatory cells at the shoulder regions of the plaque (Fig. 9-6). An important natural history study of coronary atherosclerosis was recently conducted called Providing Regional Observations to Study Predictors of Events in the Coronary Tree (PROSPECT). In PROSPECT, 697 patients who were stented in the setting of ACS underwent 3-vessel intravascular imaging to determine the clinical and lesion risk factors associated with future events. At 3 years, approximately 20% of patients experienced a major adverse cardiac event, in which nearly 50% of the adverse events were associated with nonculprit lesions. The majority of adverse cardiac events were in lesions that were mildly stenotic at the time of index angiography. Three lesions characteristics were strongly associated with a higher risk for
future adverse cardiac events in nonculprit lesions; these were a plaque burden \( \geq 70\% \), presence of a thin cap fibroatheroma, and a minimal lumen area \( \leq 4 \text{ mm}^2 \).\textsuperscript{45}

![Diagram of plaque types](image)

**FIGURE 9-6** Characteristics of stable versus vulnerable plaques. Vulnerable plaques have thinner fibrous caps and larger, more inflammatory cell–rich lipid cores. SMC, smooth muscle cell. (Reproduced with permission from Libby P. Molecular bases of the acute coronary syndromes. *Circulation*. 1995;91:2844-2850.)

A plaque’s structural integrity is regulated by vascular inflammation and dependent on the balance between the mass of smooth muscle cells and content of the extracellular matrix. Smooth muscle cell mass is regulated by cell migration from the media, neointimal proliferation, and cell death. The latter occurs due to cytokine release from inflammatory cells, leading to apoptosis.\textsuperscript{46} Extracellular matrix content depends on the interplay between production from smooth muscle and inflammatory cells and protease activity leading to degradation (*Fig. 9-7*). Within a plaque, activated T cells release IFN-\( \gamma \), which inhibits smooth muscle cell collagen synthesis. Inflammatory cells also produce enzymes (eg, MMPs and cathepsins) that degrade important structural components of the extracellular matrix (ie, collagens, elastin).\textsuperscript{18} This process weakens the structural integrity of a plaque by
decreasing smooth muscle cell mass and degrading the extracellular matrix.

**FIGURE 9-7** Thickness of the fibrous cap is a balance between synthesis of extracellular matrix proteins by smooth muscle cells (SMCs) and the breakdown of these products by degradative enzymes. These processes are largely under the influence of inflammatory cells. IFN, interferon; MCP-1, monocyte chemoattractant protein-1; M-CSF, monocyte colony-stimulating factor; TNF, tumor necrosis factor. (Reproduced with permission from Libby P. Molecular bases of the acute coronary syndromes. *Circulation*. 1995;91:2844-2850.)

Predicting how, why, and when a plaque will rupture is a subject of continuing study. An interesting historical observation is the diurnal variation in MI presentation, which peaks in the early morning hours. Additionally, MI rates increase during times of extreme stress (eg, earthquake). These observations suggest that variations in cortisol and adrenaline levels may impact plaque rupture through their systemic hemodynamic effects. The site of rupture coincides with the highest circumferential biomechanical force, which is located at the shoulder region of a plaque. Thus, a combination of biochemical and biophysical characteristics predispose the shoulder regions to plaque rupture, which is supported by histologic postmortem studies in patients who died from an AMI. Other processes may also be responsible for the thrombotic complications of ACS. Focal endothelial denudation can expose the internal elastic membrane to circulating blood and act as a substrate for thrombosis, which occurs more frequently in women and
diabetics. Also, mechanical injury during PCI can also disrupt plaque and lead to acute thrombosis.

Atherothrombosis is the final consequence of plaque rupture or endothelial denudation that leads to acute coronary vessel occlusion. Exposing the lipid core (ie, tissue factor associated with lipid-laden and necrotic macrophages) to circulating blood is a potent stimulus for thrombus formation. Thrombus formation following plaque rupture is regulated by the blood’s tight control over the balance between procoagulant-anticoagulant and fibrinolytic-antifibrinolytic factors. In the presence of an intact and robust fibrinolytic system, a thrombus may undergo rapid lysis and manifest clinically as unstable angina or non–ST-segment elevation MI (NSTEMI). Similarly, patients on antiplatelet therapy (eg, aspirin) may be protected from platelet activation and aggregation during subendothelial exposure to blood. Conversely, the presence of prothrombotic factors (eg, fibrinogen or plasminogen activator inhibitor-1) can accelerate the growth of a thrombus, leading to coronary occlusion. Nonocclusive thrombus can also become incorporated into a plaque during the healing process and provide a mechanism for plaque expansion and lumen encroachment and be a source for angina.

Importantly, antiplatelet and lipid-lowering therapy trials have corroborated the thrombotic paradigm of ACS and demonstrated marked reductions in the morbidity and mortality associated with an acute coronary event. Furthermore, these breakthroughs have been achieved despite a lack of change in lesion severity. Lipids have a central role in atherosclerosis and atherothrombosis as the critical initiating and sustaining inflammatory stimulus for plaque growth and rupture. The beneficial actions of statins include not only their lipid-lowering properties, but also the reduction in inflammation, which can stabilize the fibrous cap and reduce thrombogenicity of the inner lipid-laden necrotic core. Evidence supports that lipid-lowering therapy is vital to acute and chronic therapy for patients presenting with ACS.

A major goal of vascular biologists and clinical cardiologists is to develop a more complete understanding of the mechanisms of plaque rupture and the development of novel strategies to stabilize lesions. However, many different lesions of varying vulnerability may coexist throughout the coronary tree. Novel imaging techniques are being developed to identify plaques that are the most susceptible to rupture, which may allow for better prognostication and therapeutic developments.
RESTENOSIS

Introduction

Andreas Gruentzig ushered in the modern era of management of obstructive CAD with the publication of his experience with coronary balloon angioplasty in a landmark study of 5 patients in 1978.50 Yet, his first angiographic follow-up study revealed that 19% of patients undergoing successful initial angioplasty suffered restenosis.51 Since the early days of balloon angioplasty, the introduction of stenting has reduced certain limitations of balloon angioplasty. However, in-stent restenosis (ISR) still remains an important limitation of coronary stents. Bare metal stents (BMS) decreased restenosis compared to balloon angioplasty, but in selected studies, ISR remained as high as 30%.52 Drug-eluting stents (DES) further reduced the rates of ISR to as low as 5% to 20%, depending on the patient population.53-56

Our understanding of the pathophysiology of restenosis has evolved considerably. Early postmortem studies revealed a fibrocellular response at sites of prior balloon angioplasty.57 Initial animal studies revealed that endothelial denudation, medial dissection, and platelet deposition contribute to an immediate response to balloon injury, whereas late restenosis is a consequence of smooth muscle cell migration and proliferation.58,59 The initial paradigm for restenosis comprised 3 phases: (1) an inflammatory phase, (2) a granulation or cellular proliferation phase, and (3) a phase of remodeling involving extracellular matrix protein synthesis (Fig. 9-8).60 As with atherosclerosis, inflammation plays a critical role in the pathogenesis of restenosis. Coronary stenting has a profound impact on the vascular biologic response to vessel injury, especially the inflammatory response and vascular remodeling following injury. The aim of this chapter is to understand the pathogenesis of restenosis and the clinical indicators and biochemical markers associated with increased risk and to introduce the concepts of antirestenotic therapy.

Definitions and Clinical Sequelae of Restenosis

In clinical trials, restenosis was historically defined angiographically as a binary (ie, yes or no) reduction of ≥50% of the luminal diameter compared with the reference vessel, which does not always separate clinically relevant lesions from those without any sequelae. However, restenosis can also be defined by angiographic terms that are more relevant to our understanding of the pathophysiology. Late lumen loss (LLL) is the continuous measure of angiographic luminal narrowing and is calculated by subtracting minimal lumen diameter (MLD) at the time of index revascularization from postprocedural MLD at angiographic follow-up. LLL is an important surrogate marker used to assess the effectiveness of antirestenotic therapies and different stent platforms. It is important to note that virtually all patients have some degree of restenosis. In any given population, the severity of restenosis will follow a typical Gaussian distribution (Fig. 9-9), and only a minority of patients will have severe ISR (eg, diameter stenosis >70%) and anginal symptoms. On average, LLL is 0.8 to 1.0 mm following implantation of a BMS, regardless of the reference vessel diameter, and is critically important when considering revascularization of smaller vessels. For example, a 4-mm diameter vessel would lose 44% of lumen area with an LLL of 1 mm, whereas a 2-mm vessel with the same 1-mm loss would have a 75% loss in lumen area. LLL and angiographic restenosis are related to the reference vessel diameter, and restenosis is heavily dependent on the definition used in a given clinical study. An inventory of the wide variety of angiographic and clinical definitions used to define restenosis is shown in Table 9-2.
The discordance between LLL and binary restenosis is controversial. Late loss is a useful surrogate marker for assessing the effectiveness of therapies for restenosis. However, the relationship between late loss and binary restenosis is nonlinear and a curvilinear function (Fig. 9-10), which implies that there may be a threshold of LLL that is clinically significant. The argument is that LLL below a certain level is not clinically significant and does not portend a worse clinical restenosis rate (ie, target lesion revascularization [TLR]) (see Fig. 9-10). This argument is a contentious issue in interventional cardiology. Regardless, the clinical sequelae of angiographic restenosis are not always concordant. An example of this was observed in a meta-analysis of patients with angiographic ISR from multiple stenting trials, where ISR defined as ≥50% diameter stenosis was asymptomatic in approximately 50% of patients.65 This study highlights the multifactorial nature of restenosis and discrepancy between angiographic restenosis as a binary outcome and corresponding clinical significance.
FIGURE 9-10 A. Data from the TAXUS IV trial shows the in-stent late loss for the Taxus stent (Boston Scientific) and control bare metal stent. B. Probability of target lesion revascularization (TLR) as a function of in-stent late loss revealing a curvilinear distribution. Superimposed are the mean and standard deviations for the Taxus stent late loss (red) and the control bare metal stent (blue). The distribution of the Taxus stent late loss falls along the relatively flat portion of the curve, whereas the distribution for the bare metal stent falls along the steeper portion of the curve where there is greater correlation between late loss and TLR. (Reproduced with permission from Ellis SG, Popma JJ, Lasala JM, et al. Relationship between angiographic late loss and target lesion revascularization after coronary stent implantation: analysis from the TAXUS-IV trial. J Am Coll Cardiol 2005;45:1193-1200.)

Traditionally, restenosis has been viewed as a condition that clinically manifests as stable angina. However, there is substantial evidence to the contrary. Although the majority of patients present with stable exertional symptoms, unstable angina (26%-53%), and acute MI (3.5%-20%) are not uncommon.\textsuperscript{66,67} Restenosis following balloon angioplasty or stenting is an accelerated process compared with atherosclerosis. With balloon angioplasty, clinically significant restenosis is typically present by 6 months.\textsuperscript{68,69} Following stent implantation, the average time for ISR is approximately 5.5 months, with evidence that a shorter interval may be present in patients presenting with AMI.\textsuperscript{70} Taken together, these studies highlight that restenosis is not always a benign condition and is a distinct clinical entity from atherosclerosis.

**Risk Factors for Restenosis**

The 3 most important and historical clinical risk factors for restenosis are
In conceptualizing the risk factors for restenosis, it is helpful to classify them as biologic or mechanical, although there is considerable overlap between the 2 classifications.

**Biologic**

The risk for restenosis is high among patients with diabetes mellitus. Data from a registry involving >35,000 patients following DES (Endeavor, sirolimus-eluting stents [SES], Taxus Express, and Liberte) revealed that, at 2-year follow-up, the rates of ISR with DES implantation were significantly higher in patients with diabetes.\(^7\) Another study of 954 patients undergoing PCI revealed that TLR was also significantly higher in diabetics compared with individuals without diabetes.\(^7\) The increased risk for restenosis in diabetics is likely secondary to endothelial dysfunction, accelerated intimal hyperplasia, and increased platelet reactivity.\(^7\)

Patients may also be genetically predisposed to restenosis. For example, genetic polymorphisms associated with a higher risk for restenosis include genes for angiotensin-converting enzyme inhibitor, glycoprotein receptor IIIa PLA1/2, haptoglobin 2/2.25, and IL-8.\(^7\) Additionally, resistance to antiproliferative drugs used in DESs has been observed in patients with genetic polymorphisms to the intracellular receptor mammalian target of rapamycin (mTOR), enzymes responsible for paclitaxel or sirolimus metabolism, and mutations of proteins in the downstream signaling of mTOR.\(^7\) Thus, biologic resistance to DESs may be presents in certain individuals.

- Intravascular ultrasound
  - Neointimal area (mm$^2$)
  - Lumen size (diameter or area)

Abbreviation: PTCA, percutaneous transluminal coronary angioplasty.

Biomarkers associated with an increased risk for ISR have also been identified. Higher plasma levels of MCP-1 have been associated with a higher rate of restenosis at 6-month angiographic follow-up following balloon angioplasty.$^{79}$ CRP is considered a strong risk predictor for cardiovascular disease, but the relationship between CRP and ISR remains controversial and an area of active investigation.$^{80-84}$ Circulating MMPs have also been associated with a higher risk of developing ISR following DES implantation. MMP-2 and MMP-9 play a key role in the migration of vascular smooth muscle cells and remodeling following vascular injury. Significant elevations in MMP-2 and MMP-9 levels are strongly associated with the development of ISR following DES implantation.$^{85}$

**Mechanical**
Several mechanical factors related to stent deployment may also contribute to a higher rate of restenosis. Stent underexpansion and malapposition are associated with a higher risk of ISR, which may impact effective drug delivery in DES and cause less inhibition of neointimal hyperplasia.\(^{86,87}\) In the era of DES, geographic miss may also be responsible for restenosis. Geographic miss typically refers to an area of the treated segment that was exposed to balloon injury but not covered with a DES. Thus, this uncovered area would not receive the benefits of the antiproliferative therapy of DES. Stent fracture may also contribute to ISR in DES and lead to ineffective drug delivery.\(^{88-92}\)

**Classification of Patterns of In-Stent Restenosis**

An angiographic classification of ISR was developed and classifies restenosis according to the geographic distribution of intimal hyperplasia in reference to the implanted stent.\(^{93}\) Four classes of ISR are defined as follows (Fig. 9-11):
1. Class I: Focal ISR group
   - Lesions are ≤10 mm in length and positioned at the unscaffolded segment (ie, articulation or gap), the body of the stent, the proximal or distal margin (but not both), or a combination of these sites (multifocal ISR).

2. Class II: Diffuse intrastent ISR
   - Lesions are >10 mm in length and are confined to the stent(s), without extending outside the margins of the stent(s).
3. Class III: Diffuse proliferative ISR
   - Lesions are >10 mm in length and extend beyond the margin(s) of the stent(s).

4. Class IV: ISR with total occlusion
   - Lesions have a Thrombolysis in Myocardial Infarction (TIMI) flow grade of 0.

The pattern of ISR is different between BMS and DES, where BMS tends to present as focal ISR and DES presents as a diffuse pattern. Additionally, patients with AMI are likely to have diffuse ISR compared with patients presenting without MI.\textsuperscript{70,94}

**Pathogenesis of Restenosis**

The pathogenesis of restenosis is different than atherosclerosis. Restenosis is more rapid than atherosclerosis and sometimes referred to as an “accelerated arteriopathy.”

**Differences Between Balloon Angioplasty Versus In-Stent Restenosis**

In balloon angioplasty, intravascular ultrasound (IVUS) studies demonstrated that restenosis is secondary to both neointimal growth and shrinkage of the artery by acute recoil and negative remodeling. Acute elastic recoil following angioplasty is observed within a few minutes and results in vessel collapse. The amount of recoil is proportional to the extent of stretching with balloon inflation and can result in as much as 50% loss in cross-sectional area and 33% loss in lumen diameter.\textsuperscript{95} Negative remodeling is different from acute recoil. It involves contraction of the external elastic laminae and is a process that occurs over weeks to months following injury. Concurrently, neointimal proliferation is an inflammatory response to the site of injury, which leads to smooth muscle cell proliferation and excessive extracellular matrix production.\textsuperscript{96,97} In terms of their relative contribution, negative remodeling plays the largest role in restenosis following balloon injury without stent placement (Fig. 9-12).
Our understanding of the pathophysiology of restenosis relies heavily upon animal models and intravascular imaging. Initial IVUS studies determined that negative remodeling (ie, external elastic membrane area) and neointimal hyperplasia (ie, plaque plus media cross-sectional area) contributed to restenosis following vascular injury from balloon angioplasty. In an angiographic analysis of the first 2 large-scale coronary stent trials in humans, distinct differences were observed between the pattern of restenosis in balloon-injured compared with stented coronary arteries. Arteries that received a stent had a larger initial lumen gain, which was due to the rigid stent scaffolding that prevented acute elastic recoil and negative remodeling. Angiographic follow-up at 6 months revealed that the luminal area was greater (ie, lower restenosis) in stented vessels compared with balloon angioplasty. However, LLL was higher in stented arteries due to greater neointimal growth. These findings were later confirmed in IVUS
Thus, the benefit of stents for restenosis is largely attributable to the larger initial lumen gain and prevention of negative remodeling (see Fig. 9-12). The neointimal formation that occurs in ISR is similar to balloon angioplasty. Yet the response is exaggerated in stenting secondary to differences in vessel injury and inflammation. For example, one study demonstrated that the inflammatory response and volume of neointimal formation were increased when the stent struts perforated the internal and external elastic lamina. Potential contributing factors to the exaggerated inflammatory response with stenting may be related to the higher balloon pressures required for stent deployment or possibly a contact allergy to the stent metal. BMSs slowly elute metal ions and have the potential to stimulate a delayed-type hypersensitivity response within the stented vessel. One study of patients who underwent cutaneous patch testing for nickel and molybdenum hypersensitivity after stent placement found that patients with a positive test also had more ISR requiring revascularization. The data suggest that metallic hypersensitivity may account for a subset patients who presents with restenosis after stenting.

**Mechanisms of Leukocyte Recruitment and Infiltration**

Balloon expansion and/or stent placement causes vascular injury by dissection, crushing the smooth muscle cells, and de-endothelialization. Leukocytes are recruited to sites of injury and are deposited together with platelets. As part of the inflammatory response after angioplasty, the interaction between platelets and leukocytes is important. The initial loose attachment of leukocytes to surface-adherent platelets is mediated through the selectin class of adhesion molecules (eg, P-selectin), followed by firm adhesion and transplatelet migration via the integrin class of adhesion molecules (eg, β2 integrin Mac-1, also known as CD11b/CD18). In addition to promoting leukocyte recruitment, platelet binding to neutrophils amplifies the inflammatory response via proinflammatory molecules (eg, soluble CD40 ligand) by inducing neutrophil activation, amplifying the expression of CAMs, and enhancing signal transduction pathways that promote integrin activation and cytokine synthesis. Neutrophil-platelet and monocyte-platelet aggregates have been identified in patients with CAD and may be markers of disease activity and prognostic markers.
Inflammation: A Key Role in Restenosis

Restenosis is not typically secondary to accelerated atherosclerosis, but is a distinct temporal and pathophysiologic process. However, inflammation still plays a central role in both atherosclerosis and restenosis. In a study of pathologic samples of 116 stents from 87 patients more than 90 days after procedure, the severity of restenosis was associated with the extent of medial damage and inflammation. An additional study of tissue samples retrieved from direct atherectomy at the time of angioplasty demonstrated a strong positive correlation between the number of inflammatory cells and the risk of restenosis.

Inflammatory biomarkers have also provided insight into the mechanisms of restenosis. In one study, blood samples were collected from patients both proximal and distal to the site of injury following balloon dilatation, and inflammatory biomarkers of leukocyte activation (eg, neutrophil adhesion molecules L-selectin and CD11b) were upregulated after angioplasty. CD11b is upregulated on both neutrophils and monocytes in patients following angioplasty and is a prognostic marker for restenosis following angioplasty and stenting. Increased IL-1 production by monocytes isolated from blood before angioplasty was associated with LLL, whereas granulocyte activation was protective against luminal narrowing. Higher MCP-1 levels are associated with a risk for ISR following PCI. The nonspecific inflammatory marker CRP is also positively correlated with a risk for restenosis following stent placement.

Animal models have been invaluable in elucidating the basic cellular and molecular mechanisms of restenosis. CAMs are critical for leukocyte recruitment and are upregulated by an atherogenic diet, induction of diabetes, and increased shear stress in various animal models. VCAM-1, ICAM-1, and major histocompatibility complex (MHC) class II antigens are upregulated following balloon endothelial denudation. Stents induce a potent and early inflammatory response evidenced by an abundance of surface adherent leukocytes. In the days to weeks following stent implantation, macrophages invade the forming neointima and cluster around stent struts forming giant cells. Blockade of monocyte recruitment with anti-inflammatory agents results in reduced late neointimal thickening. A strong correlation exists between the number of tissue monocytes and
neointimal area, which suggests a causal role for monocytes in restenosis. Furthermore, activated macrophages influence vascular repair by production of a variety of inflammatory cytokines (e.g., IL family, tumor necrosis factor-α, MCP-1) and growth factors (e.g., platelet-derived, basic fibroblast, and heparin-binding epidermal growth factors).

Vascular injury leads to neutrophil infiltration within the arterial wall. A reduction in accumulation of neutrophils and smooth muscle proliferation by anti-inflammatory agents results in less neointimal growth. The mechanisms by which neutrophils affect vascular repair are less understood compared with monocytes or macrophages. Neutrophils may cause tissue injury through the release of reactive oxygen species, proteases, or inflammatory cytokines. Vascular smooth cell proliferation can also be stimulated by neutrophils.

**Smooth Muscle Cell Proliferation**

Vascular smooth muscle cell proliferation and migration are central to the development of restenosis and the target for antirestenosis therapies. Thus, it is important to understand two intracellular signaling pathways responsible for the regulation of smooth muscle cell proliferation: the tyrosine kinase cascade and the cyclic adenosine monophosphate (cAMP) pathway. Growth factors bind to the smooth muscle cell receptors and activate tyrosine kinase, which, via a phosphorylation cascade, activates the \( \text{ras/raf/mitogen-activated protein kinase (MAPKK)} \) signal transduction pathway, resulting in intranuclear activation of transcription factors that induce smooth muscle cell proliferation and migration. The cAMP pathway activates protein kinase A (PKA), which also activates the transcription factor cAMP responsive element binding protein (CREB). Additionally, PKA also phosphorylates \( \text{raf} \), which inhibits the other major pathway involved in the activation of smooth muscle cell proliferation. Importantly, inactivation of \( \text{ras} \) by activation of the cAMP pathway leads to a >50% reduction in neointimal formation at 14 days following balloon injury in rat carotid arteries. Similarly, inhibition of MAPKK by a dominant inhibitor mutant gene results in a decrease in neointima formation.

Downstream from these two important signal transduction pathways are other processes that regulate the progression of a smooth muscle cell through
the cell cycle. The progression from the G₀ (ie, quiescent) to G₁ phase is regulated by cyclin-dependent kinases, of which several endogenous inhibitors (eg, p21⁰⁰⁰⁰⁰⁰⁰¹, p27⁰⁰⁰⁰⁰⁰⁰¹, and INK4 families) regulate the process of a smooth muscle cell entering the G₁ phase. For example, vascular inflammation and injury decrease the level of p27⁰⁰⁰⁰⁰⁰⁰¹, which then promotes more cell division. However, cAMP activation leads to increased p27⁰⁰⁰⁰⁰⁰⁰¹ levels and can promote the proliferating cells to enter a quiescent phase.¹³³ Thus, intracellular signaling regulates the conversion of smooth muscle cells to differentiate into myofibroblasts and migration to the site of vascular injury. Histologic analysis demonstrates that these cells form a cap across the site of injury, proliferate toward the tunica media, produce the constituents of the extracellular matrix, and form the neointimal mass.¹³⁷ Importantly, the extent of neointimal formation is determined by the degree of the inflammatory response at the site of vascular injury.¹³⁸

Negative Remodeling

Remodeling is a change in vessel size following vascular injury and is responsible for luminal loss after angioplasty or stenting.⁹⁷,¹³⁹ Following balloon angioplasty, negative remodeling typically occurs within 1 to 6 months and accounts for up to 65% of luminal loss.⁹⁷,¹⁴⁰ The adventitia plays a critical role in both proliferation and concentric compression of the external elastic lamina (ie, negative remodeling).¹⁴¹ Upon injury to the vessel, inflammatory cells stimulate cell proliferation in the adventitia by converting adventitial fibroblasts to myofibroblasts, which begin to secrete components of the extracellular matrix, leading to vessel constriction and formation of a fibrotic scar within the adventitia surrounding the site of injury.¹⁴¹,¹⁴² Thus, the adventitia is not a passive player in the process of restenosis.

Biologic Differences Between Balloon and Stent Injury

Important differences exist between the vascular biologic responses to balloon versus stent injury. As an example, one study demonstrated a significantly higher expression of CD11b expression on neutrophils (ie, inflammatory response) following PCI compared with balloon angioplasty alone.¹⁴³ An increased inflammatory response may amplify neointimal
growth following stent implantation. In animal models, heparin is a well-known modulator of vascular repair and known to reduce neointimal growth following vascular injury after balloon injury or stent implantation.\textsuperscript{144-147} However, a notable difference exists between these mechanisms of vascular injury in animal models. Heparin inhibits neointimal hyperplasia in stented rabbit iliac arteries, only when given in a prolonged fashion (14 days), whereas maximal inhibition of balloon-injured arteries only requires an early and brief duration of heparin therapy (3 days).\textsuperscript{147} One explanation of this difference is suggested by immunohistologic and molecular studies, which demonstrate a distinct pattern of leukocyte infiltration that distinguishes the superficial injury from balloon-induced de-endothelialization from the deep chronic injury associated with stent implantation. In animal models, balloon injury causes early and transient infiltration of neutrophils without monocyte recruitment, whereas stenting leads to an early influx of neutrophils followed by a sustained monocyte accumulation over the ensuing weeks following implantation. These differences are mirrored by molecular studies, whereby MCP-1 and IL-8 are only transiently (ie, hours) expressed following balloon injury compared with sustained expression as late as 14 days following stenting.\textsuperscript{148}

**An Integrated View of the Pathophysiology of Restenosis**

When a balloon is inflated and a stent deployed at the site of a mature atherosclerotic plaque, a cascade of events is initiated (see Fig. 9-8). The first event is an inflammatory phase. Stent placement causes immediate de-endothelialization, crushing of the plaque with occasional dissection into the tunica media or adventitia, and stretching of the entire artery. Due to this injury, platelets and fibrin are deposited at the injured site. Activated platelets layered on the injured surface express adhesion molecules (eg, P-selectin and glycoprotein [GP] Ibα) and bind to circulating leukocytes, which initiates leukocyte rolling along the surface. Leukocytes bind tightly to the platelet receptors through the leukocyte integrin adhesion molecules (eg, Mac-1) and stop rolling after cross-linking with fibrinogen to the GP IIb/IIIa receptor. Migration of leukocytes across the platelet-fibrin layer and diapedesis into the subendothelium are amplified by cytokines released from neighboring
smooth muscle and resident cells. Following the inflammation phase, the granulation or cellular proliferation phase ensues with the release of cellular growth factors from platelets, leukocytes, and smooth muscle cells. Growth factors stimulate smooth muscle cell proliferation and migration from the media to the neointima. Thus, the resultant neointima is composed of smooth muscle cells, extracellular matrix, and macrophages that are recruited over a period of several weeks. Next, the remodeling phase is initiated over a longer period of time and involves extracellular matrix protein degradation and resynthesis and a shift from cellular accumulation to a greater production of extracellular matrix. In the balloon angioplasty era, this phase typically would result in luminal narrowing from negative remodeling. However, stented arteries are resistant to negative modeling due to the rigid scaffolding of the stent. Finally, re-endothelialization of the vessel surface occurs following balloon angioplasty or stenting.

**Neoatherosclerosis**

More recently, it has been demonstrated that some cases of ISR closely resemble atherosclerosis. This process is termed neoatherosclerosis and has been identified pathologically by clusters of foam cells and true thin capped atheromas identified within stents from patients at autopsy. Intravascular imaging techniques have identified lesions consistent with thin-capped fibroatheroma within prior placed stents. In particular, optical coherence tomography has been used, and some studies suggest a frequency of neoatherosclerosis as high as 50%, particularly in cases of DES ISR.

**Therapy for Restenosis**

Since the advent of percutaneous revascularization, therapies for restenosis have been heavily investigated. For years, numerous preclinical studies have shown efficacy against restenosis in animal models but failed in large-scale clinical trials. Finally, agents directed against smooth muscle cell proliferation delivered locally to the site of injury resulted in significant reductions in restenosis and revolutionized current clinical practice.

**Mechanical**
Several mechanical strategies have been employed to reduce the frequency of ISR including: (1) IVUS-guided high-pressure deployment to achieve larger MLD; (2) debulking therapy with rotational atherectomy; and (3) minimizing vessel injury with the avoidance of predilation by “direct” stenting. Although each strategy reduces restenosis rates in small clinical trials, large randomized controlled trials failed to support their overall efficacy. ¹⁵¹-¹⁵³

**Bare Metal Stents**

BMSs were developed as mechanical scaffolding to prevent recoil and negative remodeling for the reduction of restenosis. The rates of major adverse cardiac events and restenosis were significantly lower in patients with stable coronary disease randomized to BMS compared with balloon angioplasty. ⁵² The evidence from several early BMS trials confirmed the superiority of stenting over angioplasty alone. However, persistent high rates of ISR spurred the development of pharmacologic therapies.

**Pharmacologic Therapies**

Therapies directed toward the various pathways implicated in restenosis have been investigated including antithrombotic, anti-inflammatory, and antiproliferative agents. Given the breadth of agents that have been studied for their effect in restenosis, we limit our discussion to agents with established or emerging efficacy.

**Cilostazol**

Cilostazol is an antiplatelet agent predominantly used for the treatment of intermittent claudication. It is a selective inhibitor of phosphodiesterase-3 (PDE-3), which is abundant in platelets and vascular smooth muscle cells. Inhibition of PDE-3 increases intracellular cAMP and PKA activation to reduce platelet activation/aggregation, increase smooth muscle cell relaxation and cardiac contractility, and inhibit smooth muscle cell proliferation. ¹⁵⁴ Nonrandomized studies demonstrated that cilostazol was associated with a reduction in restenosis in patients who underwent balloon angioplasty or stenting. ¹⁵⁵ In the Cilostazol for Restenosis (CREST) trial, patients randomized to cilostazol following BMS had significantly larger MLD and reduced ISR (>50% diameter stenosis) compared with patients randomized to
A meta-analysis of 10 randomized studies supports the use of cilostazol for the reduction of ISR.\textsuperscript{157}

**Drug-Eluting Stents**

Local drug delivery has important advantages for the treatment of restenosis, namely, that drugs can be delivered at high doses locally without systemic toxicity. DESs predictably elute high doses of a therapeutic agent to reduce smooth muscle proliferation that is undetectable in the peripheral blood.\textsuperscript{158} The process of local drug delivery is complex and dependent on the dose, rate of release, tissue retention, and pharmacologic properties of the drug. Lower doses can be ineffective, whereas higher doses may result in tissue death, delayed healing, and higher rates of thrombosis.\textsuperscript{159,160} Prior studies determined that faster drug release is less effective at reducing LLL compared with slower release.\textsuperscript{161} Drugs can be directly bound to the stent. However, the majority of DESs use a polymer to store and time-release the drug. Nonerodable polymers were developed for effective drug delivery over a period of time and to not, by themselves, stimulate any additional inflammation or cell proliferation. The polymer release kinetics are critical to the prevention of ISR. In the Paclitaxel In-Stent Controlled Elution Study (PISCES), 10 or 30 μg of paclitaxel released over 10 days after DES implantation had little effect on neointimal formation, whereas 10 μg released over a 30-day period significantly reduced neointimal formation and LLL.\textsuperscript{162} Early clinical studies like PISCES supported the concept of a drug threshold with delivery over a sustained period of time to inhibit inflammation and smooth muscle cell proliferation.\textsuperscript{163} DESs are the preferred treatment for ISR. Compared with angioplasty, DESs significantly reduce the rate of restenosis and LLL in patients presenting with ISR.\textsuperscript{164} An emerging device for the treatment of ISR is the use of drug-coated balloons to deliver antirestenotic pharmacotherapy without the use of a polymer or metal scaffold.\textsuperscript{165} For the purposes of this chapter, we will introduce the pharmacologic agents used in DES and their mechanisms of action. In subsequent chapters, a review of the clinical trials related to DES and emerging technologies will be described in detail.

**Sirolimus**
Sirolimus (rapamycin) is a natural macrocyclic lactone with potent immunosuppressive and antimitotic action produced by a fungus, *Streptomyces hygroscopicus*. It binds to FK binding protein-12 (FKBP-12), forming an immunosuppressive complex that inhibits mTOR, which leads to higher levels of p27$^{kip1}$, blocking the G$_1$-S transition in the cell cycle and halting vascular smooth muscle cell proliferation.$^{166}$ Several pivotal trials conducted with sirolimus-eluting stents (SESs) led to US Food and Drug Administration (FDA) approval in April 2003. In the Randomized Study With the Sirolimus-Eluting Velocity Balloon-Expandable Stent (RAVEL) trial, SES demonstrated significant reductions in LLL, neointimal hyperplasia, and ISR compared with BMS at 6-month follow-up.$^{167}$ At 1 year, SES also reduced the rate of major adverse cardiac events compared with BMS.$^{63}$ The Sirolimus-Eluting Stent in De Novo Native Coronary Lesions (SIRIUS) trial recruited patients with more complex CAD and a higher prevalence of diabetes mellitus.$^{168}$ In SIRIUS, SES reduced the rates of LLL and ISR compared with BMS, and these finding were consistent across high-risk subgroups for restenosis including small vessels, long lesions, and diabetes mellitus.$^{168,169}$

**Paclitaxel**
Paclitaxel is isolated from the bark of the Pacific yew tree (*Taxus brevifolia*) and inhibits microtubule depolymerization, resulting in inhibition of cellular replication and cytokine-mediated smooth muscle cell proliferation and migration. The efficacy of paclitaxel-eluting stents (PES) was demonstrated in the TAXUS trials, where PES reduced ISR, TLR, and adverse cardiac events compared with BMS.$^{170-173}$ These benefits were maintained in specific subgroups, including patients with vessel diameters $<2.5$ mm, lesion lengths $>20$ mm, renal insufficiency, and diabetes mellitus.

**Everolimus**
Everolimus is a 40-O-(2-hydroxyethyl) derivative of sirolimus and shares the same mechanism. Abbott Vascular (Temecula, CA) produces several everolimus-eluting stent (EES) in the Xience family of DES, the latest of which are called Xience Expedition and Alpine. EESs are also produced by Boston Scientific (Marlborough, MA) as the Promus Element and Premier stent systems. In a pooled analysis of the SPIRIT (Clinical Evaluation of the
Xience V Everolimus Eluting Coronary Stent System) and COMPARE (A Trial of Everolimus-Eluting Stents and Paclitaxel-Eluting Stents for Coronary Revascularization in Daily Practice) trials, EES reduced the rates of death or MI, stent thrombosis, and ischemic-driven TLR compared with PES in patients with ACS and stable CAD at 2-year follow-up.\textsuperscript{174} EES has similar clinical outcomes (ie, major adverse cardiac events and TLR) compared with SES and a lower rate of definite stent thrombosis.\textsuperscript{175}

**Zotarolimus**

Zotarolimus is an analogue of sirolimus with a similar mechanism of action that was initially designed to have a short half-life.\textsuperscript{176} The FDA approved the Endeavor zotarolimus-eluting stent (ZES) platform in 2008 after reviewing the Medtronic (Minneapolis, MN) ENDEAVOR clinical program. Importantly, the Endeavour ZES elutes >95\% of the drug within 14 days. In a combined analysis of the ENDEAVOR trials, Endeavour ZES was associated with a significantly lower rate of adverse cardiac events (death, MI, and very late stent thrombosis) compared with a pooled cohort of SES and PES patients (ie, first-generation DES).\textsuperscript{177} Endeavour ZES did have a higher rate of angiographic restenosis compared to first-generation DES, but this did not translate into a higher rate of TLR.\textsuperscript{177} The Resolute ZES was developed by Medtronic with substantially longer polymer drug release kinetics (180 days). In the RESOLUTE All-Comers trial, the clinical outcomes were comparable between Resolute ZES and EES.\textsuperscript{178}

**Biolimus**

Biolimus A9 is an analogue of rapamycin that binds to mTOR and inhibits smooth muscle cell proliferation by blocking cell cycle progression between the G\textsubscript{1} and S phases.\textsuperscript{179} Currently, 2 stents platforms, Biomatrix and Nobori, have received approval in Europe. Unique to these stent platforms is the use of a bioabsorbable polymer that is completely dissolved by 6 to 9 months following stent implantation.

**Brachytherapy**

Intracoronary brachytherapy effectively reduces neointimal proliferation and rates of ISR.\textsuperscript{180-183} Since the introduction of DES, the use of brachytherapy
for ISR is uncommon and only performed at specialized tertiary referral centers. The practical difficulty in scheduling the procedure between radiation oncologists and the catheterization lab, reduced availability at tertiary centers, and increased rates of subacute thrombosis have deterred widespread acceptance of intracoronary radiation into clinical practice for ISR of DES.\textsuperscript{184,185}

**CONCLUSION**

Over the past decades, the molecular and cellular pathophysiology of atherosclerosis has been extensively studied. Our current understanding of plaque vulnerability and the mechanisms responsible for conversion from a stable plaque to plaque rupture and atherothrombosis has shaped the landscape of pharmacotherapy and interventional cardiology for the treatment of ACS. Inflammation plays a central role in the pathogenesis of atherosclerosis and restenosis. Important molecular and biologic differences exist between atherosclerosis and restenosis. Recognition of the differences in the biologic response to vascular injury between balloon angioplasty and stenting led to the development of local drug delivery and DES for the prevention of restenosis. Improved understanding of the molecular mechanisms of atherosclerosis and restenosis, identification of plaques prone to rupture, and more effective methods to treat restenosis will continue to advance the field of interventional cardiology.

**MULTIPLE CHOICE QUESTIONS**
1. Sectioning of atherosclerotic lesions at postmortem can reveal the architecture of atherosclerotic plaques. Which of the following would typically be present in plaques at low risk of rupture?
   A. Thin fibrous cap
   B. Abundant expression of collagen fibrils
   C. Abundant free cholesterol esters
   D. Abundant inflammatory cells
   E. High concentration of matrix metalloproteinases

2. Immune cells can be divided into those involved in the adaptive response and the innate response to antigens. Which of the following cell types belongs to the innate response?
   A. Macrophages
   B. Platelets
   C. Dendritic cells
   D. T lymphocytes
   E. Mast cells

3. A 55-year-old man presents with increasing angina despite best medical therapy. A high-grade lesion is identified in the proximal left anterior descending artery (LAD) with a minimal lumen diameter of 0.5 mm. After stent placement, the diameter is increased to 3.5 mm. The patient returns at 6 months with recurrent angina, and an angiogram shows a minimal lumen diameter of 1.5 mm. What is the loss index?
   A. 0.1
   B. 0.25
   C. 0.33
   D. 0.5
   E. 0.66

4. You are performing catheterization on a 65-year-old man who is 1 year out from bare metal stent placement in the LAD in the setting of an acute anterior myocardial infarction (MI). He now presents with stable angina on a maximal medical regimen, and a recent exercise tolerance test combined with a sestamibi scan revealed ischemia in the left circumflex coronary artery (LCX) territory. Catheterization reveals 50% in-stent restenosis in the prior placed LAD stent and a new long 80% lesion in a
2.5-mm LCX artery. What is the most appropriate strategy?
A. Treat the LCX lesion with a drug-eluting stent (DES). Defer therapy of the LAD.
B. Treat the LCX lesion with DES. Treat the LAD lesion with DES as well, given the evidence of restenosis.
C. Treat the LCX lesion with DES. Treat the LAD lesion with plain balloon angioplasty (POBA) and brachytherapy, given evidence of restenosis.
D. Recommend urgent coronary artery bypass grafting (CABG) given restenosis in the LAD, marking the patient as a poor candidate for percutaneous coronary intervention (PCI).

5. The pathogenesis of atherosclerosis has many similar features to the development of restenosis. Which of the following features would help differentiate a restenotic lesion from a primary atherosclerotic lesion?
   A. Time course
   B. Inflammatory cell involvement
   C. Smooth muscle cell proliferation
   D. Adhesion molecule expression

**ANSWERS**

1. B
Vulnerable plaques are characterized by thin fibrous caps, which are relatively poor in smooth muscle cells (SMCs) and extracellular matrix proteins (such as collagens), and large lipid-rich necrotic cores, which are abundant in inflammatory cells.

2. D
The immune response can be divided into the innate immune response, which is an immediate response to foreign antigens and injury and is largely based on phagocytic cells and preformed mediators, and the adaptive response, which is a learned response to specific antigens and involves cell-mediated and humoral immune responses. The innate immune response has traditionally been thought of as the major player in atherosclerosis, with
macrophages being the predominant cell type. However, there is mounting evidence for an important role for the adaptive response as well, as evidenced by the presence of T cells within atherosclerotic plaques.

3. E

Loss index is equal to the late loss divided by acute gain. The acute gain in this example is 3 mm and the late loss is 2 mm. Therefore, the loss index is 2/3 or 0.66.

4. A

The lesion in the LCX is long and in a small-caliber vessel, marking it as high risk for restenosis when treated with either POBA or bare metal stent. Treatment with DES is appropriate. Data would suggest that most cases of restenosis will occur within the first 6 to 12 months. There is no reason to suspect that the LAD restenosis will proceed to a clinical significant degree, and there is no evidence of ischemia in that territory. Neither PCI nor CABG to address the LAD is warranted. Conservative management of this lesion is most appropriate.

5. A

As with atherosclerosis, the mechanisms of restenosis involve an inflammatory response to injury involving leukocyte recruitment amplified by the release of cytokines and growth, which eventually lead to smooth muscle cell proliferation and migration. However, in contrast to atherosclerotic plaques, restenosis is termed an accelerated arteriopathy with a time course that is measured in months as opposed to decades.
The catheterization laboratory continues to evolve with time, initially concentrating on hemodynamic assessment of the heart and, in particular, valvular heart disease, before becoming very “coronary-centric” with the advent of balloon angioplasty and the heightened prevalence of coronary artery disease. As we enter the next phase of evolution, the catheter-based treatments of structural heart disease are bringing back some of the early lessons of the importance of ventricular performance and its evaluation. Complicating the transition is the need to synthesize information across multiple noninvasive and invasive modalities of cardiac assessment to determine clinical decision making for individual patients.

Left ventricular dysfunction may occur in the setting of impairment of systolic performance, diastolic performance, and/or abnormal hemodynamic loading conditions. Although, an in-depth understanding of left ventricular mechanics does not directly translate into improved day-to-day clinical practice for the interventional cardiologist, a general understanding of the factors impacting left ventricular performance remains imperative to appropriate therapeutic decisions.

INVASIVE ASSESSMENT OF GLOBAL LEFT VENTRICULAR FUNCTION: THE LEFT VENTRICULOGRAM
In the cardiac catheterization lab, ventricular pathophysiology is most frequently recognized by the performance of left ventricular (LV) wall motion seen on the left ventriculogram. The left ventriculogram visually portrays the relationship between stroke volume and the end-diastolic volume, and either quantitatively or qualitatively, an ejection fraction is determined. Universally, ejection fraction has been accepted as an estimate of the global LV contractile state. Furthermore, an assessment of regional LV function by wall motion on ventriculography has become an essential part of every cardiac catheterization.¹

Qualitative assessment of LV function rests on the visual appreciation between stroke volume and end-diastolic volume. An increase in end-diastolic volume (ie, dilated LV chamber size) is commonly seen in patients with volume overload states (eg, aortic insufficiency). However, stroke volume (ie, the difference between end-diastolic and end-systolic volumes, also known as ejection fraction) is dependent on the myocardial contractile state and, in part, loading conditions. A reduction in the ventricular contractile state may be secondary to intrinsic myocardial disease (ie, nonischemic cardiomyopathy) or may be secondary to coronary artery disease and its associated regional wall motion abnormalities.

Depressed regional wall motion, defined as hypokinesis, reflects a decrease in the contractile state of a particular region of the left ventricle. Noncontraction of a region (akinesis) or outward contraction of a segment during systole (dyskinesis) may reflect the occurrence of a prior myocardial infarction.² Commonly, the left ventricle is imaged in a right anterior oblique projection, giving good assessment of the anterior-basilar, anterolateral, apical, diaphragmatic, and posterior-basilar segments (Fig. 10-1). In select cases involving the lateral LV wall, the left anterior oblique projection is used to estimate the lateral, posterior, and septal walls. Assessment of regional wall motion is critical to risk stratification and management of patients with coronary artery disease.
Several methods are available to quantify the measurement of ejection fraction from the angiographic image by online software. One method is the so-called area-length method. This method assumes an ellipsoid shape to the ventricle. Calculations of ventricular volume are made from the end-systolic frames and end-diastolic frame using the dimensional measurements of the ventricle. Regression equations correct for the overestimation of the calculated volume to the true volume. A second method, the center line method, has also been used because of its ability to quantify both regional wall motion as well as ejection fraction. This method does not assume a geometric configuration of the ventricle and measures the shortening fractions of 100 chords, which are constructed perpendicular to a centerline.
that is drawn midway between the end-diastolic and end-systolic contours.

Despite the wealth of information obtained during the performance of ventriculography, practice patterns are highly variable with respect to its current performance. In a recent evaluation of practices across Veterans Affairs (VA) catheterization labs over the years 2000 to 2010, more than 450,000 catheterizations were performed, and only 58% of those procedures involved left ventriculography. In fact, when looking at the trend of performance over that decade, there was a significant drop over time (Fig. 10-2). Furthermore, there was marked variation among VA facilities in the frequency of performance of ventriculography that could not be explained by patient or clinical factors. Thus, the operator preferences seemed to predominate regarding obtaining ventriculography.

**NONINVASIVE ASSESSMENT OF LEFT VENTRICULAR FUNCTION**

In current practice, there are multiple options available to the operator in assessing LV function, and often, patients present to the catheterization lab
with prior noninvasive testing. In an evaluation of a health maintenance organization population, more than 90,000 catheterization procedures performed over the course of a year were administratively evaluated. Almost 82% of these patients had concomitant performance of left ventriculography, despite the fact that 41% of these same patients had already had noninvasive assessment within the preceding 30 days. Although this does not in itself allow conclusions to be drawn on an individual case-by-case basis, operators must be versed in the value of the noninvasive imaging testing performed prior to catheterization.

Transthoracic echocardiography has become a standard tool for the assessment of LV function. As with cardiac ventriculography, echocardiography allows the assessment of global LV function as well as regional wall motion in the 3-dimensional chamber. Furthermore, it has the ability to better assess coexistent valvular disease (whereas ventriculography essentially only evaluates for mitral regurgitation), especially for aortic and mitral pathology. In addition, assessment of the tricuspid regurgitation jet permits an estimate of right ventricular pressure and systolic function, which can alert the clinician to impaired hemodynamics that may require further evaluation. Furthermore, analysis of mitral inflow patterns and tissue Doppler signals gives great insight into ventricular mechanics, including diastolic dysfunction and restrictive physiology. Radionuclide ventricular imaging also possesses the ability to measure LV volume, ejection fraction, and regional wall motion by the adaptation of gated image acquisition techniques. By the same token, recent advances in contrast computed tomography and magnetic resonance imaging technologies have provided these noninvasive imaging techniques with the ability to evaluate LV size and function.

A large number of clinical trials have been performed to show the reliability of ejection fraction assessed by both radionuclide imaging and echocardiography. In a clinical practice, single-center cohort of unselected patients, there was a close correlation between measurements by these modalities and invasive ventriculography. There tended to be an overestimate of ejection fraction by echocardiography in the lower range of the measurements compared with ventriculography. Furthermore, nuclear imaging tended to overestimate ejection fraction compared with ventriculography at the lowest values and underestimate it at the higher values. Although all 3 modalities have some variability and are not interchangeable in a 1-to-1 fashion, the absolute variability between
measurements was not found to affect clinical decision making.

INVASIVE HEMODYNAMIC ASSESSMENT OF THE LEFT VENTRICLE

Pressure-Volume Relationships

A great deal of work has been done in evaluating the interdependence of the multiple factors affecting overall LV performance. The earliest means to understanding LV pump function was the assessment of the LV pressure-volume loop (Fig. 10-3).9,10 The lower portion of this loop (from left to right in Fig. 10-3) illustrates ventricular filling from the opening of the mitral valve (D) to end diastole (A). A steep increase in pressure occurs from end diastole to the opening of the aortic valve (B), and this is represented on the right side of the loop. The top of the loop begins at aortic valve opening (right to left) and ends at aortic valve closing (C), representing the stroke volume. The left side of the loop represents isovolemic relaxation between the closure of the aortic valve and the opening of the mitral valve.

FIGURE 10-3 A representation of a left ventricular pressure (on y-axis)—volume (on
x-axis) loop. End diastole is seen at point A and end systole at point C. Diastole occurs between points D and A, whereas systole occurs between points B and C. The total of the loop is representative of left ventricular stroke work.

The area of the pressure-volume loop represents LV stroke work, which remains a good surrogate for LV systolic function under the loading conditions present when the pressure-volume curve was obtained. One of the main drawbacks in using stroke work as an estimate for LV function is that loading conditions do not remain constant outside the experimental lab. Furthermore, stroke work represents a global estimate of LV performance and, as such, does not take into account regional differences in function that are frequently present in patients with established coronary artery disease.

The end-systolic pressure-volume relationship (ESPVR) has also been established as a marker of the overall contractile state of the ventricle. This relationship is constructed by producing multiple pressure-volume loops over varying loading conditions. A line can be drawn that connects the upper left portion of each loop (Fig. 10-4), and the slope of this line represents the ESPVR. In general, a shift in the ESPVR to the left with an increased slope is associated with an increase in contractility, whereas a decrease in slope with a rightward shift to the line is associated with decreased contractility.

**FIGURE 10-4** Multiple pressure-volume loops from the same ventricle under varying loading conditions or inotropic states can be drawn. The line that intersects all end-systolic points (Ees) is the end-systolic pressure-volume relationship (ESPVR). The
greater the slope of the line, the greater is the contractility of the ventricle. Ed, end diastole; LV, left ventricular. (Reproduced with permission from Chen CH, Nakayama M, Nevo E, et al. Coupled systolic–ventricular and vascular stiffening with age: implications for pressure regulation and cardiac reserve in the elderly. J Am Coll Cardiol. 1998;32:1225.)

LV diastolic function can also be readily appreciated by looking at the lower portion of the pressure-volume loop (see Fig. 10-3).\textsuperscript{15,16} With an increase in LV stiffness, the curve shifts upward, and with an increase in ventricular compliance, the curve moves downward along the y-axis.

**Ventricular Loading Conditions**

LV systolic function is intimately tied to loading conditions. Preload represents the load that stretches the ventricular myofibrils during diastole, and it has been quantified in the patient as the LV end-diastolic pressure. Increasing preload tends to increase the LV diameter, whereas its effects on overall function depend on the ventricle’s ability to accommodate this stretch. This ability to distend can be estimated by evaluating the ventricular diameter and extrapolating the concepts derived from the Frank-Starling curve (Fig. 10-5).
Afterload represents the force that resists the systolic contraction of the ventricle. The calculation of systolic wall stress by the Laplace law \[ \text{stress} = \frac{\text{pressure} \times \text{chamber radius}}{\text{wall thickness}} \] is generally thought to represent ventricular afterload. One caveat that applies is that this wall stress varies during systole.\(^{17,18}\) Therefore, the end-systolic wall stress remains as the best representative of afterload. Increasing afterload, in general, tends to decrease the stroke volume.

The intrinsic property of the myocardium to forcefully eject blood and do work is represented by the term \textit{contractility}. Classically, contractility is independent of preload and afterload. However, from a practical standpoint, it
is difficult to evaluate these parameters independently. Contractility, also described as inotropy, is affected by circulating catecholamines or pharmacologic agents (eg, dobutamine, β-blockers). The maximal rate of rise in LV systolic pressure per unit time (dP/dt) remains the best estimate of contractility. Increases in dP/dt are seen with exercise, norepinephrine, and isoproterenol. Although dP/dt remains as an excellent marker of ventricular contractility, its measurement in the catheterization lab requires a micromanometer catheter capable of high-frequency signal differentiation, an impractical situation in the clinical lab where fluid-filled catheters coupled to electrical strain gauges are in daily use. Thus, dP/dt is not routinely assessed.

**Left Ventricular End-Diastolic Pressure**

Proper evaluation and interpretation of LV end-diastolic pressure (LVEDP) can give the operator a strong indication of the hemodynamic health of the left ventricle without performance of ventriculography or the more complex assessment of pressure-volume relationships. First, evaluation of the trend across the diastolic portion of the LV pressure curve provides assessment of ventricular relaxation. Abnormal relaxation of diastolic dysfunction can then be exhibited by a low overall LVEDP with a decline in the diastolic pressure tracing over the diastolic phase (Fig. 10-6). Conditions such as concentric hypertrophy due to valvular stenosis, restrictive or infiltrative cardiomyopathy, or other diseases of the ventricular muscle will produce a stiffer chamber and an overall elevated LVEDP. Thus, recognition of abnormalities in the LVEDP can lead to dramatically different treatments for a given patient—from preload reduction to a ventricular assist device.

Schematic representation of the normal left ventricular (LV) diastolic pressure tracing depicting a nadir and end systole with a gradual upslope throughout the diastolic period culminating in a reflected “a” wave corresponding to atrial contraction. EKG, electrocardiogram. (Reproduced from Applegate RJ, Rankin KM, Powers JC, Little WC. Evaluation of diastolic function. Catheter Cardiovasc Interv. 2001;53:85-93.) B. Example of abnormal diastolic function as assessed by left ventricular pressure. Note the low overall left ventricular end-diastolic pressure (LVEDP) and the declining nature of this pressure during the diastolic phase. C. Left ventricular pressure tracing demonstrating marked elevation in overall LVEDP.

CORONARY ARTERY DISEASE AND LEFT VENTRICULAR DYSFUNCTION

Coronary artery disease remains the most prevalent diagnosis among patients requiring cardiac catheterization. As previously discussed, coronary artery disease usually manifests itself in regional ventricular wall motion abnormalities. In an acute setting, the wall motion abnormality may give early clues to the coronary artery involved as well as the location of the offending lesion. Severe degrees of LV dysfunction may represent the etiology of cardiogenic shock, in which the heart is unable to maintain enough forward perfusing pressure to supply blood.

Mechanical complications of acute myocardial infarction or acute coronary syndromes that compromise LV function can be detected by left ventriculography, including most notably, the occurrence of mitral regurgitation secondary to papillary muscle dysfunction and/or papillary muscle rupture, ventricular pseudoaneurysm formation, ventricular free wall rupture, and ventricular septal defects. Although the incidence of these complications is rare, it is important to recognize their existence. Early surgical intervention will decrease the morbidity and mortality associated with these conditions. Although left ventriculography per se may not routinely be performed in all patients presenting with acute myocardial infarction and/or acute coronary syndromes, the assessment of LV function remains one of the strongest predictors of short- and long-term survival in patients. Therefore, it is of critical importance to obtain either an angiographic or an echocardiographic assessment of global and regional LV function in all patients under these conditions. Furthermore, with the complex nature of myocardial necrosis with myocardial stunning, follow-up
assessment of regional and global LV function also becomes paramount in
the estimate of overall survival after primary reperfusion strategies (Fig. 10-
7).^{25}

McDermott M, et al. Interrelation of left ventricular ejection fraction, pulmonary

The patient presenting with angina-like symptoms and/or an abnormal
stress test represents the most common presentation to the cardiac
catheterization laboratory. Assessing the patient’s coronary anatomy with the
goal of improving myocardial perfusion either by coronary artery bypass
grafting or percutaneous coronary intervention remains the principal initiative
in these cases. Ventricular performance weighs heavily in the decision-
making process of revascularization techniques (Fig. 10-8).^{26-28}
Systolic LV function (ie, LV ejection fraction) has been well established as a strong independent predictor of outcomes in all cardiac patients. It is especially evident in patients with coronary artery disease in whom LV dysfunction is manifest in congestive heart failure symptomatology. The Coronary Artery Surgery Study registry firmly established that benefits of coronary artery bypass surgery were more pronounced in most patients with moderate-to-severe depression of global ejection fractions (Fig. 10-9). In fact, in this patient population, upwards of 40% of the patients will have significant improvements in their ejection fraction over time following coronary vascularization presumably secondary to the presence of hibernating but viable myocardium. Given these findings, all patients with coronary artery disease and severe LV dysfunction are evaluated for possible revascularization.
When combining data from noninvasive assessment of LV function with invasive angiography, Gimelli et al\textsuperscript{8} compared the predictive ability of this assessment by echocardiography, ventriculography, and nuclear perfusion imaging. Within their study population, clinical factors such as age, sex, history of angina, and previous infarction were shown to have a good prediction of patient survival ($\chi^2 = 35.7$). Ejection fractions as assessed by echocardiography ($\chi^2 = 38.8$) or ventriculography ($\chi^2 = 39.9$) were also highly predictive of survival, but not dramatically different than by using the clinical features alone. However, the investigators found that nuclear perfusion imaging–derived ejection fraction predicted survival the best ($\chi^2 = 40.6$, $P = .039$ vs other models using likelihood ratio test). Thus, operators
must take into account clinical variables, as well as ejection fraction if available from noninvasive imaging or from ventriculography, in assessing clinical treatment options in patients with coronary artery disease.

As suggested by the Bypass Angioplasty Revascularization Investigation (BARI) study, diabetic patients with LV dysfunction associated with 2- or 3-vessel coronary artery disease remain best treated by coronary artery bypass surgery compared to percutaneous coronary intervention (Fig. 10-10). Furthermore, decreased LV function has been proven to be an independent negative risk predictor for patients undergoing percutaneous revascularization or coronary artery bypass grafting.

### FIGURE 10-10

INTRODUCTION

Fluoroscopic radiation is a carcinogen that can also cause severe injury (“radiation burns”) in patients and practitioners. Figures 11-1 through 11-4 illustrate the severe effects of radiation. All effects pictured were caused by radiation associated with fluoroscopy. Note the characteristic demarcation of injuries with sharp borders, a feature usually but not always associated with severe radiation effects from fluoroscopy.
**FIGURE 11-1** Breast cancer and skin injuries induced by fluoroscopically guided intervention for pulmonary tuberculosis. (Adapted with permission from MacKenzie I. Breast cancer following multiple fluoroscopies. *Br J Cancer*. 1965;19:1-8.)

Figure 11-1 is a breast cancer caused by fluoroscopically guided interventional procedures performed to cure pulmonary tuberculosis in the mid-20th century. Chronic radiation dermatitis is also readily apparent in this picture, taken in the 1960s approximately 10 to 15 years after exposure to the radiation.

Figure 11-2 shows a deep necrotic wound following 2 ablation procedures 6 and 10 months previously. The ribs underlying the wound necrosed at about 4 years after the procedure. Advances in cardiac mapping during electrophysiologic procedures have mitigated the need for long-duration fluoroscopy and have reduced the likelihood of such effects in these patients.
FIGURE 11-2 Deep skin wound following 2 ablation procedures separated by 4 months and having occurred 6 and 10 months previously. Wound progressed into deep tissue necrosis and osteoradionecrosis of the ribs, shown approximately 4 years after procedures. (Copyright retained by patient and figure reproduced with permission.)

Figures 11-3 and 11-4 are skin injuries in patients who underwent fluoroscopically guided invasive cardiologic procedures. The patient in Figure 11-3 underwent coronary angioplasty and stent placement involving 63 minutes of fluoroscopy and about 5000 frames of cine fluorography. The affected skin area required a full-thickness graft. The patient in Figure 11-4 underwent a prolonged procedure for coronary artery intervention. Both cases involved x-ray irradiation with the x-ray beams oriented in a fixed trajectory for long periods of time, resulting in very high doses to the affected areas.

FIGURE 11-3 Injury following percutaneous transluminal coronary angioplasty (PTCA) and stent placement involving 63 minutes of fluoroscopy and nearly 5000 frames of cine. This left anterior oblique (LAO) view with cranial tilt resulted in a large entrance dose build-up in the lower right back. The injury required grafting. (Adapted with permission from Wagner LK. Radiation dose management in interventional radiology. In: Balter S, Chan R, Shope T, eds. Interventional Brachytherapy—Fluoroscopically Guided Interventions (American Association of Physicists in Medicine Monograph #28). Madison, WI: Medical Physics Publishing; 2002;195-218.)
The first radiation injury related to interventional cardiology occurred in 1990. By September 1994, the US Food and Drug Administration (FDA) had issued a warning to physicians and healthcare providers about occasional but severe radiation injuries in patients undergoing certain fluoroscopically guided interventional procedures. The warning described the nature of these injuries and provided numerous recommendations on how to avoid them. Many, but not all, of those recommendations are addressed in this chapter.

The FDA has since retired this warning, but their recommendations to physicians and facilities regarding the need to pursue a high level of quality radiation management for medical procedures remains and is available on their website (http://www.fda.gov/Radiation-EmittingProducts/RadiationEmittingProductsandProcedures/MedicalImaging/Rays/ucm115354.htm#imagingteam). In the years since the FDA warning, hundreds of serious radiation-induced injuries have occurred. Many have been reported in the medical literature.2,3,5-15

Many medical practitioners of the 20th century accumulated considerable
radiation doses during their medical practice and developed radiation-induced cancer, cataracts, or skin injury. The modern interventional radiation environment creates conditions conducive to the accumulation of high doses in personnel. Attention to rigorous radiation abatement measures is therefore warranted and required.

When fluoroscopy is well managed, the likelihood that these severe effects could occur is extremely low. However, when it is not well managed, the carcinogenic risk to both personnel and patient is higher than necessary, and the risk for injury to the patient increases. The goal of this chapter is to discuss factors involved in the careful management of fluoroscopic and fluorographic radiation.

**QUANTIFICATION OF RADIATION LEVELS**

No discussion of radiation management is meaningful without a clear understanding of the quantities used to measure or describe radiation levels. In particular, a well-honed understanding and use of the concepts of air kerma, absorbed dose, equivalent dose, effective dose, and dose area product are essential. Table 11-1 summarizes the relevant quantities.

| **Table 11-1** Relevant Radiation Quantities |
Air kerma relates to how much radiation is present at a specific location. The presence of x-rays at any location can be measured by analyzing the ionization they produce in air at that location. Because energy must be transferred to create ions in air, air kerma is defined as the concentration of energy released by the x-rays in air. The special unit of air kerma is the gray (Gy) or milligray (mGy). One gray of air kerma is the same as 1 joule of energy released in 1 kilogram of air. One manufacturer sometimes reports air kerma in units of microgray (μGy). Air kerma is used to monitor and manage

</table>

\(^a\)The physician should be aware that air kerma can be presented in two separate ways. Incident air kerma is the kerma to air from an incident x-ray beam measured on the central beam axis at the position of the patient and excludes backscattered radiation. Entrance surface air kerma is the kerma to air from an incident x-ray beam measured on the central beam axis at the position of the patient with backscattered radiation included. The two may differ from each other by as much as 40%.

\(^b\)Exposure and air kerma are both used for the same purpose. Exposure used to be the most common measure, but with the switch to international units, air kerma is the preferred unit.

\(^c\)For x-rays, gamma rays, and electrons, there is no difference between absorbed dose and equivalent dose (ie, 1 mGy = 1 mSv). This is not the case for neutrons and alpha particles, but these radiation types are not relevant to x-ray exposure. The important issue is that cardiologists recognize that for their interests, there is no practical difference between a measurement of mGy and that of mSv.

\(^d\)Adapted from Hirshfield JW, Balter S, Brinker JA, et al. ACCF/AHA/HRS/SCAI clinical competencies statement on optimizing patient safety and image quality in fluoroscopically guided vascular interventions: A report of the American College of Cardiology/American Heart Association/American College of Physicians Task Force on Clinical Competence (ACCF/AHA/HRS/SCAI Writing Committee to Develop a Clinical Competence Statement on Fluoroscopy). radiation delivery to patients, as discussed later.

Instantaneous air kerma and cumulative air kerma differ only in the temporal interval or sequence over which all air kerma is delivered. When air kerma is measured at some reference position in space, the air kerma is said to be instantaneous if it is measured over a short interval of time, usually on the order of seconds or less. When multiple short radiation exposures occur or when several long exposures occur, the cumulative air kerma is the summation of all air kerma measurements over the entire procedure time.

**Absorbed Dose**

Absorbed dose is used to assess the potential risk for stochastic and deterministic effects in specific tissues. *Absorbed dose* is the concentration of radiation energy transferred to and absorbed by a particular tissue. Specifically, as x-rays pass through tissues, they interact with the biologic matter, and this transfers energy that causes molecular changes. These changes can potentially lead to biologic effects. Assessing the concentration of energy deposited in the specific tissue provides a measure of the amount of biochemical disruption, and thus a measure of risk for biologic effects. The special unit of absorbed dose is the gray, and 1 Gy is the same as 1 J of energy concentrated in 1 kg of tissue.

Absorbed dose and air kerma are measured in the same units of gray, but they are not the same thing. There is no fixed relationship between the two, but there are some rules of thumb. For instance, the absorbed dose to the skin of a patient is about 40% greater than the air kerma at the location of the skin when the air kerma is measured under the same radiation output conditions but without the patient present.

**Equivalent Dose**

*Equivalent dose* is an estimate of the biologic potency that a particular radiation might have for an absorbed radiation dose delivered by that radiation. Equivalent dose is the quantity usually quoted in radiation safety reports for doses to the hands or to the eyes of personnel. For radiations other than x-rays, equivalent dose can be quantitatively greater than the absorbed dose and is specified in units of sievert (Sv) or millisievert (mSv). Because cardiologists do not apply other types of radiation during interventional work,
this quantity is used solely to communicate radiation safety doses. For our purposes in interventional cardiology, 1 Sv of equivalent dose is the same as 1 Gy of absorbed dose. (It should be remembered that this is not true for other specialties, like radiation therapy, where neutron radiation might be used.) Thus, *equivalent dose* is a radiation safety term that, for our purposes, carries the same risk as the absorbed dose in gray.

Many radiation safety reports for personnel exposures still use outdated units of *millirem*. To convert the dosimetry to units of millisievert, just divide the value in millirem by 100. That is, 100 millirem are equal to 1 millisievert.

**Effective Dose**

*Effective dose* is used to relate the potential for stochastic risk to an individual from an exposure to radiation, regardless of the spatial nonuniformities of the exposure. For example, interventionalists wear lead aprons to protect themselves. When an interventionalist is exposed in the laboratory, the arms, legs, and head are not as well protected from radiation as are the internal organs under the apron. Therefore, the spatial distribution of the radiation throughout the interventionalist’s body is very nonuniform. This is permitted because the exposed limbs and head are not as radiosensitive as thoracic and abdominal organs. The risk associated with such an exposure is not well specified by absorbed dose because low-sensitivity limbs receive a much higher dose than sensitive organs in the thorax and abdomen.

Effective dose attempts to remove this complexity in risk assessment. Effective dose is a hypothetical dose that would have to be delivered uniformly to an interventionalist’s entire body to yield the same numerical risk for stochastic effects as the nonuniform dose actually delivered. Thus, as a hypothetical uniform whole-body dose, effective dose is a risk descriptor that permits us to compare the risk associated with any type of nonuniform exposure to that of any other nonuniform exposure.

Derivation of effective dose from the nonuniform exposure is complex and not within the scope of this chapter. (For a more complete description, see the International Commission on Radiological Protection Report No. 103 entitled “The 2007 Recommendations of the International Commission on Radiological Protection.”[22]) The important thing to know is that effective dose allows assessment of stochastic risks from nonuniform dose deliveries. The special unit of effective dose is the sievert or millisievert. In cardiology,
any effective dose measured in units of millisievert may be considered to be the same as a hypothetical uniform whole-body absorbed dose of x-rays assigned the same numerical value but quoted in units of milligray. That is, an effective dose of 1 mSv in cardiology is the same as a uniform whole-body absorbed dose of 1 mGy.

**Air Kerma Area Product (or Dose Area Product)**

Air kerma area product (KAP) and dose area product (DAP) are the same thing because air kerma from cardiologic-type x-rays and the absorbed dose to air (as opposed to the absorbed dose to tissue) are the same thing. This quantity is used to assess the total stochastic risk to patients from x-rays. It is the multiplicative product of the beam area at entrance to the patient and the free-in-air air kerma located at the entrance surface of the patient. “Free-in-air” means the measurement is made as if the patient were not present. This means that the measurement is not enhanced by radiation scattered back into the area by the presence of a patient. KAP, therefore, is an indirect measure of the total number of x-rays that entered the patient. This makes it an indicator of stochastic risk to the patient.

DAP has no relevance for radiation exposure to personnel.

**Rates and Accumulation of Radiation**

All of the previous dose and kerma descriptors can be assessed as an instantaneously delivered amount or as an amount accumulated over time. The rate at which radiation is delivered can also be of importance, as, for example, air kerma rate, which is measured in units of milligray per minute (mGy/min). These concepts should be clear in the context of any discussion on dose or air kerma.

**MONITORING DOSE**

Dose delivery is monitored for both patients and personnel.

**Monitoring Doses to Personnel**
Personal radiation monitors are used to assess the cumulative amount of radiation to which an individual is exposed during the course of their work. Measurements of cumulative radiation exposure are made over intervals of months. Typically, the primary personal radiation monitor should be worn at the collar outside the lead apron. Some states might require that 2 monitors be worn, one outside and the other under the lead apron. All personal radiation exposures are reported in terms of equivalent dose or effective dose. The unit primarily used in the United States is the millirem, where 1 mrem is the same as 0.01 mSv.

Personal radiation monitoring is a serious business. It is an essential tool in assuring healthy working habits around radiation. A rule of guidance is that the annual effective dose to interventionalists from exposure to stray fluoroscopic or angiographic radiation should not exceed 20 mSv and, by regulation, must not exceed 50 mSv. If your monitor suggests you are exceeding the 20-mSv effective dose per year, then remedial action should be taken to try to reduce this dose accumulation.

Doses to extremities can also be monitored using extremity monitors that come in a variety of forms. Monitors attached to rings can be worn on a finger. These ring monitors can be sterilized using a hydrogen peroxide vapor technique. Ring badges are an important monitoring device if the hands get close to the radiation field. This might be the case, for example, for physicians assisting in transcatheter aortic valve replacement procedures.

**Monitoring Doses to Patients**

All modern cardioangiographic units have built-in monitors to help assess dose delivered to the patient. Since 2006, the air kerma and air kerma rate at a reference point must be displayed for the physician to see.

Monitoring radiation delivery to patients has many advantages. It provides useful information about radiation risks to your patients; it provides highly effective quality improvement data; and it can be applicable during a prolonged procedure, when dose buildup can be substantial and dose abatement steps may be necessary.

There are several types of monitors, including monitors that measure cumulative air kerma at a standard point located at a fixed distance from the x-ray source, cumulative KAP monitors (also known as *DAP meters*), and dose mapping monitors.
Cumulative Air Kerma at the Intervventional Reference Point

The interventional reference point (IRP) is located 15 cm from isocenter along a line between the x-ray source and the isocenter of the C-arm (Fig. 11-5). (The isocenter is the point in space about which the imaging system rotates, and an object at that point remains in the center of the image regardless of beam rotation.) The IRP roughly approximates the position of the skin where the beam enters the patient. Figure 11-5 demonstrates the location of this reference point. The measure of cumulated air kerma at this position in space is highly useful as a quality control device and as a guide to manage procedures. Almost all modern machines measure and record this quantity.
FIGURE 11-5 Location of the interventional reference point (IRP; indicated by the dark rectangle marked IRP). This point is located along a line from the x-ray source to the image receptor and 15 cm from the isocenter (dot in figure) of the C-arm in a direction toward the x-ray tube. As the C-arm is rotated, the IRP rotates with it. Although the IRP is representative of the entrance skin site, for some beam orientations and patient positions, it is located a distance from the actual skin site. Thus, the cumulative dose at the IRP might over- or underestimate the true cumulative skin dose. This dose reference must therefore be used only as a guide for patient care and not as an absolute measure of risk to the skin. (Adapted with permission from Hirshfeld JW, Balter S, Brinker JA, et al. ACCF/AHA/HRS/SCAI clinical competence statement on optimizing patient safety and image quality in fluoroscopically guided invasive cardiovascular procedures: a report of the American College of Cardiology/American Heart Association/American College of Physicians Task Force on
Because the cumulative air kerma is measured at a point fixed relative to the source, 3 things must be kept in mind when using it. First, as an accumulation monitor, it adds up all the radiation produced by the source, regardless of beam orientation. This fact means that radiation dose to a single skin site might be overestimated. Second, at any one skin site, the actual skin dose is about 40% greater than the cumulated entrance air kerma; thus, the cumulated air kerma might render an underestimated impression of the true skin dose. Third, the reference point is only an approximation of the position of the skin, and the true entry site might be closer to or further away from the x-ray tube, rendering an over- or underestimation of the true skin dose. Thus, the cumulative air kerma is not an exact measure of skin-absorbed dose and can only be used as a rough guide to assess the risk to skin when procedures are prolonged and doses are high. Regardless of these difficulties, dose at the IRP is a highly useful tool to assist the physician in management of the patient’s skin dose.

For example, guidelines might be established to assist the physician during a procedure. It might be useful, for example, to establish a 2-4-6-8 rule for management. If the reference accumulation air kerma reaches 2 Gy, then the physician is advised that dose is building and that this is an “FYI” so that the physician knows the pace of radiation buildup. The threshold for transient erythema (Table 11-2) may have been breached, but transient erythema is not a significant health concern. At 4-Gy air kerma, the physician is advised again and now knows that the threshold of skin erythema (as opposed to transient erythema; see Table 11-2) might have been reached if the beam was not reoriented and if the IRP is inside the skin surface. At 6-Gy air kerma, the potential for skin erythema is higher, and actions to abate the risk might be an important consideration. At 8-Gy air kerma, the risk of skin injury is an important possibility, especially if there was no beam reorientation earlier and the same skin site is being dosed. The purpose of this is to assist the physician in making the appropriate benefit-risk decisions for the patient and in managing the patient after the procedure. Other recommendations by national organizations are available.23

Kerma Area Product and Dose Area Product Meters

A full discussion of use of a KAP meter to monitor patient absorbed skin dose is beyond the scope of this chapter. Recall that KAP is the product of the air kerma at a position in space and the area of the beam at that position. With distance from the source, beam area naturally increases and air kerma naturally decreases in identically compensating manners. The product of these two entities is, therefore, theoretically the same at all positions along the unobstructed accessible beam. It is primarily a quality control tool and is not a very useful monitor of dose to the skin of a patient, although that task is possible. A medical physicist is usually employed in any attempts to use such

a device for management of skin doses to patients. The National Council on Radiation Protection and Measurements also provides recommendations on how to use KAP as a skin dose monitor.\textsuperscript{23}

**Skin Dose Mapping**

Skin dose mapping (Fig. 11-6) provides explicit diagrams showing the accumulation of dose to specific skin sites of a patient. This dose monitor takes the guesswork out of accumulation of skin dose during procedures. It accounts for a wide variety of factors that are not accounted for by the previously discussed dose monitors. These factors include beam orientation, scattered radiation, location of the entrance skin site from the x-ray source, table attenuation of radiation, and other factors. It is the preferred method for monitoring dose to a patient because it is the best assessment of skin dose in real time. This monitoring is visually enhanced by a patient contour map showing how dose is distributed around the patient as the beam is rotated (see Fig. 11-6).

RADIATION EFFECTS

Health effects of radiation are commonly separated into 2 categories: stochastic and deterministic.

Stochastic Effects

Stochastic effects involve alterations in single cells that render them adversely functional. Alterations of important macromolecules can conceivably result from a single interaction with radiation. Therefore, these effects probably occur at any radiation dose level, although they are extremely unlikely to occur at very minimal levels. The two prominent
stochastic effects are radiation-induced neoplasm and heritable changes in reproductive cells. The likelihood of their occurring increases as dose increases, and induced cancer becomes measurable in exposed adult populations at doses in excess of about 100 mSv.\textsuperscript{24} In children and in the fetus, lower doses have been implicated as carcinogenic.\textsuperscript{25} Although genetic effects heritable by progeny have been observed at high doses in animal studies, bona fide genetically heritable effects have never been observed in humans.

**Deterministic Effects**

Deterministic effects are the result of damage to many cells. Examples are skin erythema, depilation, and vision-impairing cataract. Because the effect results from changes in multiple cells, a certain minimal level of radiation damage is necessary before the effect can occur. This is referred to as the threshold dose. As dose increases beyond the threshold, the severity of the effect increases. The most familiar examples of this are effects in the skin. Table 11-2\textsuperscript{26} lists various effects of large doses to the skin. Note how the severity increases as dose increases. Variations on sensitivities occur for different skin sites, and there are also variations among individuals due to differences in health of the skin, medications that the patient is taking, and other factors.\textsuperscript{23,26}

The threshold for radiation-induced cataract is now known to be lower than previously believed.\textsuperscript{27} Radiation may have subtle or progressively worsening effects on vision, and only careful attention to radiation management can avoid them or reduce their severity.

**Temporal Patterns of Radiation Effects**

For both stochastic effects and deterministic effects, there is a delay between irradiation and the detection of a change. For neoplasms, delays may be as short as two years or as long as many decades. For deterministic effects in the skin, the delay is typically many days to weeks before erythema develops and is likely to be weeks to months before inflammation or necrosis develops. The delays provided in Table 11-2 are relevant to effects occurring following acute threshold doses. Delays vary depending on skin sensitivity, dose level,
and rate of accumulation of dose. The transient form of erythema can occur within 24 hours, but this does not always occur and usually goes unnoticed. It may sometimes be confused with erythema resulting from electrosurgical pads.

An important fact is that a fluoroscopy-related “burn” is markedly unlike that of a thermal burn. Thermal insults are readily recognized by conscious individuals, and immediate measures can be taken by them to defend against further injury. With medical radiation, there is no sensation that forewarns of an injury; the first signs that an injury has been induced usually do not occur until the procedure has been long over. Therefore, physicians cannot rely on any signal from the patient that a burn is occurring. In contrast to an injury from fluoroscopy, the progression of a thermal burn occurs within a short time after the injury (days), and the extent of medical care necessary for treatment can be readily determined soon afterward. For a fluoroscopic radiation injury, the progression of the injury is slow (months), and early interventions often fail because of residual injury that has yet to manifest itself. Prevention of these painful and slowly developing injuries is clearly an important goal. Proper radiation management with fluoroscopic equipment requires a knowledgeable application of the effective and careful use of radiation to keep risk of skin injury at bay. The strategic use of radiation monitoring devices is a valuable resource in achieving this goal.

DESIGN STRATEGIES TO LIMIT EXPOSURE TO RADIATION

Room Design

The primary feature of room design is space. Large rooms (~60 m² with ~15 m² control room) are preferred for many reasons, one of which is radiation management for personnel. Only a large room is conducive to maximal effective use of distance and shielding. Satisfactory space is required at ceiling level for suspended shields and other equipment. At floor level, space is required for mobile shields that are often used to protect in-room personnel who remain positioned at a single station during the procedure. Because dose decreases rapidly with distance, a large room provides the opportunity for
personnel to attend to their duties at a healthy distance from the source of radiation, which is primarily the patient, while remaining readily available to attend the patient when necessary.

**Equipment Design**

Cardioangiographic equipment is some of the most sophisticated and complex equipment used in medicine. To effectively perform procedures, at least 3 essential factors must be in place: (1) the equipment must be properly designed for the procedures; (2) the equipment must be well maintained; and (3) the users must be well trained in the use of their specific equipment. Training is related both to the technical aspects for the efficient and effective completion of a procedure and to the proper deployment of available dose-management features. These features differ from machine to machine, and important differences can exist, even for two machines that appear to be identical. Although we review general principles of operation of equipment, understanding and effectively using specific features are the responsibility of the operator.

**Fundamental Aspects of Image Production**

Fluoroscopy systems produce images by generating a beam of x-rays, transmitting the beam through the patient, and capturing the residual transmitted beam at the other side of the patient to render an image. The x-rays emanate from a point of origin inside the x-ray tube and fan out in all directions from the source. The housing of the x-ray tube is designed to permit only those that travel toward the patient to escape their enclosure (Fig. 11-7).\(^{28}\) (A small number of x-rays do escape the housing, but by regulation, this is less than 1 mGy/h at 1 m when operated at maximum continuous output. The actual leakage is typically less than this.)
X-rays are produced in all directions, but shielded housing stops most of the x-rays from penetrating the encasement. Only the beam that is directed toward the patient is permitted to escape at imaging intensities.

**FIGURE 11-7** X-ray production. X-ray photons are produced from a very small area (~1 mm$^2$) inside the x-ray housing. The housing is shielded to keep radiation levels below limits set by regulation. The beam that emerges from the imaging port is made up of x-rays that fan out in a diverging pattern, resulting in a beam that increasingly widens with distance and correspondingly decreases in intensity. (Adapted with permission from Louis K. Wagner, PhD.)

X-ray radiations are individual particles of pure energy called *photons*. They travel at the speed of light, and their path is a straight line, unless they interact with something in their way. Interaction is critical to the imaging process. **Figure 11-8** shows that a beam of evenly distributed x-rays enters the patient. There is no effective pattern to the x-ray beam at this point. As the beam passes through the patient, many of the x-rays interact with atoms and molecules of the tissues. This interaction either removes them or redirects them away from their place in the beam. Interactions of other photons continue until there emerges from the patient a residual beam of undisturbed x-rays. At this point, because of the interactions that previously took place, the beam is now very nonuniform, and this nonuniformity is the x-ray image. Only a small percentage (~1%-3%) of the original beam makes it through to exit the typical adult patient.
FIGURE 11-8 Image production. Demonstrated is how the uniform x-ray beam is transformed into an x-ray image as the beam passes through the patient. A diagram of a cross-sectional image of the patient is shown at top. A uniform beam of x-rays enters the patient. Due to anatomical structures in the paths of x-rays, many x-rays are eliminated from the beam as they pass through the patient. The residual nonuniform beam at exit from the patient is the image. A similar cross-section of the chest depicted at top is highlighted in the chest image below. (Adapted with permission from Louis K. Wagner, PhD.)

Controlling Beam Energy (kV and Filters)

Not all x rays are the same; and in fact, the x-ray beam is initially composed of a mix of useful and useless x-rays. The energy of an x-ray determines its usefulness because the energy determines the likelihood for interaction processes that create the image. Only a small portion of the x-rays that are produced are appropriate for cardiologic procedures. The two major factors that control the energy characteristics of the x-ray beam are kV and filtration. The kV is the electric potential that determines the energies of the x-rays. The kV can vary from about 60 kV to about 120 kV, sometimes up to 140 kV. This is necessary to control beam penetration and image quality for various sizes of patients and imaging tasks. The filtration is comprised of thin sheets of materials like aluminum or copper that selectively removes unnecessary x-rays from the beam. These metal filters are placed at the x-ray tube portal so that they stop the unnecessary x-rays before they escape the tube housing to expose the patient. Although some useful x-rays are also removed by the filters, the net result is an x-ray beam with a better mix of x-ray energies. Filtration is often adjustable for the same reasons that kV is adjustable. The goal is to produce an x-ray beam that results in an excellent compromise between appropriate image quality and acceptably low radiation dose to the patient. Some equipment does this better than others.

While removing unnecessary x-rays from the beam, the filtration process also reduces the useful beam intensity. To compensate for the reduced intensity, the x-ray tube must operate at higher production rates. This results in generation of a considerable amount of heat that stresses the tube. Manufacturers therefore put a great deal of consideration into tube design so that tubes can withstand or circumvent the stress of well-filtered x-ray production. Some x-ray tubes are better engineered than others; and inevitably, good engineering adds to cost.
In addition to permanent filtration that is typically equivalent to about 5 mm of aluminum, all angiocardiologic equipment should use x-ray tubes with heavily filtered x-ray sources. An option of filters should be available, typically in tenths of millimeters of copper (eg, 0.1, 0.2, or 0.3 mm). How the filters are used may differ among different machines and manufacturers. Many manufacturers incorporate filters into different dose-management schemes. The particular filter incorporated into a procedure is often decided by the dose-management option selected by the user and is also based on the mass of tissue that the beam must penetrate. Typically, thicker filters are reserved for small patients, whereas the thinnest filters are used on the largest patients. During cine fluorography (also known as cineangiocardiography, or “cine” for short), thin filters are often used because the beam intensity must be high during the acquisition. Although the user selects a dose-management scheme that influences how filters are deployed, the machine assumes control over selection of filters during the procedure.

**Variable Pulsed Fluoroscopy**

The reproduction of motion is controlled by the dynamics of fluoroscopic and cine imaging. The perception of motion is achieved by displaying in rapid succession a sequence of distinct still images, each of which represents the same scene at a progressively different moment in time. Each static image is separated from the previous image by a very short moment. The fidelity of the motion improves with shorter time intervals between images. This principle applies to fluoroscopy as well as to cine.

Most people perceive continuous motion when about 30 images per second are displayed. This rate has been a standard in the United States for the entertainment industry. However, in cardiology, the goal is not to entertain, but to use the imaging system as a tool to assist in the advancement of a catheter along a lumen. To accomplish different tasks, the necessary number of distinct images captured per second is variable. This is true for fluoroscopy as well as for serial imaging such as digital angiographic runs or cine. Choosing an adequately low image capture rate is one of the most effective user-selectable ways to limit utilization of radiation.

In fluoroscopy, the image capture rate is often called the **pulse rate**. For recorded dynamic imaging, it is often called the **frame rate**. In all modern cardiology units, each fluoroscopic image is captured using a very short pulse
of radiation (~3-15 ms). The use of short pulses is necessary to stop the action in each image. Longer pulses result in significant motion blur. Each pulse of x-rays results in one image, and the pulse rate is therefore identical to the image capture rate. Between pulses, no radiation is produced. If 30 images are captured per second, fluidity in motion is perceived, but the radiation utilization might be excessive for the task. If the pulse rate is reduced to 15 images per second, the motion might no longer appear completely fluid, but it is likely adequate for the task, and the radiation utilization is potentially reduced by 50%. For interventional procedures, a reduction in dose by 50% is substantial and could mean the difference between a severe skin reaction and no skin reaction for long procedures in large patients. For this reason, cardiologists should use the lowest pulse rate option for fluoroscopy and the lowest frame rate option for any fluorography (serial imaging such as digital angiography or cine) that is adequate for the efficient and effective completion of a procedure. (A word of caution: Not all machines or modes of operation are set up for dose-reduction options when changing the pulse rates in fluoroscopy. Users must understand what occurs when different fluoroscopic pulse rate options are used for their specific equipment.)

**Dose-Rate Control**

The challenge in all radiologic imaging tasks is to reach the best compromise in radiation dose delivery and image quality. Dose-rate control is achieved in many ways as, for example, by adjusting pulse frequency, pulse width, tube current (mA), x-ray beam energy (kV), and filtration, only some of which are under the operator’s control. Selecting a lower pulse rate, as described earlier, is a method of operator-based dose-rate control. However, that method affects the temporal image display and has only an indirect effect on the appearance of noise due to dynamics of human vision, a concept that is beyond the scope of this chapter. The effects of noise are demonstrated in Figure 11-9. Pulse width, tube current (mA), x-ray beam energy (kV), and filtration have a more direct effect on the quality characteristics of each image because they affect the radiation level that produces the image.
Angiocardiographic machines are designed to operate in different dose-rate modes that affect image quality. The temptation might be to use the dose-rate mode that produces the best image quality, but this is inevitably the mode that results in the highest dose rate. The challenge to the cardiologist is to select the dose-rate mode that draws the most appropriate compromise between dose to the patient and adequate, but not excessive, image quality. Monitoring dose rate for each mode will be a topic of later discussion.

There are frequently at least 2 types of dose-rate controls for the fluoroscopic aspects of the procedure. The first type provides a selection of dose rates, none of which allow the unit to exceed standard limits on fluoroscopy output. The other type is an option that allows the unit to operate at up to twice the standard limit. These are explained next.

**Standard Limit on Dose-Rate Options**
The FDA places legal restrictions on the manufacture of fluoroscopes. For example, for angiographic equipment, the maximum output of the radiation...
in the standard fluoroscopic mode is restricted to less than 87.6 mGy air kerma per minute when tested at 30 cm from the image receptor. Standard dose-rate options for fluoroscopy that are selectable by the user all operate under this limit. However, each option has different operating characteristics to control image quality and dose rate to the patient.

Cardiologists can determine how different modes change output rates by observing the dose-rate indicator that is available on all machines manufactured after 2006. The cardiologist or an assistant can watch that indicator during fluoroscopy to see how it changes as different modes are selected during a procedure.

Physicians should familiarize themselves with these options and understand the consequences of each selection with regard to changes in dose rate as well as image quality. Select the option that provides the best balance between imaging needs and radiation use. Regardless of which level is selected, the output should not exceed the standard maximum.

**High-Level Fluoroscopy**
The FDA allows machines to be manufactured with a high dose-rate option for fluoroscopy. Units manufactured since 1995 may have a high-level option that restricts output to less than twice the standard maximum rate for fluoroscopy. This option can result in fluoroscopic entrance-skin dose rates in excess of 0.4 Gy per minute under some configurations of use. This is a particularly important option to understand because it is a special mode that enhances image quality by amplifying radiation dose rates to patients. For this option, a special means of selection must be available and a special sound must warn the operator that the high-level mode is engaged. Sometimes this sound is barely audible to the user. Therefore, users must be aware of this mode and know when it is engaged. The dose-rate monitor on the video screen will indicate this amplified dose rate.

High-level control should be used infrequently and only when special imaging detail is momentarily necessary.

**A Word About Governmental Regulation and Radiation Output**
One of the most common errors of logic is to assume that regulatory restrictions on radiation output render fluoroscopes safe for virtually unrestricted use. This most certainly is not true. The regulations apply only to fluoroscopy and only to a standard testing configuration that places the
entrance skin surface at 30 cm from the face of the image receptor for angiographic devices. It also excludes the effects of scattered radiation in elevating the actual rates. In addition, no restrictions on output exist for serial imaging modes such as cine.

Under normal cardioangiographic beam orientations, the skin of the patient where the beam enters is frequently much further away from the image intensifier than 30 cm, placing the patient closer to the source than what is assumed during compliance testing. This frequently means that the entrance air kerma at the true skin position can be in excess of 40% greater than that at the compliance testing position. The effects of scatter boost the actual skin-dose rate by another 30% to 40%. The combined results of these two factors mean that the actual dose rates to the skin during fluoroscopy can be a factor of two or more higher than the regulatory air kerma limit, which means more than 175 mGy per minute in the standard mode of operation. At maximum standard rate, a necrosing skin injury can occur in 100 minutes of fluoroscopy on-time, and this does not take into account the additional dose from cine. If we assume for the sake of discussion that half the dose to the patient is from fluoroscopy and half is from cine, then a necrosing skin injury can occur after about 50 minutes of standard fluoroscopy in large patients. This often surprises many physicians.

Maximum cine air kerma rates can exceed 1000 mGy per minute at the compliance point. The actual dose rate to the skin of the patient can be well in excess of 2000 mGy per minute. For 20 6-second cine runs, the skin dose from cine alone could be 4 Gy (4000 mGy). Under these circumstances, a procedure involving 80 minutes of fluoroscopy and 20 6-second cine runs focused over the same area could result in a skin necrosis. This is exactly what has occurred in many cases for which necrotic skin injury has been reported (eg, see Fig. 11-3). The actual skin dose rate depends on many factors, one of the most important of which is the amount of tissue mass that must be penetrated to produce an image.

PHYSICIAN-OPERATOR STRATEGIES TO LIMIT RADIATION RISK TO THE PATIENT
The important question now becomes, “What can be done to limit radiation risk?” There are many options for the physician to limit radiation risk. Most essential is that the physician be properly trained and experienced enough for the procedure and for dose management. Inexperienced personnel typically use more radiation to complete a procedure than do veterans. The expeditious completion of a procedure is a primary factor in the conservative use of radiation.

Radiation management for the patient has three phases: before, during, and after the procedure.

**Before the Procedure**

The first phase of patient management involves an assessment of the radiation risk for the patient. Small adult patients are at low risk for skin injury because of their size. Many factors work in their favor: image quality is usually high, radiation output rates are at their lowest, and good geometry is usually easier to achieve. Large patients with difficult lesions that require highly oblique beam orientations are at greatest risk for the opposite reasons.

Facilities should assess their procedures and decide under which conditions patient counseling on radiation risk should take place. This depends on the type of procedure, the size of the patient, the number of lesions, and perhaps the anticipated difficulty in treating the lesions.

A history of a previous interventional procedure should prompt a brief physical examination of the patient’s skin, particularly the back, to determine if there might be some residual evidence of radiation effects. A previous procedure might result in a weakened skin structure that could elevate the risk of serious skin effects from additional irradiation. If residual effects are noted, the cardiologist can try to avoid the injured site, and should advise the patient of this increased risk. In addition, patients with certain diseases, patients taking medications, or patients receiving treatments for other problems may be at elevated risk for adverse and perhaps severe skin reactions. It is thought, for instance, that patients with connective tissue disease, such as discoid lupus erythematosus, scleroderma, mixed connective tissue disease, or even rheumatoid arthritis, can be at elevated risk depending on factors related to their disease at the time of the radiation exposure. Patients with diabetes mellitus are also suspected to be at higher risk. Patients homozygous for ataxia telangiectasia and patients with Fanconi anemia,
among other conditions, are known to be at high risk.

The following is an example of counseling: “Your procedure uses x-rays, and in some cases, exposure can be prolonged. Although the vast majority of procedures do not demonstrate any adverse consequences associated with the radiation, there is a small risk that an adverse response could occur. There may be a slight elevation in cancer risk associated with this exposure. In addition, there is a risk that a skin rash may result from the radiation exposure. In rare cases, severe skin effects may occur, resulting in blistering, ulceration, and sores. These extremely rare events may require surgical correction.”

**During the Procedure**

Besides using equipment-related factors minimizing fluoroscopy time, minimizing intensity, and limiting the number and rate of serial imaging frames, other highly effective strategies can be used. These include considerations regarding beam orientation and patient setup, monitoring of dose, and a more subtle factor of avoiding the presence of unnecessary body parts in the beam.

**The Importance of Positioning**

Figures 11-10 and 11-11 demonstrate how dose rate to the patient can change with simple changes in the position of the patient relative to the image receptor and the x-ray tube. This occurs because the x-ray source originates in a diverging pattern from a small spot inside the x-ray tube and the beam intensity at the skin depends in a complex way on distances between that source and the patient’s skin as well as between the source and the image receptor and the patient and the image receptor.
FIGURE 11-10 Dose rate and position of the image receptor. A. The physician performs the procedure with the image receptor well above the patient. Dose rate to the patient is highest for this configuration. B. The physician performs the procedure with the image receptor closer to the patient than in A. This reduces dose rate from that of A. C. The physician moves the image receptor to as safe a proximity to the patient as is reasonable. This reduces dose rate to its lowest level due to the reduced x-ray output that is automatically adjusted by the machine as a result of the closer proximity of the image receptor to the source. Dose rate savings of 20% to 40% are very substantial and can result in a savings on the order of several grays of absorbed dose to a patient’s skin. (Adapted with permission from Wagner LK, Archer BR. Minimizing Risks from Fluoroscopic X-Rays. 5th ed. The Woodlands, TX: Partners in Radiation Management; 2014.)
FIGURE 11-11 Dose rate and position of the patient relative to the x-ray tube and the image receptor. A. The physician performs the procedure with the patient table elevated and the image intensifier close to the patient. B. The physician uses a lower table setting. Due to the closer proximity of the patient to the source, dose rate to skin of patient increases by about 40%. C. The physician uses an even lower table height. The skin dose to the patient is now approximately 60% higher than that to the patient in A. (Adapted with permission from Wagner LK, Archer BR. Minimizing Risks from Fluoroscopic X-Rays. 5th ed. The Woodlands, TX: Partners in Radiation Management; 2014.)

Distance of Image Receptor From Patient

Dose rate to the patient’s skin decreases as the image receptor (image intensifier or flat panel detector) is moved closer to the patient (see Fig. 11-10). This is because the machine controls output rate by monitoring the input rates to the image receptor. The machine tries to keep exposure rate to the imaging device relatively constant. As the image receptor moves closer to the patient, the machine senses that the input rate to the receptor increases due to the closer proximity of the receptor to the source. The machine therefore reduces output rate of the x-ray source to nullify this change and, because the patient did not move relative to the source, the entrance skin dose rate also decreases. Thus, a very important rule for dose management is to keep the image receptor as reasonably close to the patient as is safe for the procedure.
Position of Patient Between X-Ray Source and Image Receptor

A second rule, regarding the position of the patient’s skin relative to the x-ray source, might also apply. This rule is to keep the entrance site of the patient’s skin at a maximum practicable distance from the x-ray source. This rule has two components; one component regards the position of the table, and the other component regards the angular orientation of the imaging arm. We will address table height in this section and angular orientation in the next section.

When isocentric geometry is employed for cardiac imaging, the position of the table relative to the x-ray source is essentially predetermined. The isocenter is typically at a fixed distance from the x-ray source, and the table must be raised to the level where the heart is positioned at the isocenter. This applies only to machines for which the x-ray source is at a fixed position on the C-arm and has no independent capability for linear movement, as is true for the vast majority of machines.

However, when isocentric geometry is not used, the rule is to raise the table to a height that keeps the table at a distance as reasonably far from the source as is comfortable for the safe completion of the procedure. This rule is sometimes confusing because the output rate indicator on the monitor will increase as table height increases because the image receptor must also be moved further away from the source. However, as the table height increases, the entrance skin surface of the patient also moves further away from the source. Thus, there are two competing factors at play, and the net effect is that skin dose rate decreases as distance from the source to the skin increases. So, even though output rate increases as the patient and image receptor are moved further from the source, the dose rate to the entrance skin surface actually decreases. We explain this in further detail in Figure 11-11 and Figure 11-12.

Figure 11-11 illustrates the effects of different positions of the patient relative to the image receptor and x-ray source. The dose rate at the skin of the patient in Figure 11-11B is about 40% greater than that in Figure 11-11A, and dose rate at the skin of the patient in Figure 11-11C is about 60% greater than that in Figure 11-11A. This is all due to the diverging nature of the beam. The radiation output does not change by much as a result of these table height adjustments. As the skin gets closer to the source, all x-rays have to enter the patient in a smaller and smaller area. These percentage differences in dose rate translate into very large dose differences when procedures are prolonged. The changes in dose rates are less if the image receptor is moved...
closer to the patient, as shown in Figures 11-12B and 11-12C. However, due to closer proximity of the patient to the source, the dose rate to the skin is still greater than that in Figure 11-12A.

![Figure 11-12](image_url)

**FIGURE 11-12** Dose rate and position of the x-ray tube and image receptor. A. The physician performs the procedure with the patient table elevated and the image intensifier close to the patient. B. The physician uses a lower table setting but also moves the image receptor to a distance close to the patient. Due to the closer proximity of the patient to the source and due to the machine-adjusted output rate, dose rate to skin of patient increases by about 10%. C. The physician uses an even lower table height but continues to lower the image receptor to just above the patient. The skin dose to the patient is now approximately 20% higher than that to the patient in A. While the dose rate monitor will indicate lower output rates for B and C, the actual dose rate to the skin of the patient increases due to closer proximity of the patient to the source. (Adapted with permission from Wagner LK, Archer BR. *Minimizing Risks from Fluoroscopic X-Rays.* 5th ed. The Woodlands, TX: Partners in Radiation Management; 2014.)

**Patient Size and Beam Orientation**

Large patients are inevitably the patients at greatest risk for skin injury. Their size generates a large amount of image-degrading scatter that reduces contrast. Because of their size, a high-energy beam must be used to penetrate the body mass adequately, reducing contrast even further. Beam pulse time
might increase, which leads to motion blur. These imaging difficulties are obstacles that lead to an increase in procedure time. Also, large size alone means that radiation output is markedly increased over that of a thin patient. When lesions prove difficult to treat, doses can be extremely high.

X-rays are a poorly penetrating radiation. As previously noted, only a few percent or less of the x-rays entering an average-sized patient (~23-cm thick mediastinum) actually emerge from the patient to make an image. For large patients (~30-cm thick mediastinum), this percentage is even less. To compensate for this reduced penetration, large patients require entrance dose rates considerably greater than average or thin patients. Dose rates to the patient generally double for every 4 to 5 cm of additional tissue that must be penetrated to produce the image.

The patient-related factor most influential in determining how much radiation must be used to render a proper image is the mass of tissue that must be penetrated between the positions where the beam enters to where it emerges from the patient. Oblique and cranially or caudally tilted beam orientations result in the thickest tissue mass and require markedly higher outputs than do simple posteroanterior orientations (Fig. 11-13). Not only must the machine generate radiation at a higher rate to penetrate the mass, but also the geometry of the situation inevitably places the skin of the patient closer to the x-ray source. In addition, the image receptor is often moved further away from the source to avoid collision with the patient. The combined effects of these factors greatly increase dose rate to the skin, as is demonstrated in Figure 11-3. A necrotic injury resulted from 63 minutes of fluoroscopy and more than 5000 frames of cine in this gentleman, who has an unusually large chest. The thick body mass of the chest coupled with the oblique and cranially tilted beam resulted in high radiation dose rates to the skin and the rectangular skin injury. When doses are high and procedures prolonged, the physician can consider rotating the beam to a different location so that a different skin area is irradiated.
FIGURE 11-13 Dose rates at steep beam angles. Dose rates to the entrance skin surface are highest for oblique and cranially or caudally tilted beams, especially in large patients. The primary factor increasing dose rate is the increased thickness of tissue that must be penetrated. However, there are additional factors. Steep angles also force the skin of the patient to be in closer proximity to the x-ray source, where the beam is more intense. In addition, the source to image receptor distance often increases in order to avoid collisions with the patient. This additionally causes the machine to increase output. All these factors contribute to increased dose rates to the entrance skin site of the patient. The injury shown in Figure 11-3 occurred in the case of a steep beam angle through a large-chested man. The cumulative dose resulted in necrosis and involved 63 minutes of fluoroscopy and nearly 5000 frames of cine. (Adapted with permission from Wagner LK, Archer BR. Minimizing Risks from Fluoroscopic X-Rays. 5th ed. The Woodlands, TX: Partners in Radiation Management; 2014.)

Rotating the beam to a new skin site has merit if the dose to a particular site is already at a high risk for causing injury. However, rotation has consequences. If a steeper beam angle is employed, the dose rate to the new entrance skin site will be significantly greater than before. If rotation is insufficient to eliminate overlap of x-ray fields between the old and new site, dose buildup in the overlapped area will increase. Typically beam rotations of more than 12° and up to 40° might be required to eliminate overlap, depending on many factors. If beam rotation is to a less steep angle, dose rates generally decrease.

Extraneous Body Parts

We have just seen that thick patients are more difficult to manage for good reasons. Sometimes, extraneous body parts like the breasts and arms intercept
the beam. This should be avoided because they increase the amount of tissue mass that the beam must penetrate. This drives up dose rates, reduces image quality, and places those tissues at elevated risks.

The young female breast (≤40 years of age) is known to be at substantively elevated risk for induced breast cancer; with older women, there is less risk. Working diligently to keep the breasts out of the direct x-ray beam, and especially out of the entrance x-ray beam, is a worthwhile task and has 2 potential advantages. By keeping extra tissue away from the beam, dose rates are lower, and by keeping breasts away from the direct beam, the dose to the glandular tissue is maintained at markedly lower levels. This is especially important for the breast in closest proximity to the x-ray source. For this breast, dose accumulations can be very substantive.

Arms in the direct beam are a known hazard. Figure 11-14 demonstrates the geometry of this procedure. Efforts must be made to manage arms in a manner that is comfortable to the patient (maintaining good circulation) and that keeps the arms away from the direct path of the beam. This applies to both arms. Although the arm that is on the exit side of the beam receives only an exit dose, its presence adds tissue mass to the radiation path, thus increasing output and dose rate to the entrance skin site. The arm on the x-ray tube side is at greatest risk because it not only drives up output, but also experiences the more intense beam because of its proximity to the diverging x-ray source.

FIGURE 11-14 Demonstration of arm intercepting the x-ray beam close the x-ray source. The diagram depicts a biplane fluoroscopic configuration illustrating how arms inadvertently placed in the x-ray beam can be seriously injured. The erythemas on the back healed with scarring. The injury to the arm required surgery. (Image at
After the Procedure

Counseling the Patient

After a prolonged procedure in which the skin dose may have been high, the patient should be counseled about the complexity of the procedure and that a skin reaction could develop within the next few weeks. The patient should be told the approximate location where this might occur and to report any skin reaction to the physician’s office. This information has many advantages. The first is that the patient is not surprised if it occurs. The second is that you now have feedback that your procedure did result in a reaction, and you can assess how frequently this occurs. You can use this knowledge to take any appropriate action to reduce this. The final advantage is that you can recommend that the patient see a dermatologist and the physician can call the dermatologist to let him or her know that the skin reaction might be due to x-ray radiation from the patient’s previous angiocardiographic procedure. The dermatologist can then determine if the location is correct and will not be puzzled by the rare event or by its delayed progression should it get worse. This will also render a biopsy unnecessary, and a biopsy should be discouraged because this may compromise healing. A principal course of action will be to build a shield around the affected area and provide medication to reduce skin irritation in the hope that the wound will not endure any abrasion and remain closed. This will give the wound a chance to heal and avoid ulceration and infection as long as the dose did not surpass the threshold for necrotic development.

Recording Dose

Dose utilization as a result of all fluoroscopy procedures should be recorded in the patient’s record. Since 1994, the FDA has recommended that patient dose be recorded. Recording of radiation output and the location of the principally exposed area in the patient’s record has several benefits. The first
is that dose can be reviewed when additional procedures are required. It could also become important if the patient requires radiation treatment at a later date. Maintaining records for quality control of radiation utilization is highly valuable. It can be effective at discovering ways to modify working habits to reduce radiation use, and it can be helpful in discovering which machines use radiation better. It might also be useful for administrative purposes when justifying expenditures for equipment replacement.

The Pregnant Patient

Periodically, a woman who is pregnant might require a cardiologic procedure. Pregnancy should not be considered an absolute contraindication for any needed cardiologic study. Dose to a baby from a cardiologic procedure can usually be well managed so as to avoid any radiation levels that would significantly place the conceptus at risk. For example, direct irradiation of the pelvis results in the most direct dose to an early pregnancy. In many cases, irradiation of the pelvis can either be completely avoided or be kept to a very short interval. The only radiation reaching the conceptus from fluoroscopy of the thorax is scattered radiation that must penetrate many centimeters of the patient’s abdomen before reaching the conceptus. This is much reduced in intensity from that of the primary beam. To minimize scattered radiation to the pelvis when examining anatomy in the chest, the area of the beam should be collimated to the area of interest. For a conceptus more than 10 cm from the primary beam, dose to the conceptus is typically much less than 2% of the entrance skin dose. A cumulative entrance skin dose of more, and usually much more, than 2.5 Gy would have to be delivered before dose to the conceptus would approach 50 mGy. At doses under 50 mGy, the only suspected risk to the child is a possibility of induced neoplasia. The risk for a 10-mGy dose to the conceptus is thought to be about 1 mortality in 1000 cases and, overall, less than 4 cases of induced neoplasia.29 The threshold dose for malformation is estimated at 100 mGy, but the magnitude and the likelihood depend on gestation age. Between 50 and 100 mGy, some subtle effects on the developing central nervous system might occur if development is between 8 and 15 weeks postconception. A complete discussion of these risks is beyond the scope of this chapter, and the reader is referred to other texts for a complete discussion.29 Therefore, in evaluating a pregnant patient for a procedure, a benefit-risk decision is
necessary. Well-executed dose-management practices can in select cases result in an acceptable benefit/risk for the patient.

**PERSONNEL SAFETY**

One adage of good radiation management is, “What’s good for the patient is usually very good for personnel.” Patients are infrequently exposed to radiation, but their doses during one intervention can be large. Personnel, however, are frequently exposed to radiation, but at low levels. Economic use of radiation in the patient helps circumvent unnecessary long-term buildup of high radiation doses to personnel. Therefore, practicing good radiation management for the patient has the added benefit of a safer working environment for personnel.

*Time*

Previously, we noted the importance of limiting beam-on time for the patient. This has the added benefit of also limiting exposure time for personnel. To further reduce exposure time to personnel, only those who must be in the room with the patient should be there, and only when their services are needed. Otherwise, personnel should limit their time of exposure to radiation by leaving the procedure room or by remaining behind a fixed radiation barrier.

*Intensity*

This safety measure relates to the management of the intensity of radiation delivered to the patient as previously described for both fluoroscopy and fluorography (cine and digital acquisitions).

Another aspect relates to a savvy understanding of how radiation is distributed in the room. Figure 11-15 demonstrates how radiation is distributed in an interventional environment when the C-arm is in a left anterior oblique (LAO) orientation. Scattered radiation (also called stray radiation) results from interactions of x-rays with matter. From this, it follows that stray radiation is most intense closest to sites where the most interactions occur, which is always the site where the x-ray beam enters the
patient. Generally speaking, stray radiation emanates in all directions from the site of interaction, but because of the patient’s body, the scatter distribution around the patient is very lopsided, as shown in Figure 11-15. At the exit surface of the patient, the beam is markedly reduced in intensity (by about a factor of about 30-100 in most adult patients), and thus, stray radiation from this site is much lower than that from the entrance site. Thus, personnel positioned near the entry site of the patient (near the x-ray tube) experience the most intense exposure to stray radiation, whereas those on the correspondingly opposite side experience the least. This is why the x-ray systems are usually oriented with the x-ray tube under the patient and the image receptor over the patient. In this orientation, the intense scatter off the posterior aspect of a supine patient is directed primarily at the floor. The scatter emanating from the anterior surface of an adult is much less, saving considerable radiation exposure to the face and hands. With the C-arm oriented in an LAO position with cranial tilt, the intense scatter field is directed at the feet and legs of personnel standing to the right of the supine patient. Thus, the legs and feet of cardiologists are at considerable risk to accumulate very large doses of radiation after years of work.
**FIGURE 11-15** Depiction of stray radiation intensities from a patient in an interventional environment for a left anterior oblique beam orientation. These patterns apply only to this beam orientation. In other orientations, an analogous pattern is produced, with the greatest intensity emanating from the skin area where the beam enters. A person standing at a position near where the beam enters the patient receives about three times more radiation than a person at the opposing position near the exit beam side of the patient.

Figure 11-15 applies only to the LAO orientation. The distribution of stray radiation changes with different orientations. What workers must remember is that stray radiation is most intense on the side where the beam enters the patient and least intense on the opposite side where it exits the patient.

**A Note on Equipment Design**

There is a perceptually misleading circumstance for the worker who is on the exit side of the beam when the beam is oriented in a lateral manner. The individual near the image receptor can see the port of the x-ray tube and the collimator housing. Logically, the concern is that they are standing in the direct path of the x-ray beam. This should not be the case, and some simple tests, as listed next, can be applied to make sure that no direct beam is exposing them.

1. The FDA requires that the x-ray beam that emerges from the x-ray port be directed at and confined to the area of the image receptor, regardless of any operating configuration. This should be verified by a medical physicist when the quality control survey is performed.
2. It is easy to verify that the beam is confined to the image receptor during a procedure. Simply observe the image for the presence of collimator blades. If the collimator blades are visible in the image, the beam is confined to that area and must be inside the area of the image receptor.
3. By federal regulation, the image receptor is housed in a shielded container to block stray radiation generated inside the image receptor. The small amount of radiation penetrating the shield is very low. This can be verified by a medical physicist.
4. The x-ray tube and collimator housings are also well-shielded and well-regulated devices. Their shielding can be tested by a medical physicist.
**Distance**

The use of distance to reduce radiation exposure is extremely effective. Commonly referred to as the *inverse square law*, radiation levels decrease rapidly with increasing distance from the source. Specifically, with each doubling of distance from the patient, scatter decreases by about a factor of 4. So, if you are standing at about 1 m from the patient, taking a 1-m step backward decreases the unshielded intensity by about a factor of 4. The working rule of thumb that “One should work at a practicable maximum distance from the irradiated area of the patient while in the room” is one that serves everyone well.

**Shielding**

Shielding materials are abundantly available. Generally speaking, shielding is any material that absorbs or deflects a substantial portion of the x-rays that strike it. Many forms of shielding are available and include protective aprons, protective eyewear, thyroid shields, ceiling-suspended shields to protect the upper body, floor shields or table-side shields to protect the legs, stand-up mobile barriers to protect the entire body, and flexible shields that are draped on the patient to stop scatter at its source. There is further shielding in the walls to protect people outside the room. Sometimes, due to modern construction techniques that use thin concrete slabs between floors, extra shielding in floors and ceilings may also exist. Regarding radiation shields, the following are some guidelines:

1. Verify that there is sufficient shielding in the walls, floor, and ceiling to protect people who are outside the room. In one full year, no secretary, clerk, or other member of the public should receive more than 1 mSv effective dose from man-made radiation that penetrates these barriers.
2. Radiation levels behind the barrier of a control booth should not exceed 5 mSv per year.
3. Barriers suspended from the ceiling, the table, or standing on the floor should be a minimum of 0.5 mm of lead equivalent (ie, equivalent to the same protection provided by 0.5 mm of lead). Some shields are equivalent to 1.0 mm of lead or more.
4. Barriers suspended from the ceiling must be readily accessible and should
be designed so as to block radiation from the patient. This can be achieved with a drape or by purchasing a specially contoured hard shield that fits snugly against the patient’s body. Flexible shields that lie over the patient may be alternatively used.

5. Protective eyewear is optional in most cases. Eyewear should be equivalent to about 0.5 mm of lead and should fully cover the eyes, wrapping around the sides to cover the entire eye. Goggles that also provide splash protection should be considered. Standard glasses are not satisfactory for this purpose.

6. Thyroid shields are an option. They should be comfortable to wear. (The adult thyroid of the average person is not a highly radiosensitive organ, but protection is always recommended as a precaution.)

7. Protective aprons must be comfortable. Many states require by regulation that they be 0.5-mm lead equivalent in the front. This blocks about 95% of the radiation. Protection should wrap around the sides. Aprons that are 0.35-mm lead equivalent should be adequate and are much lighter. Rear torso protection of at least 0.15 mm is also recommended for personnel working in close proximity to the patient and for personnel who might have to work with their backs sometimes toward the patient. Support belts that distribute the weight between the shoulders and hips are recommended, and a 2-piece vest-plus-skirt design is preferred by some.

8. Radiation monitors must be worn at all times during procedures to measure the amount of radiation incident on personnel. Some regulatory bodies require that the monitor be worn under the lead apron, whereas others require that it be outside the lead apron, and some require that 2 monitors be worn, 1 under the apron and 1 outside. These varying points of view often confuse workers and are the result of a conflict between the need to monitor for safety versus the need to monitor as a matter of regulatory mandate. For safety purposes, I recommend that one monitor be worn outside the lead apron near the collar on the side of the body that is closest to the x-ray source. This adequately monitors the exposure to the unprotected areas of the head and neck and provides sufficient information to assure adequate safety measures can be taken when necessary. The dose under a 0.5-mm lead equivalent apron is roughly 5% of that dose. My goal for heavy users of radiation is that the annual readings at the collar outside the lead apron not exceed 50 mSv. I never recommend that only 1 under-
the-apron monitor be worn because this renders a false sense of security and ignores potentially high doses to important unprotected body parts.

9. Cardiologists should consider monitoring, periodically at least for several months, the doses to their legs and hands. This is achieved by attaching a monitor to the pant leg and a ring badge to the dominantly exposed finger. This provides important information on the adequacy or inadequacy of protection for these areas. Extra shielding or better attention to using shields should be considered if doses to these sites exceed 50 mSv in 1 year.

THE PREGNANT EMPLOYEE

Radiation exposure to an employee who is or might become pregnant must be managed so as to adequately protect the conceptus while not interfering with the individual’s ability to execute her duties. To do this, I recommend that preparations for pregnancy be taken before any employee becomes pregnant and that certain actions be taken once her pregnancy becomes known.

Preferably, before or at the commencement of employment, the worker should be advised of policies regarding radiation and pregnancy. This should be conducted for both men and women so that all employees are familiar with the policies. It must be made clear that extra protective measures cannot be initiated until the radiation safety staff is apprised of a pregnancy. Therefore, it is incumbent on the employee to advise the radiation safety officer (RSO), preferably in writing, when she first becomes aware of her pregnancy. Her options regarding safe practices can then be reviewed and extra precautions initiated.

I recommend that all female employees of childbearing potential who are required to have a whole-body dosimeter also be provided a specially marked “abdominal badge” dosimeter. The special marking helps ensure that the badges are easily distinguished. Although the whole-body badge should be worn at the collar outside the lead apron, the abdominal badge should be worn under all protective devices at the level of the belt. The readings of these badges should be reviewed by the RSO to assure that they do not exceed 0.25 mGy per month. This limit assures that any would-be conceptus would receive less than half that of the maximum recommended by professional agencies (recommended maximum dose to the conceptus is 0.5
mGy per month). If the readings do exceed 0.25 mGy, action should be taken to determine the cause, and corrective measures should be initiated.

Once an employee advises the RSO that she is pregnant, the following should be considered:

1. Review the abdominal badge history. This should demonstrate that current practices are sufficient to protect the baby. If not, corrective actions are necessary.
2. Provide the employee with the option of wearing an additional pelvic shield. This could be as simple as a small lap apron that can be 0.25 or 0.5 mm of lead equivalent material. This further reduces any potential exposure to the child.
3. Continue to provide the abdominal badge and switch it to monthly readouts if the present exchange is less frequent. In some cases, employees might also want to wear a real-time dose monitor under their protective apron. This provides daily feedback about the radiation exposure under the apron, rather than having to wait for the badge report at monthly intervals.
4. Provide the employee with duties involving less exposure to radiation, if necessary.

CONCLUSION

Radiation can be both friend and foe. To remain a friend, it must be treated with respect. Developing respectful habits that appropriately protect patients and personnel is the goal of all radiation management training.

ACKNOWLEDGEMENT

The author extends his sincere thanks to Dr. Stephanie Leon for her astute remarks in providing a critical review of this chapter.

MULTIPLE CHOICE QUESTIONS

1. For a fluoroscopy procedure, cumulative air kerma at a reference point is best described as:
   A. The total absorbed dose to the patient
   B. The amount of radiation accumulated at a specified point
   C. The total effective dose to the patient accumulated over time
   D. The total probability of inducing a cancer in a patient

2. For doses delivered from high-dose fluoroscopically guided interventions in nonpregnant patients, stochastic effects differ from radiation-induced tissue reactions (deterministic effects) in that tissue reactions:
   A. Increase in severity as dose increases past the threshold
   B. Can occur in tissues remote from the irradiated site
   C. Become evident while the radiation is applied
D. Are independent of the patient’s specific health status

3. Why are medical staff required to wear a personal radiation monitor during fluoroscopic procedures?
   A. To assure government regulators that the machine is operating safely
   B. To assure government regulators that safe practices are being exercised
   C. To protect the staff by absorbing ambient radiation in the environment
   D. To assess their exposure over time to see if increased protection is warranted

4. Which of the following actions is most likely to result in an increase in entrance absorbed dose rate to the skin of the patient?
   A. Decrease magnification (use larger field of view)
   B. Decrease distance of image receptor from the patient
   C. Employ high-level fluoroscopy
   D. Use a lower pulse rate for fluoroscopy

5. Which beam orientation is most likely to result in the highest entrance absorbed dose rate to the skin of the patient?
   A. 10° left anterior oblique (LAO), 0° cranial
   B. 20° LAO, 0° cranial
   C. 10° LAO, 15° cranial
   D. 20° LAO, 15° cranial

**ANSWERS**

1. B
2. A
3. D
4. C
5. D
Computed tomography (CT) was developed in the early 1970s. The first computed axial tomography (CAT) scanners developed by Sir Geoffrey Hounsfield and colleagues required long acquisition and reconstruction times and were only suited for (small) stationary body parts like the head. However, within the same decade, scanners dedicated to cardiac imaging were developed that were able to acquire images in 100 milliseconds or less, which was sufficient to virtually freeze cardiac motion. Contrary to mechanical CT scanners, these electron-beam CT systems lacked mechanically rotating parts. Instead of a rotating tube-detector unit, a beam of electrons was electromagnetically swept along a stationary tungsten target ring around the patient. As the electrons hit the tungsten ring, a roentgen fan beam was created. On the opposite side of the gantry, attenuated roentgen rays were collected by a stationary ring of roentgen detectors. For over 2 decades, these scanners were in operation, primarily to image coronary calcium, but also to image the coronary lumen after intravenous contrast injection. Technical and other practical challenges to electron-beam contrast CT, such as difficulties expanding the number of simultaneously acquired slices and expanding the longitudinal scan range, stalled further exploitation.
FIGURE 12-1 Early computed tomography scanner (EMI, 1971) for brain imaging, on display at the Museum of Science, London, United Kingdom.

In the 1990s, the introduction of slip-ring technology for cableless exchange of energy between the rotating and stationary scanner components of mechanical CT scanners allowed for faster, uninterrupted scanner rotation and the development of spiral CT imaging techniques. Spiral or helical scan protocols, through continuous table movement and data acquisition, allow for faster longitudinal coverage and propelled the possibilities for contrast-
enhanced CT applications, including coronary imaging. Just before the turn of the millennium, the first 4-slice spiral CTs with electrocardiogram (ECG) synchronization for cardiac imaging were introduced.\textsuperscript{4,5} Over the next decade, the technical capabilities of cardiac CT improved rapidly, with faster rotating scanners and increasing numbers of detector rows for better and easier coronary imaging (Fig. 12-2). However, concerns about the increasing radiation burden associated with cardiac CT emerged, which motivated technical innovations to reduce the radiation dose while maintaining sufficient diagnostic accuracy.

\textbf{FIGURE 12-2} Computed tomography angiography of a patient with a single coronary artery. The right coronary artery (RCA) arises from the middle portion of the left anterior descending coronary artery (LAD) and then transverses in front of the pulmonary artery to the right atrioventricular groove.

In addition to noninvasive assessment of coronary stenosis, coronary CT
also allows for assessment of the atherosclerotic changes in the vessel wall. Endeavors to noninvasive identify vulnerable plaques are ongoing. As the technologic accuracy of coronary CT angiography (CTA) matured and the radiation exposure reached acceptable levels, scientific attention shifted toward the clinical validation of the technique to define its most effective role in cardiovascular medicine. Several trials, both small and large, have been performed to assess the value of coronary CT (eg, in patients with stable angina or acute chest pain). Over the past decade, practicing physicians have become increasingly aware of the importance of functional stenosis assessment in the management of coronary artery disease. Although coronary CTA is an excellent means to exclude coronary disease, imaging of anatomy does not allow direct interpretation of the hemodynamic relevance. Several functional CT applications, such as coronary attenuation patterns, virtual fractional flow simulations, and stress myocardial perfusion imaging, are currently being investigated as options to complement CTA to provide a comprehensive assessment of patients and guide therapy.

**PRINCIPLES AND TECHNIQUES**

*Computed Tomography*

CT is an imaging technique based on the roentgen attenuation characteristics of tissues. While the emitting roentgen tube and opposing detectors rotate around the patient, a large number of roentgen projection profiles are collected. From these projection profiles that represent the cumulative attenuation under varying angular degrees, the regional attenuation contribution, which depends on atomic composition and density, can be calculated using sophisticated reconstruction algorithms. The resulting image is the spatial distribution of the attenuation properties throughout a cross-section, relative to the attenuation properties of water, expressed in Hounsfield units (HU). By definition, the attenuation value of water is 0. Fat tissue has attenuation values just below 0, while in the relative absence of matter (air), attenuation values are very low (conventionally represented by dark shades of gray). Most (nonenhanced) soft tissues have positive attenuation values just above water, whereas tissues containing heavier atoms (eg, calcium, iodine, metals) have substantially higher attenuation values.
(bright shades).

**Contrast Enhancement**

Because the attenuation values of blood and the vessel wall are similar, the lumen cannot be imaged without the use of a contrast medium. Iodine-containing contrast media are usually injected through a peripheral vein. Arterial imaging is best during the first passage of contrast medium, and the required duration of the enhancement plateau depends on the scan duration. While with 4-slice scanners a cardiac scan took 30 to 40 seconds, current 64- to 320-detector technology requires only a few seconds, which allows for a smaller contrast bolus and more comfortable breath hold. Optimal timing of the scan relative to the arrival of contrast medium can be achieved by first performing a test bolus injection or by a bolus tracking technique, in which case the data acquisition is automatically started as soon as aortic enhancement is detected on a monitoring scan.

**Temporal Resolution**

The main challenge for coronary imaging by CT lies in the continuous movement of the coronary arteries. The temporal resolution of CT is relatively modest, at least in comparison to some other cardiac imaging techniques, which increases vulnerability to artifacts caused by coronary displacement. The temporal resolution of cardiac CT is determined by the time necessary to acquire the minimal number of projections for image reconstruction. Partial scan reconstruction algorithms can reconstruct images based on an approximately 180° gantry rotation. Consequently, for single-source scanners with a rotation time of 250 to 350 milliseconds, the fundamental temporal resolution is around 125 to 175 milliseconds. The temporal resolution can be improved in several ways. By combining 2 tube-detector systems at an angular off-set of 90°, dual-source CT scanners collect all projections over a 90° rotation, improving the temporal resolution by a factor of 2 (down to 65 milliseconds). Alternatively, phase-consistent data of the same section that were acquired over 2 or more heart cycles can be combined for image reconstruction, which improves the effective temporal resolution, albeit in a less predictable manner and at the expense of a higher radiation dose. Finally, the effective temporal resolution can also be
improved by slowing the heart rate using β-blockers or other medication.

**ECG Synchronization**

Despite efforts to improve the temporal resolution, the maximum achievable temporal resolution of CT does not allow for motion-free imaging of the coronary arteries throughout the cardiac cycle. Coronary displacement is less during mid-diastole and at the end of systole. Because most scanners cannot cover the heart in a single beat, multiple stacks of data are acquired over a number of heart cycles. To assure reconstruction of images during the optimal motion-sparse phases within the heart cycle, consistently over several heart cycles, some form of ECG synchronization is required. When coronary imaging using mechanical 4-slice CT emerged at the beginning of the 21st century, a spiral CT scan mode was applied for continuous, temporally overlapping data acquisition, after which images were reconstructed for the desired cardiac phases based on a recorded ECG trace. This robust technique allows for correction for rhythm irregularities. Often, it was necessary to reconstruct many phases to find a dataset with minimal motion artifacts, given the slower scanner rotation at the time. Although retrospectively ECG-gated spiral-mode cardiac CT is still available and applied in patients with arrhythmia or when full-cycle data are needed, for routine coronary imaging, this scan mode has been largely replaced by more dose-considerate techniques. The current default scan technique for coronary CTA is the prospectively ECG-triggered axial scan mode, also referred to as the prospective scan mode, or step-and-shoot mode (Fig. 12-3). Contrary to the spiral scan mode, using prospectively ECG-triggered axial imaging, each consecutive stack of data is acquired by roentgen exposure limited to the desired cardiac phase, based on the preceding heart rhythm, while the table remains in a stationary position. Contemporary axial scan protocols include arrhythmia recognition algorithms, which interrupt and/or repeat scans in case of a rhythm disturbance, as well as the option to extend the exposure window for reconstruction of different cardiac phases. Although spiral scan protocols have also been modified with the objective to lower dose, axial scan protocols generally achieve the lowest exposure. Second- and third-generation dual-source CT scanners can perform an ECG-triggered spiral imaging at very fast table advancement to cover the entire heart in a single heart cycle. Scanners with very wide detector arrays that completely cover
the heart require no table advancement during the scan.

**FIGURE 12-3** Cardiac computed tomography (CT) scan techniques. The spiral scan mode can be performed by continuous exposure (green) or with electrocardiogram (ECG)-triggered tube modulation and nominal exposure limited to the phase(s) of interest. Depending on the selected table speed and heart rate, a degree of overlap will be created between the consecutive acquisitions per heart cycle. Axial scan protocols minimize the exposure to the phase of interest but can be extended to allow for reconstruction of more phases (padding), with minimal longitudinal overlap between acquisitions. Second and third dual-source CT systems can perform high-pitch spiral scans, in which case all data are acquired (over a longer interval) within a single heart cycle. The purple bar superimposed over the ECG represents the minimal exposure duration for reconstruction of a single dataset/phase.

**Image Reconstruction Techniques**

Until recently, limitations in computer performance necessitated the use of filtered back-projection techniques for the reconstruction of CT images. As a
result of accelerated computer processing power, computationally more demanding iterative reconstruction algorithms can now be applied to CT data at acceptable reconstruction times. The advantage of iterative reconstruction algorithms is the improved image quality. In addition to axial scan protocols, more dose-aware operating techniques, and more efficient tube settings, iterative reconstruction algorithms have contributed to the lower radiation exposure of contemporary coronary CTA by reducing noise levels at lower tube output settings.\(^6\)\(^7\) Reported dose values peaked at around 15 mSv with the first 64-slice scanners\(^8\) but, since then, have gradually dropped to well below 5 mSv using standard CT technology and even below 1 mSv using state-of-the-art technology in selected populations.\(^9\)

CORONARY CT ANGIOGRAPHY

*Image Interpretation*

A cardiac CT scan is essentially a large stack of overlapping axial slices. Each image slice consists of 512 × 512 image elements, whereas the dimensions of each 3-dimensional image element, called a voxel, are approximately 0.3 × 0.3 × 0.4 mm. The images can be assessed slice by slice or with the use of secondary postprocessing techniques to visualize longer sections of the coronary arteries and facilitate interpretation of obstructive disease. These secondary reconstruction techniques include double-oblique cuts, curved cross-sections along the axis of the vessel, and 3-dimensional volume-rendered reconstructions. Often a combination of techniques is used for interpretation. Guidelines recommend classification of the stenosis severity into categories rather than exact percentages of lumen narrowing (Table 12-1).\(^{10}\) Standardized coronary classification systems may be used to specify the location of disease. The recently published Coronary Artery Disease Reporting and Data System (CAD-RADS) criteria can be used to classify coronary CTA findings.\(^{11}\)

| Table 12-1 | Society of Cardiovascular Computed Tomography Recommended Stenosis Grading and Qualitative Interpretation of Flow Limitation |\(^{10}\) |
Diagnostic Performance

Over the past 2 decades, noninvasive coronary CTA has gradually evolved into a reliable technique for the assessment of obstructive coronary artery disease (Fig. 12-4). Many single-center studies, as well as a number of multicenter trials, have been performed to test the technical accuracy of coronary CTA against invasive coronary angiography (Table 12-2).\textsuperscript{12-17} The sensitivity of CTA is high (93%-100%) on a per-patient level, and the probability of coronary disease is very small in case of a normal CT angiogram because the per-patient negative predictive value approaches 100%. The specificity of CTA is slightly lower (78%-96%), which means that the angiographic disease severity is overestimated in comparison to invasive angiography. There are several contributory factors to this. The spatial resolution of CTA prevents visualization of small vessels, but also increases the apparent size of calcifications and other high-attenuating material in combination with filtering effects. The appearance of obstruction may be created by artifacts, including motion blurring and misalignment between data stacks. The propensity toward overcalling stenosis severity may also be the indirect result of the visualization of atherosclerotic plaque. Similar to intravascular ultrasound the perceived stenosis severity on CTA may increase in the presence of large plaques and outward vessel remodeling (Fig. 12-5). Naturally, the performance of CTA will improve with better image quality. Nonmodifiable technical and patient characteristics, such as

temporal resolution and longitudinal coverage or the heart rhythm and size of the patient, need to be factored into the expectations for the examination. A high calcium burden decreases the diagnostic performance of CTA, and patients with a very high calcium score may benefit more for another type of testing than CTA. Aspects amenable to optimization include patient cooperation and heart rate. Adequate patient instructions and practice can avoid breathing and other patient movement during the scan. β-Blockers are recommended for all patients with a heart rate over 65 to 70 bpm to reduce motion artifacts and allow for more dose-efficient scan protocols. A fast-acting β-blocker may be administrated orally or intravenously. Alternatively, calcium antagonists or sinus node inhibitors may be used to slow the heart rate. Nitroglycerin is administrated sublingually for coronary vasodilation and improves image quality.

Note: Meta-analysis based on the pooled results from 13 studies using low-dose coronary computed tomography angiography, including 789 patients, 2622 vessels, and 11,518 vessel segments.10
FIGURE 12-5 Invasive angiography (A and C) and computed tomography angiography (CTA) (B and D). In the proximal left anterior descending coronary artery (LAD), a noncalcified lesion (arrow) can be observed on CTA, corresponding with a similarly severe lesion on invasive angiography. CTA also shows a large calcified plaque in the distal left main (arrowhead). Stenosis appears more severe on computed tomography compared to invasive angiography due to a combination of outward vessel remodeling and blooming effect of the highly attenuating calcium. D1, first diagonal branch; LCX, left circumflex coronary artery.
Coronary Anomalies

Cardiac CT is regarded as the clinical reference for the in vivo anatomic depiction of coronary anomalies (see Fig. 12-2). Without the need for selective catheter intubation, aberrant branches will opacify regardless of whether the origin of the vessel is known. The exact course, the relation with other structures, and the termination of fistulas can be visualized unambiguously. Mechanical effects like intra-arterial compression may be displayed using dynamic cardiac CT reconstructions. Myocardial bridging is frequently observed on CT angiograms.

PLAQUE IMAGING

Nonenhanced Calcium Imaging

Without injection of contrast medium, ECG-synchronized CT can be used to image and quantify calcium deposits in the coronary artery wall. Although there are many ways to quantify the coronary calcium burden, the semi-quantitative Agatston score remains the most widely used method (Fig. 12-6). Population studies have demonstrated an age-, sex-, and race/ethnicity-dependent distribution and progression of coronary calcium. The calcium score is associated with the risk of adverse cardiac events, adds (substantial) prognostic value to conventional risk predictors, and appears to outperform other secondary risk predictors such as C-reactive protein, N-terminal pro-B-type natriuretic peptide, or carotid intima-media thickness. The calcium score can correctly reclassify the risk of asymptomatic individuals and appears most effective in those at intermediate risk by conventional factors.
FIGURE 12-6 A. Coronary calcium imaging. Nonenhanced cardiac computed tomography (CT) shows calcified disease in the aortic root and the coronary arteries (3-dimensional [3D] rendered reconstruction). B. Automatically highlighted tissues with an attenuation value above 130 HU and belonging to the coronary arteries can be manually selected, after which an Agatston score is calculated based on the calcified lesion areas and maximum attenuation value per lesion. C. 3D-rendered CT angiogram of the same patients showing the extensive calcification in relation to the coronary anatomy. LAD, left anterior descending coronary artery; LCX, left circumflex coronary artery; RCA, right coronary artery.

Contrast-Enhanced Plaque Imaging

In addition to the calcified components, CTA also has the ability to show noncalcified plaque tissue (see Figs. 12-4 and 12-5). The global angiographic disease burden is associated with clinical outcome. In addition to the stenotic disease burden, the presence of nonobstructive plaque also predicts adverse events. When coronary disease is absent on CTA, the probability of an adverse cardiac event is extremely low over the subsequent 6 years. Because differentiation from the perivascular tissues is more difficult, the sensitivity for the detection of noncalcified plaque is lower than for calcified
plaque, and absolute quantification remains only moderately reproducible between different software packages. Based on measured attenuation values, the differentiation of lipid-rich (lower attenuation values) and fibrous-rich plaques (higher attenuation values) has been demonstrated in several studies. However, absolute values depend on contrast enhancement and scan conditions; within studies, overlap between plaque types is considerable, and between studies, the reported thresholds vary substantially. Various plaque characteristics associated with plaque rupture can be reproduced by CTA, including plaque size, large low-attenuating plaque, outward vessel remodeling, and calcified nodules. Identification of large lipid cores on CTA has been reported by a number of investigators. While it is not possible to image several other parameters of plaque instability, such as cap thickness, macrophages, or intraplaque hemorrhage, prospective studies suggest that the aforementioned CT characteristics, in addition to plaque progression, predict the occurrence of adverse cardiovascular events.

**CLINICAL ROLE OF CT ANGIOGRAPHY**

*Evaluation of Coronary Artery Disease in Patients with Angina Pectoris*

Based on the diagnostic performance of CTA, in particular the high negative predictive value in comparison to invasive angiography, the technique is thought to be most effective in patients with a low to intermediate probability of coronary disease. The 2014 American College of Cardiology (ACC)/American Heart Association (AHA) guidelines for stable ischemic heart disease included several recommendations on the use of coronary CTA (Table 12-3). Coronary CTA angiography was considered a reasonable first-line option in patients with an intermediate probability of coronary artery disease (CAD), in particular for patients with contraindications to stress testing. Coronary CTA may also be considered for patients with a nonconclusive stress test result. Coronary CTA should only be considered if adequate CT scanner technology and expertise are available and patient
characteristics suggest that diagnostic image quality can be achieved. Since publication of the American and European guidelines, the results of several randomized controlled trials on the clinical effectiveness of coronary CTA compared with current standard diagnostic management were published. The largest of these, the National Institutes of Health–sponsored PROMISE trial, randomized over 10,000 patients between coronary CTA and standard care (mostly stress imaging). Both strategies performed equally well in terms of hard end points, which occurred at a lower rate than originally anticipated. The use of CTA was associated with a higher rate of catheterizations and revascularizations, but a lower rate of normal invasive angiograms. The Scottish SCOT-HEART trial tested whether the addition of cardiac CT to standard care (including exercise ECG) improved diagnostic confidence. In addition to an increased certainty about the diagnosis, secondary analysis demonstrated a lower event rate in patients in whom CTA was added. The CRESCENT trial randomized 350 patients between a tiered cardiac CT protocol and standard care (mostly exercise ECG). In this study, CTA was only performed in patients with a positive calcium scan or high pretest probability, which reduced radiation exposure and cost, without a negative effect on outcome. Meta-analyses of these trails suggest an overall increase in subsequent catheterization and revascularization rates after CTA, but also suggest a lower myocardial infarction rate.

Table 12-3 Coronary Computed Tomography Recommendations
**Acute Chest Pain**

The triage of patients with acute chest pain but no evident myocardial ischemia or necrosis remains a diagnostic challenge that physicians confront on a daily basis. While a small proportion of patients will suffer from a (potentially) life-threatening condition, the vast majority of patients presenting at the emergency department will have a more benign cause. The diagnostic algorithm for triage of these patients requires sufficient sensitivity to identify conditions that benefit from immediate intervention, while avoiding excessive use of resources for the entire group. While currently

Abbreviations: ABI, ankle-brachial index; ACC, American College of Cardiology; ACS, acute coronary syndrome; AHA, American Heart Association; CAC, coronary artery calcium; CAD, coronary artery disease; CCTA, coronary computed tomography angiography; CMR, cardiac magnetic resonance imaging; hs-CRP, high-sensitivity C-reactive protein; IHD, ischemic heart disease; MPI, myocardial perfusion imaging.
confident rule-out of an acute coronary syndrome often requires prolonged observation, serial sampling of myocardial biomarkers, and noninvasive or invasive investigations, cardiac CT has been introduced as a means to expedite the clinical triage of acute chest pain.

According to several observational trials, the absence of atherosclerotic plaque on coronary CTA virtually rules out an acute coronary syndrome. However, the absence of calcium (on a nonenhanced calcium scan) or the absence of >50% coronary stenosis lowers the probability of an acute coronary syndrome considerably but does not provide the same certainty as the absence of any plaque. In addition to severe coronary obstruction, cardiac CT can detect several other life-threatening conditions, such as aortic dissection or pulmonary embolism.

Based on these observations, several randomized controlled trials have been performed to study the value of cardiac CT in comparison with standard care in low (or intermediate)-risk patients with acute chest pain. The CT-STAT trial compared coronary CTA with single-photon emission CT myocardial perfusion imaging in 700 patients and demonstrated that CTA resulted in a shorter time until diagnosis and reduced expenses at the emergency department. The ACRIN-PA trial demonstrated in 1370 low-risk patients with chest pain, randomized 2:1 between CTA and standard care, that triage by CT is safe and allows for earlier discharge of patients. ROMICAT II compared coronary CTA and standard care in nearly 1000 patients and also found that cardiac CT was associated with a shorter length of stay and higher early discharge rate. Despite these advantages, cardiac CT was also associated with higher rates of invasive angiography and revascularization procedures. The BEACON trial compared coronary CTA with standard care in a European setting after the introduction of high-sensitivity troponin assays. While the use of cardiac CT was found to be safe and reduced the need for further downstream testing, previously observed logistic advantages were not reproduced in this trial. Shorter lengths of stay and high early discharge rates were observed in both arms, likely facilitated by the use of high-sensitivity troponins. The 2014 ACC/AHA guideline for the management of non–ST-segment elevation acute coronary syndromes concludes that CTA can result in a more rapid, more cost-effective diagnosis than stress myocardial perfusion imaging and considers cardiac CT a reasonable option in patients with a possible acute coronary
syndrome, normal ECG, normal cardiac troponins, and no history of CAD (Class IIa, Level of Evidence A; see Table 12-3).\textsuperscript{52}

**Early Detection of Subclinical Coronary Disease**

Semi-quantification of the coronary calcium burden on a nonenhanced cardiac CT scan has incremental prognostic value over conventional risk factors. It allows for better risk stratification compared to other secondary prognosticators and appears particularly effective in individuals at intermediate risk. Contrary to the European guidelines, the 2013 ACC/AHA guidelines do not provide strong recommendation of the use of calcium imaging for risk stratification (see Table 12-3).\textsuperscript{53,54} Although, contrast-enhanced CTA allows for more in-depth interpretation of the total atherosclerotic burden, as well as the presence of subclinical stenosis, there is currently insufficient evidence for CTA screening of asymptomatic individuals.\textsuperscript{55,56} Based on registry data, CTA seems to have incremental prognostic value over calcium imaging in high-risk populations, such as diabetic patients or patients with hypercholesterolemia.\textsuperscript{56,57} Since their diabetic status generally qualifies them for intensive risk factor management already, it is unclear whether additional testing provides outcome benefit.\textsuperscript{58}

**CT Guidance for Coronary Interventions**

CTA can provide additional information to invasive angiography that may be of value for interventional procedures. Whereas invasive angiography provides 2-dimensional projections of selectively enhanced coronary arteries, CTA visualizes the coronary arteries in 3-dimensional space without vessel overlap or foreshortening. Vessel segment length and angles between branches may be more reliable on CT (Fig. 12-7). CTA also visualizes less intensely opacified structures and can provide information about plaque location, size, and composition, potentially relevant to the intervention procedure. For recanalization of coronary occlusions, CTA can provide information about the occluded section, such as occlusion length and course, the presence of side branches, and the presence, location, and extent of calcifications, all of which are relevant before and during the revascularization procedure. Independent CT-derived predictors of complicated lesion crossing include the extent of the calcifications, long
occlusion length, multiple occlusions, negative vessel remodeling, blunt stump, and bending of the occlusion.\textsuperscript{59-62} While CT may not be performed routinely, it should be considered for second-attempt procedures. CT images have been used for magnetic navigation in the treatment of complex CAD.\textsuperscript{63}

\textbf{Avoiding Invasive Angiography}

Overall, coronary CTA can reduce the proportion of invasive angiograms without obstructive coronary disease. There are specific situations where an invasive procedure is particularly undesirable. Aortic valve endocarditis or aortic dissections add challenges and risks to catheterization procedures, while the yield of invasive angiography tends to be low in these situations (Fig. 12-8). Prior to noncoronary cardiac surgery or solid organ transplantation, invasive angiography is often part of the routine workup, although the proportion of abnormal examinations is relatively low. In the
majority of these patients, noninvasive coronary angiography by CT provides sufficient reassurance to avoid another invasive procedure. In addition, in patients with (assumed to be) nonischemic heart failure, CTA can be offered as a means to exclude CAD.

**FIGURE 12-8** A and B. Patient with endocarditis involving the aortic and mitral valves (*arrows*). C and D. Coronary computed tomography angiography was performed to rule out coronary artery disease prior to surgery. Nonobstructive, partially calcified coronary disease was found in the left anterior descending coronary artery (LAD; *arrow*, D). LCX, left circumflex coronary artery.

**FUNCTIONAL INTERPRETATION OF**
CORONARY LESIONS

The negative predictive value of CTA is excellent, and CAD can be ruled out reliably. However, for previously described reasons, CTA overestimates the angiographic severity of coronary disease. In addition, angiographic techniques generally overestimate the functional severity, at least when conservative stenosis thresholds are applied (50% diameter narrowing). In most cases, the finding of a stenotic lesion on CTA is not sufficient for revascularization decisions. There are various invasive and noninvasive techniques to establish the functional importance of angiographic lesions, as discussed elsewhere. Instead of performing a second examination, there is also substantial interest in secondary CTA parameters that inform us about the functional relevance of angiographic obstructions.

Coronary Attenuation Patterns

In case of a severe stenosis, one can imagine that blood flow to the distal vessel will be delayed. Therefore, similar to the invasive Thrombolysis in Myocardial Infarction (TIMI) score, it may be possible to demonstrate slow flow by differences in lumen opacification. Chow et al\(^6^4\) compared attenuation values proximal and distal to coronary stenoses, normalized for attenuation values in the left ventricle, and found that larger opacification differences were associated with low TIMI flow on invasive angiography. By extensive sampling of the intracoronary attenuation throughout the coronary artery, the transcoronary attenuation gradient (TAG) can be calculated. While initial experiences showed promising correlation between the TAG and the functional stenosis severity by invasive fractional flow reserve (FFR), subsequent studies reported lower diagnostic performance.\(^6^5-6^7\) These contradicting results may be explained by differences in CT technology (incomplete vs complete heart coverage) and CTA techniques (late scanning using contrast bolus tracking).

CTA-Derived Fractional Flow Reserve

The CTA-derived FFR is a relatively new technique to calculate the hemodynamic significance of CAD on CT angiograms (Fig. 12-9). By
applying computational fluid dynamics onto a CT angiogram, it is possible to model the blood flow through the coronary arteries and estimate intracoronary pressures at rest and during simulated hyperemia.\textsuperscript{68} By comparing the calculated blood pressure in the coronary arteries during hyperemia with the pressure in the aorta, FFR measures can be calculated throughout the coronary arteries. Computational CTA-FFR does not require additional scans or injection of vasodilators, but can be performed on any CT angiogram of sufficient image quality. The CTA-FFR application developed by HeartFlow Inc. (Redwood City, CA) has been tested against invasive FFR in a series of multicenter studies. The technique correlates well with invasive FFR and shows better specificity and accuracy in comparison to CTA (50% stenosis threshold).\textsuperscript{69,70} CTA combined with CTA-FFR can avoid normal invasive angiograms in patients referred for catheterization, which can reduce costs.\textsuperscript{71,72} HeartFlow CTA-FFR is commercially available, and performance of the simulations on dedicated computers requires transfer of the CT data. Alternative CTA-FFR applications are under development, of which some can be performed locally on regular workstations by applying less complex computational fluid dynamic solutions.\textsuperscript{73-76} Initial results with these new CTA-FFR applications are promising, but none is yet commercially available. Thus far, CTA-FFR has only been validated in fairly standard populations, without other abnormalities or prior revascularization procedures.

\textbf{FIGURE 12-9} Computed tomography angiography (CTA)–derived fractional flow
reserve (FFR) after percutaneous coronary intervention with a bioresorbable scaffold. Curved multiplanar reformation of a dominant left circumflex coronary artery (LCX) with the remains of a bioresorbable scaffold (arrowheads) in the distal segment (A). CTA-derived FFR with color-coded FFR display. Blue to green shades represent CTA-FFR values above 0.80, ruling out hemodynamically significant stenosis (B). RCA, right coronary artery.

**Stress Myocardial Perfusion Imaging**

In a manner similar to other stress imaging modalities, CT can be used for stress myocardial perfusion imaging. Infusion of a vasodilator causes myocardial hyperemia but less flow increment for myocardium supplied by obstructed coronary arteries. These variations in hyperemic blood flow are reflected by differences in myocardial contrast enhancement. For cardiac CT, there are 2 myocardial perfusion imaging methods. Either a single high-resolution CT scan is performed after contrast injection to capture instantaneous qualitative differences in myocardial enhancement (static perfusion imaging), or a sequence of low-resolution CT images is acquired to depict the time-resolved changes in myocardial enhancement for quantitative myocardial perfusion measures (dynamic perfusion imaging). Static perfusion imaging can be performed on most clinically used CT scanners and is associated with a lower radiation dose (equal to or lower than a standard CTA on the same system), whereas the dynamic perfusion imaging approach requires wide detector coverage and dedicated reconstruction software and results in a higher radiation dose (Fig. 12-10). In both single-center and multicenter studies, static perfusion imaging has been shown to correlate well with other stress imaging techniques and improves the specificity of CTA alone.\(^{77-80}\) In largely single-center studies, dynamic myocardial perfusion shows at least equal diagnostic performance.\(^{81-84}\) While there are many options to assess the hemodynamic severity of CAD, the combination of CTA and CT myocardial perfusion imaging may have practical advantages and provide a complete comprehensive assessment in a single session.
FIGURE 12-10 Severe angiographic obstruction (arrows) of the left circumflex coronary artery by computed tomography (CT) angiography (A) and invasive angiography (C). Dynamic CT myocardial perfusion imaging shows a discrete area (between arrows) of decreased myocardial perfusion in the lateral wall of the left ventricle (short-axis, myocardial blood flow map, B).

CARDIAC CT AFTER CORONARY REVASCULARIZATION

After Coronary Stenting
Conventional stents are made of highly attenuating metal alloys. The combination of strong attenuation and image filtering causes blooming artifacts (ie, the stent struts appear much larger than they are in reality). Beam hardening occurs when heterochromatic roentgen passes through a high-density structure. Disproportionate attenuation of low-energy roentgen and low attenuation of the remaining high-energy roentgen behind the high-density structure cause shadowing. Consequently, stented coronary segments are more difficult to interpret. The severity of the artifacts and the ability to interpret the lumen within the device depend on the type of alloy, the metal density, and the diameter size of the stent.\textsuperscript{85,86} Artifacts are aggravated by inferior image quality, particularly the presence of residual motion. Most studies that validated CTA against invasive angiography in (selected) patients with a history of coronary stenting report that a substantial proportion of devices cannot be interpreted and diagnostic accuracy is lower compared with nonstented vessels (sensitivity 86% and specificity 93%).\textsuperscript{87} While complete occlusion or patency can often be concluded with reasonable certainty, stenoses of intermediate severity are more difficult to assess (Fig. 12-11). Cardiac CT is most reliable in larger stents, in the proximal coronary arteries, and in grafts, provided that sufficient image quality can be achieved. Iterative reconstruction and dedicated filters can improve the interpretation of stents (Fig. 12-12). Stents without a metal backbone can be imaged better. Biodegradable scaffolds made of polylactic acid are invisible on CT, except for the small platinum markers at the edges of the device (Fig. 12-9 and Fig. 12-13).\textsuperscript{88} Cardiac CT has been used for mid- and long-term angiographic follow-up in the ABSORB trials.\textsuperscript{89} Whether the scaffold is still present shortly after implantation, or fully resorbed, CTA can be performed unhindered.
FIGURE 12-11 Three-vessel percutaneous coronary intervention and computed tomography angiography follow-up. Two stents of different make (arrows) in the left anterior descending coronary artery (A). The first stent appears incompletely deployed. Occluded stent in the proximal left circumflex coronary artery, as well as severe obstruction proximal to the stent, and collateral opacification of the distal vessel (B). Multiple stents in the right coronary artery with diffuse in-stent hyperplasia (insert) of uncertain obstructive severity (C).

After Bypass Graft Surgery
Because of the large diameter and less displacement during cardiac contraction, bypass grafts can be imaged well by CT. A number of technical validation studies have been performed that showed that CTA is a reliable technique to assess graft patency (accuracy approaching 100%) and detect graft restenosis (accuracy >95%) (Fig. 12-14).\textsuperscript{90-92} Surgical material in the form of vascular clips, sternal wires, and indicators at the proximal anastomosis site may obscure parts of the graft. Clips at the level of the distal anastomosis of arterial grafts may prevent reliable interpretation, particularly when residual motion is present. In patients who underwent bypass graft surgery, the native coronary arteries, distal run-off branches, and nongrafted vessels are more difficult to assess due to frequent diffuse atherosclerotic disease. Interpretation of angiographic findings often requires some form of functional testing, particularly in case of multiple lesions, prior myocardial infarction, or collateral coronary development. Cardiac CT may have incremental value over invasive angiography in certain situations. Because selective catheter engagement is not required, knowledge of the surgical anatomy is less important to image the grafts. In case of re-thoracotomy, CTA better visualizes the intrathoracic relations, the proximity of patent grafts to the sternum, adhesions, and so on.
FIGURE 12-12 Reconstruction of a stent in the left main and left anterior descending coronary arteries, using 0.8-mm slices and a smooth kernel (A), 0.8-mm slices and a sharper kernel (B), and 0.5-mm slices and a sharper kernel (C), which shows better stent definition, but also increases image noise.
FIGURE 12-13 Follow-up after treatment with bioresorbable scaffolds. Platinum markers at borders of the device remain present after absorption (arrowheads). Patent proximal right coronary artery (A); patent proximal marginal branch with visible plaque and overlap with conventional metal stent (B); severely calcified left anterior descending coronary artery (C); and proximal left anterior descending coronary artery with severe stenosis of the previously treated vessel (D).
FIGURE 12-14 Computed tomography angiography after bypass graft surgery. **MULTIPLE CHOICE QUESTIONS**

1. Interpretation of the in-stent coronary lumen by computed tomography angiography is improved by which of the following?
   - A. High heart rates
   - B. High metal strut density
   - C. Larger stent diameter
   - D. Absence of drug coating

2. In case of *moderate* coronary stenosis on computed tomography (CT), hemodynamic significance is thought to be:
   - A. Impossible
   - B. Unlikely
   - C. Possible
   - D. Likely

3. Which statement about plaque characterization by CT is true?
   - A. Fibrous plaques are expected to have lower attenuation values than lipid-rich plaques.
B. Metabolic activity on CT angiography predicts plaque rupture.
C. The border between vessel lumen and plaque is more difficult to delineate than the outer plaque border.
D. Contrast medium affects the measured attenuation values in the plaque.

4. Which statement regarding CT angiography (CTA)–derived fractional flow reserve is true?
   A. It requires dedicated CT equipment.
   B. It requires administration of an intravenous vasodilator.
   C. It requires detailed segmentation of the coronary arteries.
   D. It requires purchase of a supercomputer.

5. Which statement regarding coronary CTA for the assessment of coronary stenosis is true?
   A. The negative predictive value of CTA is higher than the positive predictive value.
   B. The sensitivity of CTA is lower than the specificity.
   C. CTA underestimates angiographic stenosis severity.
   D. CTA underestimates functional stenosis severity compared to fractional flow reserve.

**ANSWERS**

1. C

   The size of the artifacts depends on the strut size and the quality of the scanner and is fairly constant regardless of the stent diameter. Therefore, the proportion of artifact-free, interpretable, lumen increases disproportionally with increased vessel size. High heart rates and denser metal create more artifacts, whereas nonmetal drug coatings have no effect.

2. C

   Moderate stenosis means a 50% to 70% lumen narrowing, which may or may not cause hemodynamic obstruction.
3. D
Due to image filtering, motion, and perhaps microvascular enhancement, the attenuation values measured in plaques increase when the adjacent lumen contains more contrast. If anything, fat should result in lower attenuation values than soft tissues. Metabolic activity cannot be assessed by CT angiography. Due to the vasa vasorum and small attenuation differences with the epicardial tissue, the delineation of the outer plaque borders is more difficult.

4. C
Segmentation of the coronary arteries is necessary for the computational fluid dynamics model. It can be performed on regular scanners without injection of a vasodilator. It is performed on a regular workstation on site, or the CT scan is transferred to a remote high-performance computer.

5. A
Compared with invasive angiography, CTA has the tendency to overestimate stenosis severity. Therefore, sensitivity and negative predictive value are high, whereas specificity and positive predictive value are lower. Angiographic techniques generally overestimate the functional severity (using conservative stenosis thresholds).
Intracardiac echocardiography (ICE) is an intravascular ultrasound (IVUS) modality that provides diagnostic imaging of cardiac structures from within the heart and has become widely used for guiding noncoronary interventions in the catheterization and electrophysiology laboratories. The first IVUS catheters used high-frequency transducers (20-40 MHz) containing a single ultrasound crystal that rapidly rotated at the end of the catheter, producing a radial 2-dimensional image.\(^1\) This type of high-frequency IVUS transducer provides excellent spatial resolution in the near field, making it uniquely suited for imaging the coronary arteries and other small vessels. The main limitation of IVUS in this frequency domain, however, is the short imaging depth (several millimeters).\(^1\)\(^-\)\(^2\) To accomplish ICE imaging from atria to apex, lower frequency transducers (5-12 MHz) have been miniaturized and mounted onto catheters capable of percutaneous insertion and manipulation within the heart.\(^1\)\(^,\)\(^3\)\(^-\)\(^7\) These lower frequency transducers are capable of greater tissue penetration and imaging depth, permitting high-resolution two-dimensional imaging of the whole heart.\(^2\)\(^,\)\(^8\)\(^-\)\(^11\) The earliest experiences with such low-frequency ICE catheters were described in the late 1970s and early 1980s.\(^3\)\(^,\)\(^4\) More recently, with the introduction of the newest phased array transducers, full Doppler flow data can be obtained.
Two different types of ICE catheters are currently available for clinical use. A mechanical transducer, similar to that used with IVUS, has a rotating ultrasound transducer driven by a motor unit at the opposite end of the drive shaft, which results in a 360° “radial” view perpendicular to the axis of the catheter. The second type is a fixed or phased array catheter-mounted transducer that uses electronically controlled transducers mounted on one side of the catheter shaft, which results in a wedge-shaped 90° image sector similar to that of transthoracic or transesophageal echo probes.

Both types of catheters provide high-resolution, real-time images of cardiac morphology and devices or catheters in the heart. Current ultrasound catheters, with a diameter size between 6- and 10-Fr, are typically introduced via a sheath in the femoral vein. Phased array catheters offer a large depth of field and add Doppler imaging capabilities, whereas mechanical catheters offer superior near-field resolution.

**BENEFITS OF INTRACARDIAC ECHOCARDIOGRAPHY**

ICE offers imaging that is comparable or, in some cases, superior in quality to transesophageal echocardiography (TEE). ICE adds substantial anatomic information to x-ray fluoroscopy for electrophysiologic ablation procedures and transcatheter atrial septal defect closure. ICE has been shown to provide procedural benefits in the context of radiofrequency ablation procedures for atrial fibrillation and transcatheter atrial septal closure procedures, and as such, ICE has become the “reference standard” for imaging during these procedures. The major advantage over TEE is that no general anesthesia is needed for ICE. Patients who have contraindications to TEE, eg, those with significant esophageal disease, can also avoid TEE while maintaining adequate imaging using ICE. In addition, if sufficiently skilled and knowledgeable, the operator performing the percutaneous closure can also manipulate the ICE catheter and interpret the images. In this setting, ICE has been shown to improve patient comfort and shorten procedure and fluoroscopy time, at comparable cost, compared to TEE-guided interventions under general anesthesia. ICE is currently used as the primary imaging modality during percutaneous transcatheter closure (PTC) without need for
supplemental transthoracic echocardiography (TTE) or TEE. ICE has also been shown to provide incremental diagnostic benefit over TTE and TEE. In a series of 94 patients undergoing PTC,\textsuperscript{28} ICE revealed additional diagnoses in 32\% of patients, despite preprocedural performance of TTE and TEE in the vast majority of patients. These diagnoses included additional atrial septal defects, atrial septal aneurysms, atrial septum redundancy, anomalous pulmonary venous return, pulmonary arteriovenous malformations, and pulmonary vein stenoses.

Additional interventional applications of ICE include guidance of transseptal catheterization, left atrial appendage occlusion, placement of ventricular assist device cannulas, percutaneous mitral balloon valvuloplasty, and many others (Table 13-1).\textsuperscript{29-43} Intracardiac imaging may serve as a diagnostic alternative in patients with contraindications for TEE (eg, esophageal pathology) or to assess anatomic regions that are inadequately visualized by TEE (eg, tracheal shadowing of the aorta).\textsuperscript{44-46} Similarly, ICE can readily evaluate native and prosthetic valves that are not invariably well visualized by TEE.

In the electrophysiology laboratory, ICE provides guidance for pulmonary vein isolation in patients with atrial fibrillation, sinus node modification, ablation procedures for idiopathic ventricular tachycardia (right ventricular outflow tract and aortic sinus locations), ablation procedures in the left ventricle, and extraction of pacemaker or ICD leads.\(^{13,47-50}\) In the electrophysiology laboratory, shorter procedure times, reduced arrhythmia recurrence, and reduced pulmonary vein stenosis occurrence have all been attributed to ICE guidance.\(^{13-16,18,19,51}\)

**ICE SYSTEMS**

Currently there are 3 commercially available ICE systems, each with unique features and advantages.\(^ {52}\) The Boston Scientific UltraICE Plus system uses a mechanical radial ICE imaging transducer, is not steerable, and does not provide Doppler-derived information. This 8.5-Fr system requires a short amount of time for catheter preparation: the housing must be flushed with saline and then physically spun prior to use. The transducer rotates at 1800 rpm and has a fixed frequency of 9 MHz. Both Siemens AcuNav and the St. Jude (formerly EP Medsystems) ViewFlex Xtra use phased array transducers. These transducers are steerable and deflectable. They provide 2-dimensional sector imaging with color and spectral Doppler capabilities. The ViewFlex Xtra and AcuNav systems have 4 directions of steering (anterior, posterior, right, and left). All 3 systems use a single-use ICE imaging catheter, require 8- to 11-Fr venous access, and are relatively expensive, with an approximate price range of $800 to $2800. The 8-Fr transducer catheters provide
somewhat less depth of imaging when compared to larger French systems.

Phased array ICE systems are generally bulkier than rotational ICE, with a handle and 2 dials to aid in maneuvering the catheter to a desired image while providing a 90° field of imaging. They also provide color Doppler and do not require flushing prior to use. Real-time 3-dimensional imaging is under investigation in the United States for both phased array systems. A housed rotational ICE system provides single 360° planar imaging but does not provide color Doppler. It is also less bulky and less maneuverable. No 3-dimensional imaging is currently available with rotational ICE.

**Limitations of ICE**

Current limitations of ICE include the relatively high cost of the single-use catheters and their large shaft diameters (less of an issue with the release of 8-Fr catheters). They provide only single-plane imaging with a relatively narrow field of view. Complications from the use of ICE are rare, but include all of the traditional vascular access–related complications, as well as perforation of the caval vein or cardiac chambers, which could result in cardiac tamponade *(Table 13-2)*.

**Principles of Imaging**

Images acquired with the newer phased-array steerable transducers such as the AcuNav catheter produce images that are similar to TEE images, except
that they originate from within the heart and accordingly require that the interpreter become familiar with a different set of image orientations. The AcuNav transducer has lockable steering controls, so that a particular imaging plane may be set and held in a stable position. Typically, AcuNav images are 90° sector images originating from the transducer location within a cardiac cavity. The AcuNav catheter is usually inserted via a femoral vein. Advancing and withdrawing the catheter shifts the images sideways (in-plane) on screen. A small marker placed outside the imaging sector indicates the proximal boundaries of the image (“operator end”). By emerging convention the image is displayed with the (marked) proximal end of the cross-section on the left side of the screen. Similar to the handling of a TEE probe, subtle rotation of the catheter will result in different angular cross-sections. While the transducer is typically positioned in the right atrium, images can be obtained from any cardiac and vascular structure into which the transducer tip of the catheter can be maneuvered. By systemic venous vascular access, the right atrium, the venae cavae, and the right ventricle can be reached, as well as the left atrium through the atrial septum. In contrast, with radial ICE imaging, the catheter is typically placed in the right atrium or venae cavae, with a more limited range of motion, as these catheters are neither steerable nor deflectable.

**RIGHT ATRIAL IMAGING VIEWS**

The imaging sequence with AcuNav usually begins from the right atrium, with the catheter in a neutral position and the locking mechanism disengaged. In the default position, the ultrasound array is sagittally oriented, parallel to the catheter, and upward in correspondence with the indicator line on the handle. All subsequent maneuvers are described relative to this starting position. The catheter is gently rotated approximately 15° to 30° clockwise from the default position to image the “home view” (Fig. 13-1). This view provides excellent imaging of the mid-right atrium, tricuspid valve, and right ventricle, and typically provides an oblique or short-axis view of the aortic valve.
Further clockwise rotation up to approximately 30° will display the right ventricular outflow tract and pulmonic valve. The aortic valve appears in a near short-axis view (Fig. 13-2). With clockwise rotation up to approximately 45°, the left ventricle can be seen in an oblique long-axis view with the apex toward the outer edge of the imaging sector. Also the left ventricular outflow tract and aortic valve will be visible (Fig. 13-3). Color-flow Doppler interrogation in this orientation may reveal aortic regurgitation (Fig. 13-4).
FIGURE 13-2 Echocardiographic image of the “right ventricular outflow tract view.” AV, aortic valve; PV, pulmonic valve; RA, right atrium; RV, right ventricle.

FIGURE 13-3 Echocardiographic image of the “left ventricular outflow tract view.” AV, aortic valve; LV, left ventricle; RA, right atrium; RVOT, right ventricular outflow tract.
FIGURE 13-4 Echocardiographic image of the “left ventricular outflow tract view” demonstrating mild aortic regurgitation (AR) by color-flow Doppler. RA, right atrium.

Further clockwise rotation to approximately 60° will provide a long-axis view of the left ventricle (LV) and the mitral valve (Fig. 13-5). Minimal anterior tilting toward the septum may improve visualization of the LV. At 70° to 80° clockwise rotation, the interatrial septum (IAS) is visualized, with the left atrial appendage in the far field (Fig. 13-6). At 90° to 100° clockwise rotation and with the ICE transducer positioned along the IAS, the left inferior and left superior pulmonary veins in the far field are seen (Fig. 13-7). Color-flow Doppler and pulse-wave Doppler flow patterns help differentiate the left atrial appendage (LAA) from the left pulmonary veins. From this position, the beam is aligned parallel to the pulmonary vein flow direction for optimal Doppler interrogation.
FIGURE 13-5 Echocardiographic image of the “left ventricular long-axis view.” IAS, interatrial septum; LA, left atrium; LAA, left atrial appendage; MV, mitral valve.

FIGURE 13-6 Echocardiographic image of the “interatrial septal view” in a patient with a PFO. AV, aortic valve; DAo, descending thoracic aorta; LA, left atrium; PFO, patent foramen ovale; RA, right atrium.
At 150° to 180° clockwise rotation, the right-sided pulmonary veins can be visualized, as well as the right atrial appendage (Figs. 13-8 and 13-9) with continued rotation. These views can also be reached by up to 30° counterclockwise rotation if these structures are the primary imaging targets (ie, crista ablation, pulmonary vein isolation for atrial fibrillation). To image the superior vena cava (SVC) entry into the right atrium (RA), the catheter is rotated approximately 210° to 240° from the starting position, with posterior tilting of the catheter to image upward (Fig. 13-10).

FIGURE 13-9 Echocardiographic image of the “right atrial appendage view.” CT, crista terminalis; RAA, right atrial appendage.
ALTERNATIVE IMAGING VIEWS

Imaging with the transducer in the left atrium is achieved by passing the catheter through an atrial septal defect (ASD), a patent foramen ovale (PFO), or potentially other structures. Imaging from the left atrium (LA) provides excellent images of the LAA, as well as of the mitral valve (Figs. 13-11 and 13-12). Imaging from the SVC demonstrates the ascending aorta and arch (Fig. 13-13). Imaging from the RV through the intraventricular septum (IVS) provides near long-axis views of the LV and the mitral valve (MV) (Fig. 13-14), as well as of the right ventricular outflow tract (RVOT) and pulmonic valve. Imaging from the aorta has also been performed and used to guide endovascular interventions and biopsy procedures.

ICE GUIDANCE FOR PERCUTANEOUS SEPTAL CLOSURE PROCEDURES

PTC of ASDs and PFOs serves as a model for the use of ICE in the catheterization laboratory. Using steerable and deflectable catheters, images are obtained with the transducer in the right atrium. Using posterior and rightward tilting of the transducer away from the IAS, excellent imaging of the septum and surrounding structures can be achieved. Posterior tilting increases the distance between the IAS and the ICE probe and improves spatial resolution for structures in the near field. This is particularly helpful in imaging the septum in the presence of an atrial septal aneurysm. From this position, radial sweeping to obtain the desired imaging plane may be accomplished either by gentle catheter rotation or by moving the right and left control wheel.
The preprocedural assessment of the IAS by ICE includes a complete evaluation of the entire IAS and its surrounding structures. A *patent foramen ovale (PFO)* is defined as a right-to-left communication through the fossa ovalis, in the anatomic region where septum primum overlaps the septum secundum (*Fig. 13-15*). Right-to-left shunting can be demonstrated by intravenous injection of agitated saline at rest or by applying shunt provoking maneuvers such as Valsalva, coughing, or sniffing (Mueller maneuver) (*Fig. 13-16*). It is important to image the passage of contrast through the foramen itself, as opposed to merely evaluating for the appearance of echo-contrast on the left side of the heart. Intrapulmonary shunting from pulmonary arteriovenous malformations or other right-to-left shunts may also cause contrast opacification of the left side of the heart and may be misinterpreted as a PFO. When right atrial pressure exceeds left atrial pressure, resting or intermittent right-to-left Doppler color flow may be seen, although this finding is not invariably present in all patients with PFO. An *atrial septal aneurysm* is usually defined as greater than 15 mm of total movement of a 15-mm length of atrial septal tissue. This can be demonstrated by M-mode echocardiography (*Fig. 13-17*) and measurement of the total peak-to-trough excursion. A *stretched PFO* is defined as an interatrial communication at the fossa ovalis in the anatomic region where the septum primum overlaps with the septum secundum, accompanied by a resting or intermittent left-to-right flow by color-flow Doppler imaging (*Fig. 13-18*). A stretched PFO is often the result of elevated left atrial pressure.

FIGURE 13-18 Imaging from the mid-right atrium (RA) demonstrating a stretched patent foramen ovale with left-to-right color-flow Doppler. DAo, descending aorta; LA, left atrium.
Associated abnormalities of the pulmonary veins, IVC, SVC, coronary sinus, and atrioventricular valves should be excluded. Careful evaluation of the pulmonary veins should be performed to exclude anomalous drainage that could require surgical correction. Measurement of the largest static diameter of the atrial septal defect is performed using 2-dimensional imaging (Fig. 13-19). Assessment of the rim of tissue around the defect is important in anticipation of PTC. Generally, a rim of 5 mm is considered adequate for percutaneous closure (Fig. 13-20). The inferior and superior rims may be particularly important. However, successful PTC has been reported in small series with deficient rims.

**FIGURE 13-19** Imaging from the mid-right atrium (RA) demonstrating a prominent atrial septal aneurysm with a large ostium secundum atrial septal defect. DAo, descending aorta; LA, left atrium.
Sizing of the ASD using balloons can be achieved by 1 of 2 methods. For the “pulling technique,” a sizing balloon is inflated in the left atrium to a size larger than the ASD and then pulled to occlude the defect, which is documented by lack of flow on color Doppler imaging. The balloon is then gradually deflated until it passes through the ASD to the right atrium. By measuring the remaining fluid in the passing balloon and comparing it with a size reference chart, the diameter size of the ASD can be determined. The simpler and more commonly used “stationary balloon” or “stop-flow” technique involves inflation of a soft, low-pressure balloon across the ASD monitored by ICE as well as fluoroscopy. When the defect is completely occluded, flow will no longer be observed by color-flow Doppler imaging, and a “waist” may appear in the balloon contour. The balloon waist diameter measured by echocardiography and fluoroscopy corresponds to the stretched diameter of the ASD (Fig. 13-21).
FIGURE 13-21 Imaging during balloon stretch sizing of an ostium secundum atrial septal defect. The arrows represent the “waist” of the balloon, corresponding to an average diameter of the defect. LA, left atrium; RA, right atrium.

The balloon is then removed with the guide wire left in place (Fig. 13-22). A device delivery sheath of appropriate size is then passed over the wire into the left atrium under ICE guidance (Fig. 13-23). The closure device is delivered through the sheath into the left atrium. Various devices and insertion techniques are currently in use, but typically it involves opening the disc or arms of the device on the left side and pulling it back to the interatrial septum (Fig. 13-24). Once the left atrial aspect of the device is in position, the right-sided aspect is employed, thereby “sandwiching” the septum. Because the arms of the device rest on atrial tissue around the defect, it is more difficult to achieve a stable position of the device when the ASD lacks adequate rims. For specific devices (eg, Amplatzer Septal Occluder), stable device positioning is confirmed by moving the connecting cable with the attached device back and forth (Fig. 13-25).
FIGURE 13-22 Image demonstrating the guide wire passing from right atrium (RA) to left atrium (LA) through the atrial septal defect.
FIGURE 13-23 Image demonstrating the device delivery sheath passing from right atrium (RA) to left atrium (LA) through an ostium secundum atrial septal defect. GS, Guide Sheath.
FIGURE 13-24 Image demonstrating the Amplatzer ASO disc opening in the left atrium (LA). RA, right atrium.
FIGURE 13-25 Image demonstrating the push–pull maneuver (“Minnesota wiggle”) to ensure stability of the Amplatzer device. LA, left atrium; RA, right atrium.

After confirmation of satisfactory placement, and before the device is finally released, the surrounding structures need to be evaluated. Large ASD or PFO closure devices may obstruct the right pulmonary veins, venae cavae, and coronary sinus, and occasionally may interfere with the function of the tricuspid and mitral valves. After final release of the device, echocardiography is repeated to assess for immediate ASD or PFO closure, as well as changes in device position, which often occur as traction from the connecting cable is released (Fig. 13-26). In PFO closure, a bubble contrast study is typically performed with and without Valsalva to document the immediate postprocedural adequacy of closure.
ICE GUIDANCE FOR OTHER PROCEDURES

As noted above, electrophysiology procedures may also benefit from ICE. ICE is typically used to aid in transseptal punctures and to aid in delineation of other structures within the left atrium, such as the left atrial appendage, pulmonary veins, and mitral valve, as well as to help localize ablation catheters along the RV outflow tract. These electrophysiology ICE procedures are often used with other mapping and imaging devices, such as CARTO, and may allow the use of zero or near-zero fluoroscopy for routine ablation.\textsuperscript{53-56} The significant reduction in radiation exposure to both the patient and the operator, without loss of efficacy and safety, may lead to wider adoption of this technique.
Another use of ICE is to obtain biopsy specimen of intracardiac masses.\(^{57}\) In this procedure, ICE is deployed from the right internal jugular vein through a large venous sheath. The biopsy equipment is delivered via a long sheath from the femoral vein into the right heart, and ICE is used to direct the biopsy needle to its intended target. An incision is made in the long femoral sheath, after estimating the distance from the right femoral vein access site to the level of the planned biopsy. A wire is then directed into the right heart, and the smaller sheath from the internal jugular vein is used to house a snare to pull the wire externally and overlap the 2 sheaths above the site of the planned biopsy needle exit to help stabilize the system. The ICE is deployed from the internal jugular vein near the level of the planned biopsy to guide the fixed curve biopsy needle through the slit into position and obtain the necessary samples.

An alternative to this method is to simply deploy ICE in the vicinity of the mass and guide a bioptome to the mass while monitoring bioptome contact and the removal of sample tissue\(^{59}\); this technique generally involves the use of bilateral femoral venous access, although there are other case reports of the ICE from the groin and the bioptome from the internal jugular vein.

**FUTURE DIRECTIONS**

Further refinement and miniaturization of ICE transducers, through continued technologic progress, will facilitate primary operator–controlled, integrated ultrasound–guided interventional devices. Smaller catheters under development may extend the range of catheter rotation, as well as reduce the risk of vascular complications. Online, real-time, 3-dimensional ICE, which offers additional advantages in the guidance of percutaneous noncoronary interventions, is currently being developed.\(^{59-61}\) These modalities offer the advantage of being able to delineate the complex relationships among intracardiac anatomy, physiology, and device function, although they have not been evaluated systematically in these settings.

Cardiac Catheterization Laboratory
Physiologic Recorders

John W. Hirshfeld, Jr.

HISTORICAL BACKGROUND

Today’s clinical cardiac catheterization laboratory evolved from facilities that were originally human hemodynamic research laboratories. In the 1940s and 1950s, these facilities worked out much of our current understanding of human cardiovascular physiology and pathophysiology with a principal focus on cardiac valve disease.

Catheterization laboratory physiologic recorders were developed to meet 2 needs of these endeavors:

1. The need to monitor a patient’s condition during invasive procedures
2. The need to make permanent analog recordings of physiologic signals from patients

The catheterization laboratory physiologic recorder evolved from multichannel oscillographic physiologic recorders that had been developed for animal physiologic research in the first half of the 20th century. The original physiologic recorders were ink-writing multichannel oscillographs.

The importance of displaying and recording multiple superimposed channels of physiologic signals was rapidly recognized. Thus, the first major development was the move from ink-writing oscillographs to multichannel oscillographic recorders. These instruments could display multiple channels of
physiologic signals in real time on an oscilloscopic screen. The physician operator could view the screen in order to monitor in real time both the data being obtained and the patient’s condition. These instruments also added an important adjunct—the ability to superimpose multiple analog signals in a time-based display. This capability enhanced signal interpretation by displaying the nuances of relationships between different signals. (eg, superimposing pressure signals from adjacent cardiac chambers facilitates the recognition and measurement of pressure gradients.) This capability required incorporating photo-optical recorders that could record the individual superimposed oscilloscopic beams on light-sensitive paper, enabling permanent recordings of the physiologic signals.

These early instruments made the development of cardiac catheterization possible. However, they also had many shortcomings. They did not have the ability to record the events of a procedure in their entirety. The photo-optical recordings were fragile and easily degraded. It was difficult to make recordings available for remote review or to make illustrations for teaching and publication.

During the past 25 years, progress in electronic instrumentation, computer capability, and networking and improvements in display technology have fostered an evolution of the cardiac catheterization laboratory recorder, refining its functionality and enabling it to incorporate additional information management and reporting capabilities.

Currently available catheterization lab recorders are the core component of a comprehensive information system that, through hospital information system networking, has become an integral part of an overall cardiovascular information system and a health care institution’s electronic medical record.

In addition to serving their original function, current systems also serve as front ends for patient flow management, clinical database management, hospital information system data, clinical report generation, laboratory inventory management, and quality assurance analysis. Although these functionalities provide enhanced capabilities, they also require more detailed planning when selecting and configuring a system in order to optimize configurations and connectivities.

**Original Purposes**

The purpose of the original catheterization laboratory recorders was to
receive, condition, and display various types of patient physiologic signals that were of value for monitoring the patient and for assessing the patient’s pathophysiology. In addition to displaying signals in real time, they also had the capability to record signals for subsequent analysis.

Cardiovascular physiologic signals fall into 3 basic types:

1. Pressure signals from pressure transducers
2. Electrocardiogram (ECG) signals
3. Direct current (DC) voltage signals representing either voltages recorded from the patient or signals from other instruments such as flow meters, respiration and pulse oximetry probes, and other instruments

The early recorders had the capability to display these processed signals with appropriate gain in a variety of superimposition formats in order to present a comprehensive picture of the patient’s condition and the relationships between the phenomena represented by the different signals. In addition, the early recorders could produce a hard copy output to preserve selected signal recordings for archiving and analysis.

EVOLUTION TO CURRENT UNITS

Several developments have refined and extended the capabilities of physiologic recorders, yielding the highly capable units that are in current use. These include the following:

1. The development of stable, reliable, solid-state electronics and computer technology
2. The refinement of displays to high-resolution multicolor flat panel monitor units
3. The application of computer technology to system control, signal display, signal archiving, data analysis, and hard copy output generation
4. The evolution of cardiovascular and hospital information systems leading to the interface of catheterization laboratory recorders with hospital information systems and cardiovascular databases

The principal development in the evolution of the catheterization laboratory physiologic recorder was the incorporation of a computer for operational control. This transformed recorder design to fundamentally a
computer-run device. The physical recorder itself is now an assembly of generic computer hardware, input devices, output devices, display devices, and network connections. Because computer hardware is now mostly generic, system capabilities and the distinction between different systems are determined by the operating software. Thus, in the final analysis, a cardiac catheterization laboratory recording system is essentially a software product. The software generates the system’s human interface and operates the system’s components.

**CAPABILITIES OF AND PERFORMANCE CRITERIA FOR CURRENT UNITS**

**Capabilities**

A current fully functional catheterization laboratory physiologic recorder should have the following capabilities and features:

1. Accept, condition, and display a minimum of 8 physiologic signals from patient. These should include intravascular pressure from pressure transducers, 12-lead ECG, DC signals from other portable equipment such as flow meters and other transducers that produce a DC output signal, pulse oximetry, noninvasive blood pressure, and respiration.
2. Display the analog signals and their derived numeric values on a color monitor available for the operating physician to view in order to monitor the patient during the procedure.
3. Record the physiologic signals both as a hard copy and as a digital archive that can be exported as a Digital Imaging and Communications in Medicine (DICOM) object to a laboratory archiving system. The recorder should record and archive and be able to retrieve a complete record of the procedure from beginning to end (full disclosure).
4. Perform physiologic calculations such as valve orifice areas and conduct image analysis such as quantitative ventriculography and coronary arteriography.
5. Interface with the catheterization laboratory x-ray system to link the x-ray
images to the physiologic recordings from the procedure and incorporate the 2 outputs into a single record.

6. Maintain a time-stamped narrative procedure log of the procedure’s events including patient vital signs for the purposes of conscious sedation monitoring.

7. Interface with the hospital information system in order to read admissions/discharge/transfer (ADT) demographic data from the hospital information system as well as to export procedure utilization data back to it.

8. Record supplies used during the procedure for inventory management and billing purposes.

9. Generate a final catheterization report, ideally integrated with the x-ray system so that it can incorporate angiographic images.

10. Archive the report on the laboratory archive as a DICOM object.

11. Export the report to the hospital information system to facilitate clinical information transfer.

Performance Criteria

There are 9 performance criteria that should be assessed when judging a cardiac catheterization laboratory physiologic recorder.

1. **Stability and reliability:** This is the core performance criterion for any cardiac catheterization laboratory system and is a major component of the US Food and Drug Administration (FDA) certification criteria. These systems are computer applications that run on top of any one of several commercially available operating systems. The introduction of the computer into the cardiac catheterization laboratory recording system creates a new issue not previously present in earlier non–computer-based units—the computer crash. This is particularly important because a computer crash could potentially render the system inoperable until the computer is successfully restarted and reinitialized. Current systems, although based on very fast computers, are also based on complex operating systems, and the applications that they run are complex. Consequently, the “boot” or initialization time for a system to either start up after being shut off or reinitialize after a crash can be tiresomenly long. Therefore, it is important that these systems have very robust code that is
relatively crash-proof. Ideally, these systems should be isolated from the Internet so that they are at less risk of virus infection. Successful isolation may be challenging to achieve because the system must interact with the hospital information system and also needs to be accessed from outside for servicing and upgrade installation. Because systems are networked to data archives for deep storage of images and data, they should be capable of functioning autonomously in the event that the network connection is disrupted. Finally, it is essential that systems have a “limp home” mode that permits them to continue to perform basic monitoring functions even if the main computer system has crashed or is in the process of being restarted. This capability will ensure patient safety by continuing to provide patient monitoring during a restart if necessary.

2. **User interface:** This must be intuitive and easy to use. During a procedure, the recorder operator has multiple responsibilities in addition to actually operating the recorder. These include monitoring the patient and maintaining communication outside of the laboratory. These systems now have many features and functions that are accessed through a graphical user interface. As they have become more complex and have acquired additional capabilities, interface design has become increasingly demanding. The organization of that interface, including the menus, the design and placement of icons, and the overall screen layout, presents a major challenge to the interface designer. A good interface has menus that contain functions organized logically according to typical catheterization laboratory workflow. This facilitates the performance of the “routine” procedure. In addition, however, it should be easy and straightforward to configure the recorder for an unusual circumstance.

3. **X-ray system interface:** The system must interface with the laboratory’s x-ray system, which may be furnished by a different vendor. The system should read and record x-ray exposure data from the x-ray system for incorporation into the overall procedure record. In addition, the system should transmit patient demographic information to the x-ray system in order to enable linking of the x-ray images to the rest of the procedure information. When more than 1 vendor is involved, issues of proprietary protocols may interfere with some of this important functionality.

4. **Portable equipment interface:** A variety of portable equipment is used in cardiac catheterization laboratories. This includes various ultrasound machines, blood analysis meters, thermal dilution cardiac output
computers, oxygen consumption instruments, pressure wires, and more. The system should be able to accept signals from these devices and incorporate them into the overall procedure record and into the final procedure report.

5. **Hemodynamic measurements and calculations:** Although many cardiac catheterization procedures are principally angiographic procedures with only basic hemodynamic measurements, laboratories also need to evaluate valve disease, which may be complex, and, on occasion, complex congenital heart disease. The system must perform hemodynamic calculations including valve areas, vascular resistance, shunt calculations, and fractional flow reserve according to valid algorithms. It is important that the system display the component data employed in a hemodynamic calculation so that the validity of the calculation may be easily verified.

6. **Hospital information system interface:** Whereas earlier recorders were stand-alone systems, current systems are tightly linked to the hospital information system, the x-ray system, and the catheterization laboratory’s database and DICOM archive. Although considerable progress has been made to systematize data structures and communications protocols, building communication interfaces across different vendors has the potential to be problematic because of proprietary coding within individual systems. It is important to verify prior to installation that a selected system is also compatible with the other systems with which it must interface.

7. **Report generation:** The system must generate a properly organized report that is constructed in a manner that effectively communicates the procedure’s findings and, in particular, effectively reports any unusual circumstances or findings. Particular care must be taken in the report design to allow adaptation to the exigencies of particular procedures so that the reports do not all come out with a generic quality to them. Some systems may incorporate the report-generating function into the system. Other systems may export structured reporting data elements to a third-party report generator.

8. **National registry interface:** Most laboratories participate in national registries such as the American College of Cardiology National Cardiovascular Data Registry (NCDR). These registries receive a dictionary of defined data elements and store them for statistical analysis.
A well-designed system can automatically extract the core data elements stored by the registry and transmit them automatically to the registry’s data archives.

9. **Electronic medical record interface:** The completed catheterization procedure report should be exported to the hospital electronic medical record system and be distributed either electronically or as hard copy to constituent health providers. If the system generates the report internally, the completed report can be transmitted as a document to the electronic medical record. Alternatively, the electronic medical record may be configured to archive the data elements as data in addition to archiving the clinical report.

**CONCLUSION**

Current cardiac catheterization lab physiologic recorders are complex units that have many valuable capabilities made possible by the sophisticated application of computer technology to the task of monitoring a patient and recording, analyzing, storing, and reporting physiologic and imaging data obtained during cardiac catheterization procedures. Such systems have the potential to streamline cardiac catheterization laboratory operations and, through enhanced access to information and systematizing, can substantially improve overall quality of cardiac catheterization laboratory operations. However, given these systems’ complexity, careful advance planning for system design and configuration is necessary to create an optimally functioning system. Such advance planning will be rewarded by a system that operates efficiently and effectively.

16 Antiplatelet Therapies in Contemporary Percutaneous Coronary Intervention

17 Thrombolytic Therapy

18 Radiographic Contrast Media

19 Renal Complications of Contrast Media

20 Contemporary Patient Sedation and Anesthesia in the Cardiovascular Catheterization Laboratory
INTRODUCTION

Acute coronary artery occlusion is a dynamic process that involves three essential processes: compromise of vascular integrity, platelet activation and aggregation, and acceleration of the coagulation cascade with fibrin formation. Although the role of thrombin (factor IIa) is well documented in blood coagulation, fibrin formation, and thrombus stabilization, it is also central to interplay among these processes. Angiographic, intravascular ultrasound (IVUS), and pathologic studies during acute coronary syndromes (ACS) have helped delineate the pathophysiology of coronary artery occlusion: atherosclerotic plaque rupture leads to release of tissue factor (TF), which has broad impact to stimulate platelets and generate thrombin. TF activates factor VII, which activates the common pathway via the extrinsic pathway, and also activates factor IX, activating the intrinsic pathway (Fig. 15-1). Subsequent generation of factor Xa leads to thrombin activation.
Inhibition of thrombin, along with the other serine proteases, is crucial in breaking this cycle and allowing either endogenous or exogenous fibrinolysis to occur. Thrombin is a well-suited target for therapeutics given its central role in arterial thrombosis. Current clinically available anticoagulants work via direct inhibition of either thrombin or an immediate upstream target, largely factor Xa.
HEPARIN

Mechanisms of Action

Heparin was first studied in ACS in 1988 and has been a mainstay for acute ischemic heart disease therapy since then. Heparins represent a heterogeneous group of negatively charged, heavily sulfated glycosaminoglycans. Heparins have a heterogeneous effect on the coagulation cascade, although most of the effect is mediated through binding with antithrombin, causing a conformational change leading to inactivation of multiple enzymes in the coagulation cascade. While factors IXa, Xla, and XIIa are targets as well, thrombin (factor IIa) and factor Xa are the most clinically relevant. As mentioned, thrombin inhibition leads to inhibition of fibrin formation and factors needed for its cross-linking and stabilization. Heparins also have an impact on arterial and venous thrombosis by increasing vessel wall permeability and binding to von Willebrand factor, leading to some inhibition in platelet activation. Unfractionated heparin (UFH) represents a heterogeneous compound with some important limitations:

- Propensity to bind to plasma proteins
- Inability to inhibit clot-bound thrombin
- Does not inhibit thrombin’s activation of platelets via protease-activated receptor-1 (PAR-1)
- Can induce an immune-mediated response, leading to heparin-induced thrombocytopenia

Low-molecular-weight heparins (LMWHs) are modified derivatives of UFH created by depolymerizing the larger heparin molecules. LMWH exert most of their anticoagulant effect via antithrombin-mediated inhibition of coagulation factors. Factor Xa is more affected than factor IIa in a ratio of 2:1 to 3:1. LMWHs have a benefit biochemically over heparin in that they have less of a propensity to bind to plasma proteins and cells, leading to a more predictable anticoagulant response and requiring less monitoring. However, LMWHs can cause heparin-induced thrombocytopenia, cannot inhibit clot bound thrombin, and do not inhibit thrombin’s activation of platelets.
Pharmacology and Dosing

Unfractionated Heparin

One of the major challenges in predicting the pharmacologic response to UFH is the significant heterogeneity in the product delivered. Appropriate levels of anticoagulation can be monitored by either activated partial thromboplastin time (aPTT) levels or activated clotting time (ACT) levels, with the latter being used in many catheterization labs. Although the following discussion is based on current guidelines and represents current practice, it is important to note recent data that show less correlation between ACT levels and hard clinical outcomes. With concurrent glycoprotein (GP) IIb/IIIa inhibition, the intravenous (IV) loading dose of UFH is 50 to 70 U/kg to achieve a therapeutic ACT of 200 to 250 seconds. Without concurrent GP IIb/IIIa inhibition, the IV loading dose of UFH is 70 to 100 IU/kg to achieve a therapeutic ACT of 250 to 300 seconds (HemoTec device; HemoTec Medical, Munich, Germany) or 300 to 350 seconds (Hemochron device; Accriva, Piscataway Township, NJ). These are listed as a Class I, Level of Evidence (LOE) C in the most recent American College of Cardiology (ACC)/American Heart Association (AHA)/Society for Cardiovascular Angiography and Interventions (SCAI) ST-segment elevation myocardial infarction (STEMI) guidelines. ACTs may be checked as soon as 5 minutes after bolus is given. If therapeutic ACT has not been achieved, additional bolus doses of 2000 to 5000 IU can be given to achieve target ACT. Continuation of heparin after percutaneous coronary intervention (PCI) has not been shown to be beneficial, but rather increases bleeding complications.

Low-Molecular-Weight Heparin

An intrinsic benefit to LMWH use is the predictability of its anticoagulant effect. Enoxaparin is the most widely studied and clinically used LMWH. The plasma half-life of enoxaparin is approximately 4 to 6 hours with peak effect seen within 3 to 5 hours after subcutaneous injection and a duration of action of up to 12 hours in normal renal function. Enoxaparin is hepatically metabolized and renally cleared (40% of actual dose and 10% of its active metabolites). There is little binding to plasma proteins and a more uniform molecular structure, leading to its more predictable effect. Routine
monitoring is not necessary. Anti–factor Xa activity is the monitoring test of choice, with a suggested therapeutic range of 0.8 to 1.8 IU/mL.

Maintenance enoxaparin dosing is dependent on age, renal function, and clinical scenario. Standard dosing is 1 mg/kg administered subcutaneously every 12 hours provided age <75 years and creatinine clearance (CrCl) >30 mL/min. In patients with age >75 years, a lower dose of 0.75 mg/kg per dose has been associated with lower bleeding complications. In patients with CrCl >15 mL/min but less than 30 mL/min, 1 mg/kg subcutaneously every 24 hours is recommended. In patients with CrCl <15 mL/min, enoxaparin is contraindicated. While no specific recommendations are noted in the guideline for concurrent GP IIb/IIIa use, some experts feel 0.75 mg/kg per dose may be more appropriate than a full dose. For ACS patients undergoing PCI, therapeutic anti–factor Xa levels were observed in 98% of those who received subcutaneous enoxaparin between 2 and 8 hours prior.\textsuperscript{3,4} For patients who received subcutaneous enoxaparin more than 8 hours prior to PCI, an IV enoxaparin dose of 0.3 mg/kg resulted in therapeutic anti–factor Xa levels in nearly all patients.\textsuperscript{4} Table 15-1 summarizes key concepts in pharmacology and dosing of UFH, LMWH, and fondaparinux.

| Table 15-1 Comparison of Key Characteristics of Unfractionated Heparin, Low-Molecular-Weight Heparin, and Fondaparinux |
Clinical Trials

Unfractionated Heparin

Over the past 2 decades, UFH has been a cornerstone therapy for ACS. A meta-analysis of 6 small trials showed that combination of heparin and aspirin conferred a 33% relative risk reduction in myocardial infarctions compared to aspirin alone. Subsequent ACS studies included UFH in the control arm. In a meta-analysis of trials testing LMWH, the UFH arm had an average rate of death and reinfarction of 11.0% in non–ST-segment elevation (NSTE) ACS and 11.8% in STEMI. The cumulative rates of major bleeding for UFH in these studies were 1.8% among STEMI patients and 5.4% among NSTE-ACS patients.

Some initial studies showed the rates of ischemic events to be related to degree of antithrombotic activity. A meta-analysis of six randomized controlled trials compared UFH to different regimens of antithrombotic and
antiplatelet therapies to assess whether level of antithrombotic activity as measured by ACT had an effect on 7-day ischemic event rates. A total of 5216 patients were included in the ischemic event rate analysis with only 15% of patients receiving stents and initially no patients receiving dual antiplatelet therapy. Of note, the vast majority of these patients had their ACT measured via the Hemochron device, and the ACT levels were divided into 25-second intervals for analysis, starting at 275 seconds. Ischemic end points followed a U-shaped distribution with relation to minimum ACT levels, with the lowest event rate at 7 days being 6.6% among patients with minimum ACT between 350 and 375 seconds. This optimal range was consistent among different subgroups, including diabetics, those presenting with ACS, and those receiving stents. Of note, minimum ACT levels above 375 seconds showed an increase in ischemic event rate, supporting the hypothesis of heparin-induced platelet activation at higher levels.

In the same analysis, rates of major and minor bleeding indexed for maximum ACT levels showed a similar U-shaped distribution. The lowest rate of major and minor bleeding was 8.6% and was seen among patients with maximum ACT levels between 325 and 350 seconds. There was a steady increase in bleeding rates with higher ACT levels, with a substantial increase between 350 and 375 seconds (12.4%) and ACT levels beyond that.

Based on these data, the STEMI guidelines have included target ACT levels to help guide dosing for antithrombotics. However, more recent data suggest less correlation between ACT levels and ischemic and bleeding event rates after ACS and PCI. This is likely due to multiple advances in medical therapy (eg, newer thienopyridines, earlier initiation of antiplatelet therapies, lower antithrombotic dosages) as well as changes in procedural technique (eg, radial access, smaller sheaths, changes in stent design).

Subsequent analysis of those receiving abciximab showed that concurrent GP IIb/IIIa inhibition has lower optimal ACT ranges with a plateau of ischemic events from 275 to 375 seconds, but a steady increase in bleeding risk with ACT levels from 275 to 375 seconds. The analysis of the different devices used was consistent with the 28% lower readings with the HemoTec device compared to the Hemochron device.

**Low-Molecular-Weight Heparin**

Multiple early clinical trials were conducted showing the efficacy of
enoxaparin in different clinical scenarios. A meta-analysis done in 2007 looked at 6 randomized controlled trials comparing enoxaparin with UFH in NSTE-ACS patients and 6 randomized controlled trials comparing enoxaparin with UFH in STEMI patients.\textsuperscript{6} In the NSTE-ACS cohort, there were 21,945 patients, with a consistent enoxaparin dose of 1 mg/kg twice a day versus varying dosages of UFH. There was a modest reduction in the combined ischemic end point of death and nonfatal myocardial infarction (MI) in the group receiving enoxaparin compared to UFH (10.0% vs 11.0%; odds ratio, 0.90 [95% confidence interval [CI], 0.81-0.996]; \(P = .043\)). This was driven by a reduction in nonfatal MI (8.0% vs 9.1%; OR, 0.87 [95% CI, 0.79-0.96]; \(P = .005\)), and there was no reduction in death (3.0% each; OR, 0.99 [95% CI, 0.83-1.18]; \(P = .890\)) (Fig. 15-2). However, there was also a non–statistically significant increase in major bleeding in the enoxaparin group (6.3% vs 5.4%; OR, 1.13 [95% CI, 0.84-1.54]; \(P = .419\)) (Fig. 15-3). The net effect of death, nonfatal MI, and nonfatal bleeding was not different between enoxaparin and UFH (14.1% vs 14.3%; OR, 0.97 [95% CI, 0.86-1.09]; \(P = .607\)).

**FIGURE 15-2** Enoxaparin (Enox) versus unfractionated heparin (UFH) in the comparison of death or nonfatal myocardial infarction (MI), using a random effects model. Black squares represent odds ratios (ORs), the size of which reflects the statistical weight of a trial in calculation of the OR. The horizontal lines represent
95% confidence intervals (CIs). There was evidence of heterogeneity between ST-segment elevation myocardial infarction (STEMI) and non–ST-segment elevation acute coronary syndromes (NSTEACS) \((P = .005)\). (Reproduced with permission from Murphy SA, Gibson CM, Morrow DA, et al. Efficacy and safety of the low-molecular weight heparin enoxaparin compared with unfractionated heparin across the acute coronary syndrome spectrum: a meta-analysis. Eur Heart J. 2007;28(17):2077-2086.)

![Figure 15-3 Enoxaparin (Enox) versus unfractionated heparin (UFH) in the comparison of major bleed, displayed using a random effects model. Black squares represent odds ratios (ORs), the size of which reflects the statistical weight of a trial in calculation of the OR. The horizontal lines represent 95% confidence intervals (CIs). NSTEACS, non–ST-segment elevation acute coronary syndrome; STEMI, ST-segment elevation myocardial infarction. (Reproduced with permission from Murphy SA, Gibson CM, Morrow DA, et al. Efficacy and safety of the low-molecular weight heparin enoxaparin compared with unfractionated heparin across the acute coronary syndrome spectrum: a meta-analysis. Eur Heart J. 2007;28(17):2077-2086.)](image)

In the pooled STEMI cohort, there were 27,131 patients, with the ExTRACT-TIMI 25 trial providing the majority of patients \((n = 20,479)\). The enoxaparin dose was 1 mg/kg twice daily in most of the trials. In ExTRACT-TIMI 25, the dose of enoxaparin was reduced to 0.75 mg/kg twice daily for patients over the age of 75. The dose of UFH was most often 60 units/kg as a bolus with a continuous infusion of 12 units/kg/h. The combined ischemic end point was lower in the enoxaparin group than UFH group \((9.6\% \text{ vs} \)
Similar to the NSTE-ACS cohort, this combined end point was driven mainly by nonfatal MI (3.4% vs 5.1%; OR, 0.64 [95% CI, 0.52-0.78]; \( P < .001 \)) with no difference in mortality (6.6% vs 7.1%; OR, 0.92 [95% CI, 0.84-1.01]; \( P = .097 \)) (see Fig. 15-2). The rates of major bleeding were also higher with LMWH in the STEMI cohort (2.6% vs 1.8%; OR, 1.45 [95% CI, 1.23-1.72]; \( P < .001 \)) (see Fig. 15-3). The net effect of death, nonfatal MI, and nonfatal bleeding was lower in the enoxaparin group (11.1% vs 12.9%; OR, 0.84 [95% CI, 0.73-0.97]; \( P = .018 \)). One of the challenges in the clinical application of earlier trials is the lack of contemporary use of PCI. Three major clinical scenarios specifically warrant comment: elective PCI, PCI in NSTE-ACS, and PCI in STEMI, with a brief discussion on rescue PCI after fibrinolysis.

The Safety and Efficacy of Enoxaparin in Percutaneous Coronary Intervention Patients and International Randomized Evaluation (STEEPLE) study compared 2 doses of IV enoxaparin versus UFH in elective PCI. This was an open-label randomized trial where 3528 patients were randomized to 1 of 3 arms (0.5 mg/kg IV enoxaparin vs 0.75 mg/kg IV enoxaparin vs UFH) with a primary outcome of major or minor bleeding not related to coronary artery bypass grafting (CABG). Approximately 94% of patients received a stent (>50% drug-eluting stent [DES]). The trial was deemed to be underpowered to assess for differences in ischemic end points. The occurrence of major or minor bleeding within the first 48 hours was lower in the 0.5 mg/kg enoxaparin arm compared to UFH (5.9% vs 8.5%; \( P = .01 \)). The occurrence of major or minor bleeding within the first 48 hours was also lower in the 0.75 mg/kg enoxaparin arm (6.5% vs 8.5%; \( P = .05 \)). Importantly, major bleeding was significantly lower in both LMWH groups (1.2% vs 2.8% in the UFH arm; \( P = .004 \) for the 0.5 mg/kg enoxaparin arm and \( P = .007 \) for the 0.75 mg/kg enoxaparin arm). Conclusions from this trial were that lower dose enoxaparin (0.05 mg/kg) was deemed superior to UFH in elective PCI in decreasing rates of major or minor non–CABG-related bleeding, driven predominantly by decreased rates of major bleeding. It is important to note that the trial was underpowered to detect differences in ischemic end points that might have offset the reduction in bleeding.

In the Enoxaparin Versus Unfractionated Heparin in High-Risk Patients With Non-ST Segment Elevation Acute Coronary Syndromes Managed With an Intended Early Invasive Strategy (SYNERGY) trial, 9978 patients were analyzed after randomization to either enoxaparin or UFH. Of these patients,
over 47% received PCI and 19% underwent CABG. This trial was included in the meta-analysis discussed earlier. In the overall analysis, there was no difference in the combined ischemic end point of death and nonfatal MI (14.0% vs 14.5%; hazard ratio [HR], 0.96 [95% CI, 0.86-1.06]). Specifically, in patients undergoing PCI, there was no difference in ischemic complications, with similar rates of abrupt closure (1.3% vs 1.7%), threatened abrupt closure (1.1% vs 1.0%), unsuccessful PCI (3.6% vs 3.4%), or emergency CABG (0.3% each). However, there was an increase in Thrombolysis in Myocardial Infarction (TIMI) major bleeding (9.1% vs 7.6%; \( P = .008 \)), but not in Global Use of Strategies to Open Occluded Arteries (GUSTO) severe bleeding (2.7% vs 2.2%; \( P = .08 \)) or transfusions (17.0% vs 16.0%; \( P = .16 \)). Compared to previous NSTE-ACS trials, the patients in SYNERGY were older, and a more aggressive antiplatelet strategy was used. Conclusions from this trial were that enoxaparin was noninferior to UFH in terms of preventing ischemic end points both in the overall cohort and the PCI subgroup, despite the short duration of antithrombotic use prior to PCI (<48 hours) compared to those undergoing medical therapy. However, there was an increase in overall bleeding, but not in life-threatening bleeding or bleeding requiring transfusions.

As compared to ExTRACT-TIMI 25, which was a fibrinolysis study, the ATOLL trial enrolled patients undergoing primary PCI. The ATOLL trial randomized 910 patients to either enoxaparin 0.5 mg/kg IV or UFH in an open-label fashion.\(^\text{10}\) Stents were implanted in 95% of patients (18% DES). Roughly three-fourths of patients in both arms received GP IIb/IIIa inhibitors. This trial did not meet its primary composite end point of net clinical benefit of death, complication of MI, procedure failure, or major bleeding (28% in the enoxaparin arm vs 24% in UFH arm; risk ratio [RR], 0.83 [95% CI, 0.68-1.01]; \( P = .063 \)). However, there was a net reduction in its main secondary end point, which was a combined ischemic end point of death, nonfatal MI or ACS, or urgent revascularization (7% vs 11%; RR, 0.59 [95% CI, 0.38-0.91]; \( P = .015 \)), and no difference in procedural failure, defined as definite stent thrombosis, bailout use of GP IIb/IIIa inhibitor, non-TIMI 3 flow after procedure, or <50% reduction in ST elevation after procedure (26% vs 28%; RR, 0.94 [95% CI, 0.75-1.19]; \( P = .61 \)). In addition, there was also no difference in rates of major or minor bleeding (11% vs 12%; RR, 0.92 [95% CI, 0.64-1.32]; \( P = .65 \)) or rates of blood transfusions (2% each; RR, 0.81 [95% CI, 0.32-2.04]; \( P = .65 \)). Conclusions from this trial were that although
enoxaparin led to fewer combined ischemic events compared to UFH with no increase in procedural failure or clinically significant bleeding in patients with STEMI undergoing a primary PCI strategy, enoxaparin was not superior to UFH in net clinical benefit.

Rescue PCI has become more of a historical clinical scenario, but with STEMI networks often encompassing large geographical areas, it is still occasionally encountered. ExTRACT-TIMI 25 was discussed previously as a part of the large meta-analysis comparing LMWH to UFH. One notable subgroup analysis from this landmark trial was evaluation of rescue PCI within 30 days of initial event. While noting limitations in any post hoc analysis, this was a relatively robust analysis, with 2272 patients in the enoxaparin group undergoing PCI within 30 days and 2404 patients in the UFH group undergoing PCI within 30 days. The only pre-PCI variable that differed between the 2 groups was concomitant use of a GP IIb/IIIa inhibitor, which was higher in the UFH group (15.4% vs 19.2%; \( P = .001 \)). Among patients undergoing PCI, enoxaparin use was associated with a decreased incidence of the combined ischemic end point of death or nonfatal MI at 30 days (10.7% vs 13.8%; RR, 0.77 [95% CI, 0.66-0.90]; \( P = .001 \)), which was driven by a decrease in nonfatal MI (8.2% vs 11.3%; RR, 0.73 [95% CI 0.61-0.87]; \( P < .001 \)). There was also no difference in TIMI major or minor bleeding (4.6% vs 4.0%; RR, 1.15 [95% CI, 0.88-1.51]; \( P = .310 \)).

Conclusions from this trial were that enoxaparin is superior to UFH in rescue PCI after fibrinolysis in preventing the combined end point of death and nonfatal MI without an increased risk in major or minor bleeding.

**Summary and Guidelines**

**Medical Management and Fibrinolysis**

UFH provides the background upon which subsequent anticoagulants have been tested. Meta-analysis of UFH shows continued efficacy and a broader application given contraindications for other agents. In the most recent 2012 focused update from the ACC/AHA on unstable angina (UA)/non–ST-segment elevation MI (NSTEMI) patients undergoing an initial medical management strategy, enoxaparin and UFH carried a Class I recommendation with LOE A given the numerous randomized clinical trials comparing these
two therapies. The decreased ischemic event rates at the expense of slightly increased incidence of major bleeding shapes the Class IIa indication that for patients undergoing initial medical management, enoxaparin may be preferable to UFH. Duration of anticoagulation therapy in medically managed patients should be 48 hours for UFH and for the duration of hospitalization, up to 8 days, for enoxaparin.

Based on the 2013 focused update from the ACC/AHA on STEMI, both UFH (LOE C) and enoxaparin (LOE A) are Class I indications for adjunctive anticoagulation with fibrinolysis. The current guidelines do not recommend a particular agent, despite the findings of ExTRACT-TIMI 25.

**Percutaneous Coronary Intervention**

In UA/NSTEMI patients undergoing an early invasive strategy, both enoxaparin and UFH have a Class I, LOE A recommendation for initiation as soon as possible. In those undergoing PCI, anticoagulation should be discontinued as soon as PCI is completed, provided PCI was uncomplicated. Of note, in the STEMI guidelines, enoxaparin is not recommended due to the lack of supporting evidence, as the ATOLL trial failed to meet its primary composite end point of net clinical benefit of death, complication of MI, procedure failure, or major bleeding.

In patients undergoing PCI after fibrinolysis, UFH (LOE C) or enoxaparin (LOE B) may be continued through PCI. Additional boluses of UFH may be needed to achieve target ACT, depending on whether concurrent GP IIb/IIIa inhibitors are used. If subcutaneous enoxaparin was last given >8 hours prior to PCI, a single dose of 0.3 mg/kg of IV enoxaparin should be given.

**PENTASACCHARIDES**

*Mechanism of Action*

Pentasaccharides derive their name from the pentasaccharide sequence of heparin (Fig. 15-4). The only available pentasaccharide is fondaparinux. Fondaparinux works through a high affinity toward antithrombin (AT), leading to a conformational change in AT. This conformational change leads
to markedly increased affinity for factor Xa with little effect on its AT activity. The effect of fondaparinux is dependent on AT levels, and once plasma AT is depleted, the antithrombotic effect plateaus. The binding of fondaparinux to AT is reversible; however, the binding of AT to factor Xa is irreversible and requires subsequent clearance from plasma. The effect on thrombin is indirect via decreased thrombin generation from decreased factor Xa levels.

Thrombocytopenia is often seen with fondaparinux with reported rates of moderate and severe thrombocytopenia of 2.9% and 0.2%, respectively, in clinical trials. In addition, although fondaparinux does not cross-react with the serum of patients with heparin-induced thrombocytopenia, it can induce the production of anti-PF4 antibodies, leading to a low risk of heparin-induced thrombocytopenia. This association is controversial. Similar to heparin and LMWH, fondaparinux cannot inhibit factor Xa bound to prothrombinase complex.

**Pharmacology and Dosing**

Fondaparinux has 100% bioavailability after subcutaneous administration, reaching maximum serum concentrations in less than 2 hours. The antithrombotic effect is thought to be linear in most healthy patients with doses between 2 and 8 mg. The plasma half-life is slightly longer in elderly patients (21 hours) as compared to younger patients (17 hours). Based on this plasma half-life, the drug reaches steady-state levels after 3 to 4 days. Most of the drug is excreted unmodified in the urine, and moderate to severe renal insufficiency decreases clearance by 40% to 55% (see *Table 15-1*). There is some evidence to suggest that fondaparinux may be dialyzable.
Clinical trials assessing fondaparinux in deep vein thrombosis (DVT) prophylaxis and ACS have used doses of 2.5 mg subcutaneously once daily. Some DVT and pulmonary embolism trials have used larger dosages (up to 7.5 mg daily), but these doses are not recommended for ACS patients. Currently, there is no antidote, and protamine is not effective in reversing the effects of fondaparinux. Nonspecific agents, such as recombinant factor VIIa (rFVIIa), rapidly restored thrombin generation time and normalized mildly elevated aPTT in patients who received a single large dose of 10 mg of subcutaneous fondaparinux. Despite this biochemical relationship, the clinical efficacy of reducing bleeding with rFVIIa has not been tested.

aPTT and international normalized ratio (INR) are not effective monitoring tools for fondaparinux activity. Although aPTT and prothrombin time experience an average mild increase with fondaparinux, the increase is mild at best, and it is unclear whether it is dose dependent. There is minimal interference with INR, making fondaparinux an ideal tool for monitoring oral anticoagulation with warfarin. The most effective monitoring tool is anti–factor Xa activity, which closely reflects anticoagulation with fondaparinux.

**Clinical Trials**

There have been two major clinical trials looking at the role of fondaparinux across the ACS spectrum. The Fifth Organization to Assess Strategies in Acute Ischemic Syndromes (OASIS-5) trial was a randomized, double-blind, double-dummy trial to assess whether patients who presented with NSTE-ACS had lower rates of ischemia and bleeding with fondaparinux (2.5 mg daily) or enoxaparin (1 mg/kg twice daily for a mean of 6 days). A total of 20,078 patients were randomized, and there was no difference in the primary outcome of death, MI, or refractory ischemia at 9 days (5.8% vs 5.7%; HR, 1.01 [95% CI, 0.90-1.13]; \( P = .007 \) for noninferiority). This effect persisted at 30 days (8.0% vs 8.6%; HR, 0.93 [95% CI, 0.84-1.02]; \( P = .13 \)) and 180 days (12.3% vs 13.2%; HR, 0.93 [95% CI, 0.86-1.00]; \( P = .06 \)). A decrease in mortality was noted in the fondaparinux group at both 30 days (2.9% vs 3.5%; HR, 0.83 [95% CI, 0.71-0.97]; \( P = .02 \)) and at 180 days (5.8% vs 6.5%; HR, 0.89 [95% CI, 0.80-1.00]; \( P = .05 \)). The primary safety outcome was incidence of major bleeding, which was lower in the fondaparinux group compared to the enoxaparinux group at 9 days (2.2% vs 4.1%; HR, 0.52 [95% CI, 0.44-0.61]; \( P < .001 \)), 30 days (3.1% vs 5.0%; HR, 0.62 [95% CI, 0.54-
The net clinical benefit of death, MI, refractory ischemia, and major bleeding consistently favored fondaparinux over enoxaparin at 9 days (7.3% vs 9.0%; HR, 0.81 [95% CI, 0.73-0.89]; \( P < .001 \)), and this persisted over 30 days (10.2% vs 12.4%; HR, 0.82 [95% CI, 0.75-0.89]; \( P < .001 \)) and 180 days (15.0% vs 17.1%; HR, 0.86 [95% CI, 0.81-0.93]; \( P < .001 \)). An interesting finding was noted in the 39.5% of patients who underwent PCI. Although rates of overall procedural complications were not different between the 2 groups, there was a higher rate of catheter-associated thrombi in patients who received fondaparinux (0.9% vs 0.4%; HR, 3.59 [95% CI, 1.64-7.84]; \( P = .001 \)). Conclusions from this trial were that fondaparinux had similar rates of combined ischemic end point and lower incidence of major bleeding compared to enoxaparin up to 180 days from initial randomization in patients who presented with NSTE-ACS, but higher rates of catheter-associated thrombi in those undergoing PCI.

OASIS-6 was conducted to assess the effect on ischemic events and bleeding rates in 12,092 patients who presented with STEMI when randomized to fondaparinux or heparin.\(^\text{15}\) OASIS-6 was a randomized, double-blind trial and stratified patients based on whether they had an indication for UFH. Patients in stratum 2 were further stratified based on whether they were proceeding to PCI. Approximately 36.8% of patients had PCI during their index hospitalization, with an additional 3.4% having PCI after discharge. More than 44% of patients in both arms underwent thrombolytic therapy during their index hospitalization. Analysis of the primary end point showed no difference between fondaparinux and either placebo or UFH with regard to death or reinfarction at 9 days (7.4% vs 8.9%; HR, 0.83 [95% CI, 0.73-0.84]; \( P = .003 \)), and this persisted at 30 days (9.7% vs 11.2%; HR, 0.86 [95% CI, 0.77-0.96]; \( P = .008 \)) and at study end, which was 3 to 6 months (13.4% vs 14.8%; HR, 0.88 [95% CI, 0.79-0.97]; \( P = .008 \)). Of note, there was a reduction in death and reinfarction rates at each of these time points. The rate of severe bleeding in the overall analysis was not different in the fondaparinux group compared to placebo or UFH at 9 days (1.0% vs 1.3%; HR, 0.77 [95% CI, 0.55-1.08]; \( P = .13 \)). The prespecified subgroup analysis showed no improvement in death or reinfarction rates in the PCI group at 9 days (4.2% vs 4.1%; HR, 1.01 [95% CI, 0.74-1.38]; \( P = .96 \)), 30 days (6.1% vs 5.1%; HR, 1.20 [95% CI, 0.91-1.57]; \( P = .19 \)), or at the end of the study (8.5% vs 8.2%; HR, 1.06 [95% CI, 0.84-1.33]; \( P = .61 \)).
The patients undergoing no reperfusion strategy saw a reduction in ischemic events at 30 days (12.2% vs 15.1%; HR, 0.80 [95% CI, 0.65-0.98]; \( P = .003 \)), as did those who received a fibrinolytic agent (10.9% vs 13.6%; HR, 0.79 [95% CI, 0.68-0.92]; \( P = .003 \)). This was clearly not observed in the primary PCI group. Conclusions from this trial were that in STEMI patients not pursuing a primary PCI strategy, fondaparinux as compared to placebo or UFH significantly reduced mortality and reinfarction without increasing bleeding risk.

Summary and Guidelines

Medical Management and Fibrinolysis

The role of fondaparinux is firmly rooted in medical management and as an adjunctive antithrombotic agent to fibrinolysis. The current UA/NSTEMI guidelines have a Class I indication for fondaparinux in either an early invasive strategy (LOE B) or an initial conservative strategy (LOE B).\(^ {13} \) There is also a Class IIa indication recommending fondaparinux over UFH in those pursuing an initial conservative strategy (LOE B). In those patients, fondaparinux is recommended for the duration of the hospitalization up to 8 days. This is a reflection of the clinical efficacy and safety seen in OASIS-5.

As adjunctive therapy to fibrinolysis, fondaparinux has a Class I indication (LOE B) as long as CrCl is greater than 30 mL/min, based on the significant reduction in mortality and reinfarction rates in OASIS-6 among patients who received fibrinolysis.\(^ {2} \)

PCI

Fondaparinux has a limited role in support for either primary PCI or for rescue PCI after fibrinolysis due to the increased risk of catheter thrombosis seen in both OASIS-5 and OASIS-6, as well as the lack of clinical efficacy seen in OASIS-6. Currently, sole use of fondaparinux has a Class III indication for both primary PCI (LOE B) and rescue PCI after fibrinolysis (LOE C).\(^ {2} \) Current guidelines recommend an agent with activity against factor IIa, although optimal dosing and agents have not been clearly defined.
DIRECT THROMBIN INHIBITORS

Mechanism of Action

Direct thrombin inhibitors (DTIs) have become ubiquitous in their use over the last decade. In addition to thrombin’s effect on platelets, one of the principle mechanisms of activated thrombin is to cleave soluble fibrinogen into insoluble fibrin. This occurs at the active, or catalytic site, where fibrinogen is cleaved via serine protease activity. There are also 2 exosites, with exosite 1 being the binding site for fibrinogen and exosite 2 being the principle binding site of heparins (Fig. 15-5). DTIs are divided into bivalent inhibitors, which bind at both the active site and exosite 1, and univalent inhibitors, which primarily bind to the active site. As can be expected, bivalent inhibitors, such as hirudin and bivalirudin, are more selective than univalent inhibitors, such as argatroban. This is particularly important since the active site of thrombin is structurally similar to other serine proteases, and there can be significant unintended effects. This is appreciated clinically in the form of increased heterogeneity in clinical outcomes among different DTIs.
Overall, DTIs offer some potential benefits over heparins:

- They do not induce an immune-mediated response.
- They can inactivate clot bound thrombus.
- They do not bind to plasma proteins.

Currently, there are 4 parenteral DTIs available in the United States, with only bivalirudin and argatroban carrying indications for use in ACS patients. The single US Food and Drug Administration (FDA)–approved oral DTI, dabigatran, is only indicated at this time for nonvalvular atrial fibrillation and
is beyond the scope of this discussion.

The first 2 available DTIs were recombinant hirudin (rhirudin)—lepirudin and desirudin. Hirudin was originally isolated from the saliva of a medicinal leech, *Hirudo medicinalis*, and was subsequently produced synthetically using recombinant DNA technology in *Saccharomyces cerevisiae*. Lepirudin is an IV rhirudin and differs from the original 65-amino acid polypeptide by 2 amino acids. Desirudin is a subcutaneous rhirudin. Both bind irreversibly to thrombin at both the active site and exosite 1, with a strong affinity and no available antidote. Although the rhirudins are 10 times less potent in their binding with thrombin compared to hirudin, they still form irreversible 1:1 complexes with thrombin. This led clinically to increased bleeding events compared to heparin in ACS patients.

As a result, bivalirudin was developed. Bivalirudin is a synthetic analog of hirudin. This synthetic polypeptide is composed of 20 amino acids, and the active site is cleaved by thrombin, leaving only binding at exosite 1. This forms a significantly weaker bond with thrombin at both the active site and exosite 1 (approximately 800 times weaker than hirudin), allowing for potential competitive displacement of bivalirudin. Clinically, this was manifest as decreased bleeding rates compared to hirudin.

Argatroban is the only FDA-approved univalent DTI and binds reversibly to the active site. Unlike other univalent inhibitors, there is less cross-reactivity with other serine proteases, leading to a more consistent degree of anticoagulation.

**Pharmacology and Dosing**

Table 15-2 summarizes the key pharmacologic characteristics of the 4 FDA-approved DTIs. Because only bivalirudin and argatroban are currently indicated in ACS patients, the rest of the discussion will focus on these 2 agents.

Table 15-2 *Comparison of Different Direct Thrombin Inhibitors*
Bivalirudin has a plasma half-life of approximately 25 minutes in patients with normal renal function. Most of the drug metabolism occurs via proteolytic cleavage in the bloodstream and hepatic metabolism; however, approximately 20% is excreted via the kidney. In patients with moderate renal impairment (glomerular filtration rate [GFR] between 30 and 59 mL/min), the plasma half-life is 34 minutes, and in patients with severe renal impairment (GFR between 10 and 29 mL/min), the plasma half-life is 57 minutes. In patients on renal replacement therapy, the plasma half-life is 210 minutes. Therefore, in patients with a CrCl of 15 to 60 mL/min, a dose reduction is recommended, and bivalirudin is contraindicated in patients with a CrCl of <15 mL/min.

Monitoring for bivalirudin is most often clinically achieved via ACT, although aPTT can also be used. INR can also be prolonged during infusion, although it is not a reliable marker clinically. In patients with normal renal function, anticoagulant effects return to baseline within 2 hours (4 half-lives). In renal failure patients, large amounts of the drug can be cleared via
plasmapheresis or hemofiltration with large-size pores.

The onset of action for bivalirudin is immediately following IV injection, with a linear dose-response relationship. With a bolus infusion, therapeutic ACTs are achieved usually within 5 minutes, making it an ideal antithrombin for the catheterization lab. Target ACT levels vary clinically depending on many factors, including GP IIb/IIIa use, oral anticoagulation status, bleeding risk, and hypercoagulable states. Bivalirudin is also used in heparin-induced thrombocytopenia patients undergoing PCI.

Argatroban is hepatically metabolized and eliminated, and in patients with normal hepatic function, the plasma half-life is approximately 45 minutes. Steady-state plasma concentrations take longer to achieve regardless of bolus dosing. Therefore, argatroban is started without bolus dosing, followed by 2 μg/kg/h. In patients with hepatic dysfunction, dose adjustments are often necessary, and argatroban is contraindicated in severe liver failure. Monitoring is achieved with either aPTT or ACT. Target aPTT is 1.5 to 3 times that of baseline. INR will also be prolonged, and argatroban attenuates INR prolongation of warfarin.

**Clinical Trials**

The story of DTIs in ACS is a continuously evolving one, with recent data adding to our understanding of their effect. Initial clinical trials of DTIs in ACS were heterogeneous in their choice of DTI as well as their use of PCI. This led to heterogeneity of results as well as concerns of applicability in the current era of early invasive approach in ACS patients.

The Direct Thrombin Inhibitor Trialists Collaborative Group conducted a meta-analysis published in 2002 that assessed several DTIs in the larger ACS trials conducted up to that point. There were 11 total ACS trials comprising of 35,790 patients, with only 2 of the 11 trials being PCI trials. In the pooled efficacy analysis, patients treated with DTIs compared to UFH experienced a decrease in the cumulative end point of death and MI at the end of treatment (4.3% vs 5.1%; OR, 0.85 [95% CI, 0.77-0.94]; \( P = .001 \)) and at 30 days (7.4% vs 8.2%; OR, 0.91 [95% CI, 0.84-0.99]; \( P = .02 \)). However, this was driven primarily by a decrease in MI (2.8% vs 3.5%; OR, 0.80 [95% CI, 0.51-0.90]; \( P < .001 \)), and there was not an observed reduction in death rates (Fig. 15-6). These results were observed at 180 days as well. In patients undergoing PCI, there was no difference in the combined end point of death
and MI between DTIs and UFH, although over 75% of the patients came from 1 trial (Bivalirudin Angioplasty Trial). Analysis of the different DTIs showed a decrease in the cumulative end point of death and MI for the bivalent inhibitors (hirudin and bivalirudin) but not the univalent inhibitors (inogatran and argatroban).

FIGURE 15-6 Efficacy and safety of direct thrombin inhibitors (DTIs) versus heparins. Black squares represent odds ratios (OR), the size of which reflects the statistical weight of a trial in calculation of the OR. The horizontal lines represent 95% confidence intervals (CIs). There was evidence of heterogeneity among the DTIs \((P < .0001)\). (Reprinted from Direct Thrombin Inhibitor Trialists’ Collaborative Group.)

*Heterogeneity \(p<0.0001\)
In the safety analysis of the pooled data, there was a decrease in the DTI group of major bleeding, with no difference in the rates of intracranial hemorrhage. However, there was significant heterogeneity between the different DTIs, specifically an increased rate of major bleeding with hirudin (1.7% vs 1.3%; OR, 1.28 [95% CI, 1.06-1.55]) and a decreased rate of major bleeding with bivalirudin (4.2% vs 9.0%; OR, 0.44 [95% CI, 0.34-0.56]). Subgroup analysis showed higher rates of major bleeding in patients with no ST elevation (1.0% vs 0.5%; OR, 1.79 [95% CI, 1.29-2.50]); however, there was no significant difference in major bleeding when used in conjunction with thrombolytics or PCI. However, heterogeneity between the different DTIs was observed in each of these subgroups.

Based on the paucity of data in PCI patients as well as the emerging evidence on the benefit of early invasive strategies in ACS patients, subsequent trials looked at the role of DTIs in patients undergoing PCI. Given the lack of efficacy of univalent inhibitors and the increased rates of major bleeding with hirudin, subsequent trials used bivalirudin as the DTI of choice. However, most of the subsequent trials were compared to UFH and routine use of GP IIb/IIIa inhibitors.

The Randomized Evaluation in PCI Linking Angiomax to Reduced Clinical Events (REPLACE-2) trial was a randomized, double-blind trial with 6010 patients who underwent elective or urgent PCI to assess whether bivalirudin with provisional GP IIb/IIIa inhibition (used in approximately 7% of patients randomized to this arm) reduced clinical events compared to UFH with planned GP IIb/IIIa inhibition. All patients received dual antiplatelet therapy, and 85% of patients received stents. There was no difference between bivalirudin and UFH with GP IIb/IIIa inhibition in the cumulative ischemic end point of death, MI, and severe myocardial ischemia requiring urgent revascularization (7.6% vs 7.1%; OR, 1.09 [95% CI, 0.90-1.32]; P = .40). Major bleeding rates were decreased in the bivalirudin group versus the heparin plus GP IIb/IIIa inhibition group (2.4% vs 4.1%; P < .001).

Conclusions from this trial of relatively low-risk patients, specifically including elective PCI patients, are that bivalirudin is noninferior in terms of clinical efficacy but has decreased rates of major bleeding when compared to
UFH plus GP IIb/IIIa inhibition.

Long-term follow-up of these patients showed no difference in mortality, nonfatal MI, or repeat revascularization at 6 months or 1 year between bivalirudin and UFH plus GP IIb/IIIa, suggesting comparable long-term efficacy.\(^{19}\)

Given the intrinsically low-risk group studied in REPLACE-2, the question still remained as to whether high-risk ACS patients would also derive this benefit. The Acute Catheterization and Urgent Intervention Triage Strategy (ACUITY) trial included 13,819 patients who presented with high-risk UA or NSTEMI and assessed whether bivalirudin either with or without GP IIb/IIIa inhibition reduced ischemic event rates compared to heparin plus GP IIb/IIIa inhibition.\(^{20}\) Patients were randomized to 1 of 3 arms: bivalirudin alone, bivalirudin plus GP IIb/IIIa inhibition or UFH, or enoxaparin plus GP IIb/IIIa; patients underwent PCI within 72 hours. The combined ischemic end point was similar to that in REPLACE-2 and included death, MI, and myocardial ischemia requiring revascularization within 30 days. Not surprisingly, there was no difference in the combined ischemic end point between bivalirudin plus GP IIb/IIIa inhibition and heparin plus GP IIb/IIIa inhibition (7.7% vs 7.3%; RR, 1.07 [95% CI, 0.92-1.23]; \(P = .39\)). Bivalirudin monotherapy was also found to be noninferior compared to heparin plus GP IIb/IIIa inhibition (7.8% vs 7.3%; RR, 1.08 [95% CI, 0.93-1.24]; \(P = .32\)). There was a significant reduction in major bleeding in the bivalirudin monotherapy group compared to both bivalirudin plus GP IIb/IIIa inhibition and heparin plus GP IIb/IIIa inhibition (3.0% vs 5.3% and 5.7%, respectively; RR, 0.53 [95% CI, 0.43-0.65]; \(P < .001\) for bivalirudin monotherapy vs heparin plus GP IIb/IIIa inhibition). Similar to REPLACE-2, conclusions from this trial were that bivalirudin monotherapy is noninferior in preventing ischemic events but significantly reduces major bleeding rates compared to either bivalirudin or heparin plus GP IIb/IIIa inhibition. Of note, the only prespecified subgroup that showed higher rates of the composite ischemic event in the bivalirudin monotherapy group compared with the heparin plus GP IIb/IIIa group were patients who did not receive upstream thienopyridine (ischemic event rates of 9.1% vs 7.1%; RR, 1.29 [95% CI, 1.03-1.63]; \(P = .054\)).

Long-term follow-up of these patients showed no difference in all-cause mortality or composite ischemic events at 1 year, suggesting once again noninferiority in preventing ischemic events with bivalirudin monotherapy.
compared to UFH plus GP IIb/IIIa inhibition.\textsuperscript{21,22}

Although these studies investigated the role of bivalirudin in non–ST-segment elevation ACS and stable angina, there still were questions regarding role of DTIs in STEMI. Initial trials looked at concurrent use of DTIs in fibrinolysis, with GUSTO-IIb and TIMI 9b showing similar rates of the composite ischemic end points of death and reinfarction at 30 days, but with a potentially higher rate of nonintracranial major bleeding seen in TIMI 9b when comparing hirudin versus UFH in conjunction with thrombolytic therapy. In HERO-2, patients were randomized to bivalirudin versus UFH in conjunction with streptokinase. At 30 days, there were similar rates of death and major bleeding but more minor and moderate bleeding in the bivalirudin group. Of note, there were fewer reinfarction rates in the bivalirudin group at 96 hours.\textsuperscript{23}

The Harmonizing Outcomes With Revascularization and Stents in Acute Myocardial Infarction (HORIZONS-AMI) study attempted to address the role of bivalirudin in primary PCI for STEMI.\textsuperscript{24} STEMI patients (n = 3602) were randomized to receive either bivalirudin or heparin plus GP IIb/IIIa. All patients were preloaded with thienopyridine (>99% with clopidogrel), and over 95% of patients received a stent. Of note, more than 91% of patients were Killip class I, and 7.2% of patients in the bivalirudin group received GP IIb/IIIa inhibition, noted by the authors to be due to suboptimal results of the PCI. In the combined ischemic end point of death, reinfarction, revascularization for ischemia, and stroke, there was no difference between bivalirudin and UFH with GP IIb/IIIa inhibition (5.4% vs 5.5%; RR, 0.99 [95% CI, 0.76-1.30]; \(P = .95\)). Similar to NSTE-ACS trials, there was a reduction in major bleeding with bivalirudin (4.0% vs 8.3%; RR, 0.60 [95% CI, 0.46-0.77]; \(P < .001\)). The conclusions from this trial, similar to the NSTE-ACS trials, were that bivalirudin is associated with similar rates of ischemic events but a significantly decreased rate of major bleeding, conferring a net clinical benefit compared to UFH with GP IIb/IIIa inhibition. There was a reduction in cardiovascular mortality (2.1% vs 3.8%; HR, 0.57 [95% CI, 0.38-0.84]; \(P = .005\)) and all-cause mortality (3.5% vs 4.8%; HR, 0.71 [95% CI, 0.51-0.98]; \(P = .037\)) out to 1 year with bivalirudin.\textsuperscript{25}

However, this mortality benefit was not seen in the longer term follow-up from REPLACE-2 or ACUITY (Fig. 15-7).\textsuperscript{26}
Since these trials, there has been a shift in procedural practice, with routine use of GP IIb/IIIa inhibition being supplanted by early initiation of potent oral antiplatelet agents. Also, the vast majority of PCIs were done via femoral access, and with routine use of radial access virtually eliminating access site bleeding, it is speculated whether the reduction in bleeding with bivalirudin would still be seen in a more contemporary trial. In addition, there is limited evidence on bivalirudin versus UFH without routine use of GP IIb/IIIa inhibition. Both the EUROMAX and HEAT-PPCI studies attempted to address these gaps in the evidence.

The European Ambulance Acute Coronary Syndrome Angiography (EUROMAX) study was an international, open-label, randomized controlled trial that randomized patients being transported with STEMI to early bivalirudin or UFH with optional use of GP IIB/IIIa inhibition in both arms. A total of 2198 patients were randomized (1089 in the bivalirudin arm and 1109 in the UFH arm), with acetylsalicylic acid (ASA; aspirin) and P2Y$_{12}$ inhibitor loading in 98% of patients. Radial access was used in approximately 47% of patients, and a stent was implanted in approximately 92% of patients. Of note, there was a significant difference in both arms in the total use of GP IIB/IIIa inhibition (11.5% in the bivalirudin arm and 69.1% in the UFH arm), as well as the routine use of GP IIB/IIIa inhibition (3.9% in the bivalirudin arm and 58.5% in the UFH arm). The primary outcome was the composite of death and non-CABG major bleeding and was significantly lower in the bivalirudin arm (5.1% vs 8.5%; RR, 0.60 [95% CI, 0.43-0.82]; $P = .001$). The principle secondary outcome, which was a composite of death, reinfarction, or non–CABG-related major bleeding, was also lower in the bivalirudin arm (6.6% vs 9.2%; RR, 0.72 [95% CI, 0.54-0.96]; $P = .02$). There was no difference in mortality between the 2 groups (2.9% vs 3.1%; RR, 0.96 [95% CI, 0.60-1.54]; $P = .86$), and the primary end point was driven by non-CABG major bleeding (2.6% vs 6.0%; RR, 0.43 [95% CI, 0.28-0.66]; $P < .001$).
addition, there was an increase in acute stent thrombosis (defined as <24 hours) in the bivalirudin arm (1.1% vs 0.2%; RR, 6.11 [95% CI, 1.37-27.24]; \( P = .007 \)). Conclusions from this trial were that early initiation of bivalirudin on transport to a PCI-capable hospital for STEMI had decreased rates of the composite of death and non-CABG major bleeding as compared to UFH but higher rates of stent thrombosis. The net clinical benefit, as defined by the principle secondary outcome, favored the routine use of bivalirudin. Although the use of GP IIb/IIIa inhibition was optional, there was still significantly higher use in the UFH arm, similar to previous trials.

The Unfractionated Heparin Versus Bivalirudin in Primary Percutaneous Coronary Intervention (HEAT-PPCI) study was an open-label, single-center randomized control trial that randomized patients presenting to a high-volume, tertiary care center with STEMI to either bivalirudin or UFH with provisional use of GP IIb/IIIa inhibition in both arms. A total of 1812 patients were randomized (905 in the bivalirudin arm and 907 in the UFH arm), with ASA and P2Y_{12} inhibitor loading occurring in 99% of patients. In addition, radial access was used in approximately 80% of patients, and PCI was attempted in 82% of patients, with a >97% successful intervention rate in each arm (stent implanted in 90% of patients). GP IIb/IIIa inhibition was not significantly different in the 2 arms (13% in bivalirudin arm and 15% in UFH arm). The primary efficacy end point was the composite of all-cause mortality, cerebrovascular accident, reinfarction, or unplanned target vessel revascularization at 28 days and was higher in the bivalirudin arm (8.7% vs 5.7%; RR, 1.52 [95% CI, 1.09-2.13]; \( P = .01 \)). Specifically, there was a higher rate of definite or probable stent thrombosis in the bivalirudin arm (3.4% vs 0.9%; RR, 3.91 [95% CI, 1.61-9.52]; \( P = .001 \)) and a higher rate of acute in-stent thrombosis (2.9% vs 0.9%; RR, 3.26 [95% CI, 1.32-8.07]; \( P = .007 \)). The primary safety end point was major bleeding (Bleeding Academic Research Consortium type 3-5) and was not different between the 2 arms (3.5% vs 3.1%; RR, 1.15 [95% CI, 0.70-1.89]; \( P = .59 \)). Conclusions from this trial were that there was an increase in major adverse cardiovascular event rates among STEMI patients treated with bivalirudin compared to UFH with no difference in rates of all bleeding or major bleeding. This increase in major adverse cardiovascular events was driven by acute stent thrombosis and was consistent with the bivalirudin arms of the HORIZONS-AMI and EUROMAX trials.

HEAT-PPCI was met with significant controversy, specifically regarding
its controversial consent process as well as the discrepant results from previous trials. Given that it is a single-center experience, validation of these findings are important, but the trial likely represents a more contemporary experience than the landmark trials. This also raises the question as to the effect of provisional versus planned GP IIb/IIIa inhibitor use on the bleeding risk in the landmark trials.

A recent meta-analysis attempted to look at the composite bivalirudin experience in patients undergoing PCI. Data from 16 trials involving almost 34,000 patients across the spectrum of stable angina and ACS were included. There was an increase in major adverse cardiovascular events with bivalirudin-based regimens compared to UFH-based regimens (RR, 1.09 [95% CI, 1.01-1.17]; \( P = .02 \)) driven primarily by increase in MI (RR, 1.12 [95% CI, 1.03-1.2]). This likely is due to an increase in acute stent thrombosis, which was pronounced in the 3 most recent randomized controlled trials (RR, 4.27 [95% CI, 2.28-8]; \( P < .0001 \)). Major bleeding rates were lower in the bivalirudin group (RR, 0.62 [95% CI, 0.49-0.78]; \( P < .0001 \)); however, this effect was heterogeneous depending on use of GP IIb/IIIa inhibition. The provisional use of GP IIb/IIIa in both arms (RR, 0.78 [95% CI, 0.51-1.19]; \( P = .25 \)) and the planned use of GP IIb/IIIa in both arms (RR, 1.07 [95% CI, 0.87-1.31]; \( P = .53 \)) showed no difference in rates of major bleeding. Conclusions from this analysis suggest an increase in acute stent thrombosis with bivalirudin-based regimens, which is consistent with the 3 most recent randomized controlled trials (Fig. 15-8).

**FIGURE 15-8** Acute stent thrombosis rates between bivalirudin- and unfractionated

One proposed reason for the increase in stent thrombosis with bivalirudin is the relatively short duration of action, and different protocols for bivalirudin may offset the increased risk of acute stent thrombosis. As an optimal protocol is identified, the risk of acute stent thrombosis will likely need to be reassessed.

The extent of the decrease in bleeding with bivalirudin has been brought into question, and may be due, at least in part, to the use of GP IIb/IIIa inhibitors in the major trials (Fig. 15-9). The most contemporary trials have been split on the risk of bleeding with bivalirudin, and further investigation in a multicenter randomized controlled trial will be needed.
**Summary and Guidelines**

Univalent inhibitors have been shown to be ineffective compared to heparin in ACS patients and, therefore, are limited to use in patients who cannot receive heparin due to absolute contraindications, such as heparin-induced thrombocytopenia. Recombinant hirudins are also limited in clinical use to non-ACS indications due to the increased bleeding risk in ACS trials.
Bivalirudin is the only clinically relevant DTI, with its major clinical application in patients undergoing PCI. Based on recent randomized clinical trials, there appears to be an increased risk of acute stent thrombosis with bivalirudin-based regimens. The majority of clinical trials show a reduction in bleeding risk with bivalirudin versus UFH; however, the impact of GP IIb/IIIa inhibition on this bleeding risk is under investigation.

**Medical Management and Fibrinolysis**

Current ACC/AHA guidelines for NSTE-ACS have a very limited scope for the use of bivalirudin for medical management, predominantly due to the lack of data in this patient population. In patients undergoing an initial conservative strategy, bivalirudin is not currently indicated. In patients who undergo diagnostic angiography after which a conservative strategy is pursued, bivalirudin can either be discontinued immediately or continued at 0.25 mg/kg/h for up to 72 hours per the physician’s discretion. For patients undergoing CABG, bivalirudin should be stopped 3 hours prior to surgery.

Use of bivalirudin in patients undergoing fibrinolysis is limited to patients who have presumed or documented heparin-induced thrombocytopenia, due to increased bleeding risk seen in fibrinolysis trials.

**Percutaneous Coronary Intervention**

Bivalirudin’s largest contribution to ACS management has been in patients undergoing PCI. The guidelines are driven by the data that showed similar ischemic event rates with decreased incidence of major bleeding compared to UFH with GP IIb/IIIa inhibition. Bivalirudin use in patients undergoing an initial invasive strategy carries a Class I indication (LOE B) in the most recent ACC/AHA UA/NSTEMI guidelines. It is important to note, however, that the rate of acute stent thrombosis is higher, even in studies that had thienopyridine loading prior to PCI.

**SPECIFIC CLINICAL SCENARIOS**

**Oral Anticoagulant Use**
There has been a substantial increase in the clinical availability and use of oral anticoagulants, both DTIs and anti–factor Xa agents. All clinical trials have looked at oral agents in the setting of recent ACS. The anti–factor Xa agents apixaban and darexaban were shown to have increased rates of major bleeding compared to placebo, limiting their use in this clinical scenario. Rivaroxaban has been studied more extensively in the stable post-ACS patient. In a phase II clinical trial of rivaroxaban, ATLAS ACS-TIMI 46, there was no net clinical benefit seen in patients undergoing revascularization; however, in medically managed patients, there was a decrease in ischemic end points with a concomitant increase in major bleeding. This led to a phase III clinical trial, ATLAS ACS-TIMI 51. In ATLAS ACS-TIMI 51, rivaroxaban at a lower dose (2.5 mg twice a day) was associated with a decrease in the primary end point of cardiovascular death, nonfatal MI, or nonfatal stroke compared with placebo (9.1% vs 10.7%; HR, 0.84 [95% CI, 0.72-0.97]; P = .02), with a decrease in both cardiovascular death and all-cause mortality.\textsuperscript{31} There was also an increase in both TIMI major bleeding and intracranial hemorrhage, but not fatal bleeding. The phase II RE-DEEM study compared multiple dosages of the oral DTI dabigatran versus placebo in patients with recent ACS, showing increased rates of bleeding with dabigatran compared to placebo. The study was not powered to assess for ischemic end points. This has led to a potential role, albeit a limited one, for oral anticoagulants in the post-ACS patient.

A more salient question is what to do about antithrombotic use in patients already on oral anticoagulants. Over 5% of patients referred for PCI are on oral anticoagulants chronically. Unfortunately, there are limited available data to guide therapy and currently no prospective data. A retrospective, multicenter analysis showed an increase in rates of major bleeding and vascular site complications in patients who had their warfarin interrupted, which was hypothesized to be due to increased use of parenteral anticoagulants and GP IIb/IIIa inhibition.\textsuperscript{32} Multiple retrospective analyses support the performing of PCI on therapeutic warfarin if the INR is between 2 and 3. However, there is an increase in femoral access complications with therapeutic warfarin, especially if additional heparin is given periprocedurally, and radial access is recommended. Interrupting or bridging systemic anticoagulants has not been shown in the limited data available to decrease either ischemic or bleeding complications and leads to prolonged hospitalization and more time with subtherapeutic anticoagulation.\textsuperscript{33} Given
warfarin’s predictable effect on ACT, some propose using a parenteral antithrombotic (preferably UFH) as needed to maintain therapeutic ACTs during the PCI. Newer oral anticoagulants have even less data, and any current recommendations are made based on anecdotal evidence.\textsuperscript{34} Table 15-3 summarizes the proposed management for patients on oral anticoagulants proceeding to PCI.

Abbreviations: ACT, activated clotting times; BMS, bare metal stent; DAP, dual antiplatelet therapy; DES, drug-eluting stent; NOAC, new oral anticoagulant; NSTEMI, non-ST-segment elevation myocardial infarction; OAC, oral anticoagulant; PCI, percutaneous coronary intervention; STEMI, ST-segment elevation myocardial infarction; UA, unstable angina; UFH, unfractionated heparin; VKA, vitamin K antagonist.

**Heparin-Induced Thrombocytopenia**

Heparin-induced thrombocytopenia (HIT), while rare, is especially problematic in ACS patients given the proven benefit of AT therapies. The incidence of HIT is variable based on series studied and confirmatory test used, but can be as high as 5% of patients exposed to heparins for longer than 4 days. It is an immune-mediated condition with antibodies to the complex of heparin and platelet factor 4 (PF4). This leads to platelet activation and a prothrombotic state. These bound platelets are then cleaved from circulation, leading to an observed thrombocytopenia. Clinical scoring systems help to identify patients at high risk for HIT. Anti-PF4 antibodies are extremely sensitive but lack specificity to diagnose HIT. Anti-PF4 antibodies are the first-line test for any patient at low or intermediate pretest probability for HIT. The gold standard test is the serotonin release assay (sensitivity of 100% and specificity of 97%), but other confirmatory tests are available to aid in the diagnosis, including heparin-induced platelet aggregation assays.
(sensitivity of 80% and specificity of >90%) and solid phase immunoassay (sensitivity of >90% but low specificity).

Given the risk of thrombosis in HIT, any patient suspected of having HIT should be on AT therapy. UFH and LMWH are absolutely contraindicated. Given case reports of HIT with fondaparinux, this is often avoided as well, although this relationship is controversial. DTIs have a very specific role across the clinical spectrum of HIT. rHirudins, such as lepirudin and desirudin, are not indicated in ACS patients due to increased incidence of major bleeding. Current STEMI guidelines recommend bivalirudin as first-line therapy in patients undergoing revascularization either with fibrinolysis or PCI. Argatroban may also be used for ACS patients with HIT. Current guidelines do not specifically recommend an agent for medical management of ACS patients.

**Cardiac Surgery**

The decision to proceed with cardiac surgery is often made after an initial ACS presentation. Although some smaller studies suggest bivalirudin is safe and effective during CABG, UFH remains the cornerstone of therapy. Current guidelines recommend discontinuation of enoxaparin 12 to 24 hours prior to CABG, fondaparinux 24 hours prior to CABG, and bivalirudin 3 hours prior to CABG, with patients being maintained on UFH per institutional protocol (Class I, LOE B recommendations).13

**CONCLUSION**

AT therapies have evolved significantly to mirror clinical need. Although UFH has remained an important therapeutic option, multiple additional agents, including LMWH, fondaparinux, and DTIs, have been added to the armamentarium of the clinician to help individualize therapy for ACS patients, especially those proceeding to revascularization. With further developments in antiplatelet therapy, stent design and deployment, and postacute care management, more data will help guide combination therapies to further decrease both ischemic and bleeding complications of ACS. This will help further direct our use of AT therapies.

MULTIPLE CHOICE QUESTIONS

1. A 64-year-old woman presents to the emergency department with substernal chest pressure that started approximately 3 hours ago. She had an electrocardiogram (ECG) done within 10 minutes, which showed ST-segment elevation in the inferior leads with reciprocal changes noted anteriorly. The catheterization laboratory is activated, and as the team prepares the lab, you are asked about procedural anticoagulation since the patient had a recent serious heparin allergy. Laboratory results, other than troponin, are within normal limits. Which of the following antithrombotic regimens would be most appropriate?

A. Enoxaparin 0.3 mg/kg intravenously (IV) × 1 followed by 1 mg/kg subcutaneously (SC) at 12 hours
B. Fondaparinux 7.5 mg SC × 1 with subsequent dosing based on activated clotting time (ACT) levels
C. Unfractionated heparin 60 units/kg × 1 with subsequent dosing based on ACT levels
D. Argatroban 350 μg/kg × 1 with subsequent dosing based on ACT levels
2. A 73-year-old woman with a past medical history notable for coronary artery disease (CAD), multiple PCI procedures, and remote cerebrovascular accident (CVA) presents to the emergency department with intermittent chest pressure with exertion over the last 2 to 3 days. The pain was occurring with less exertion until this morning, when she started having rest pain. In the emergency department, she is noted to have 1-mm ST-segment depression with T-wave inversion in the anterolateral leads with the chest pain, and the first troponin is elevated. The patient’s pain persists despite medical therapy, and the decision is made to activate the catheterization laboratory. She has had significant procedural bleeding in the past including a large retroperitoneal hematoma. Which of the following strategies can reduce the risk of major bleeding in this patient?
   A. Radial approach
   B. Upstream glycoprotein (GP) IIb/IIIa use
   C. Aspirin plus prasugrel instead of aspirin plus clopidogrel
   D. Planned intra-aortic balloon pump (IABP) due to concern for an anterolateral infarction

3. A 57-year-old man with a past medical history notable for diabetes, hypertension, and hyperlipidemia presents to your clinic with recurrent exertional chest pain for the past 3 to 6 months and lower extremity edema and orthopnea for the past 2 to 3 weeks. He states that the chest pain is stable, but the new orthopnea and edema are concerning. Echocardiography shows left ventricular dysfunction with an ejection fraction of 25% to 30% with anterior and anteroseptal akinesis and diffuse hypokinesis. Coronary angiography reveals multivessel coronary artery disease with good bypass targets, and you plan to recommend urgent surgical revascularization. Of the strategies presented, which would be the most appropriate preoperatively?
   A. Enoxaparin SC with final dose given just prior to sending the patient to the operating room (OR)
   B. Fondaparinux SC with final dose within 12 hours of going to the OR
   C. Bivalirudin IV with infusion stopped 3 hours before going to the OR
   D. Bivalirudin IV with infusion continuing en route to the OR

4. A 65-year-old man presents for follow-up after primary PCI to the right
coronary artery. He is doing well on optimal medical therapy and has just
started cardiac rehabilitation. He remembers being told in the hospital that
his heart attack was due to a “clot” in his artery, and he asks about
whether he should be on a “blood thinner” as well as his antiplatelet
agents. Which of the following statements is the most accurate regarding
maintenance antithrombin agents after an acute coronary syndrome
(ACS) event?
A. They reduce clinical event rates with a reduction in bleeding
complications.
B. They reduce clinical event rates with an increase in bleeding
complications.
C. They result in no change in clinical event rates with a reduction in
bleeding complications.
D. They result in no change in clinical event rates with an increase in
bleeding complications.

5. All of the following are advantages of bivalirudin over heparin products
except:
   A. Does not induce an immune response
   B. Can inactivate clot bound thrombus
   C.Reduces acute stent thrombosis risk
   D. Does not bind to plasma proteins

ANSWERS

1. D

In the setting of confirmed or suspected severe heparin allergy or heparin-
induced thrombocytopenia, unfractionated heparin and enoxaparin are
contraindicated due to risk of recurrent adverse events. Fondaparinux does
not have this same risk of complications; however, it should not be used as
monotherapy in primary percutaneous coronary interventions (PCIs) due to
the risk of catheter thrombosis. Another therapy with better activity against
factor II (thrombin) would need to be added to fondaparinux to minimize the
risk of catheter thrombosis. In these settings, any direct thrombin inhibitor
would be appropriate and is the only indication for argatroban in the most
recent STEMI guidelines. In contemporary practice, bivalirudin is the most commonly used direct thrombin inhibitor.

2. A

The question centers on strategies to reduce major bleeding risk in an elderly woman with a previous history of a CVA. Radial approach has been shown to reduce the risk of access site bleeding, particularly in experienced laboratories, and despite the slightly higher risk of nonaccess site bleeding, the overall risk of major bleeding is reduced. Prasugrel is contraindicated in this patient given an increased risk of intracranial hemorrhage and is generally associated with more bleeding than clopidogrel. The other two options are associated with an increase in the risk of major bleeding.

3. C

The decision to proceed with cardiac surgery is not uncommonly made after an acute coronary syndrome presentation. Current guidelines recommend discontinuation of enoxaparin 12 to 24 hours prior to coronary artery bypass grafting (CABG), fondaparinux 24 hours prior to CABG, and bivalirudin 3 hours prior to CABG, with patients being maintained on unfractionated heparin per institutional protocol (Class I, Level of Evidence B recommendations).

4. B

In ATLAS ACS-TIMI 51, rivaroxaban at a lower dose (2.5 mg twice a day) was associated with a decrease in the primary end point of cardiovascular death, nonfatal myocardial infarction, or nonfatal stroke compared to placebo (9.1% vs 10.7%; hazard ratio, 0.84 [95% CI, 0.72-0.97]; \( P = .02 \)), with a decrease in both cardiovascular death and all-cause mortality. There was also an increase in both Thrombolysis in Myocardial Infarction (TIMI) major bleeding and intracerebral hemorrhage, but not fatal bleeding. The phase II RE-DEEM study compared multiple dosages of the oral direct thrombin inhibitor dabigatran versus placebo in patients with recent ACS, showing increased rates of bleeding compared to placebo. The study was not powered to assess for ischemic end points.
5. C

Several major studies comparing bivalirudin to heparin in the setting of an ACS have shown either similar stent thrombosis risk or higher stent thrombosis risk with bivalirudin. A recent meta-analysis showed higher acute stent thrombosis risk with bivalirudin, but this risk may be mitigated by a postprocedural infusion of bivalirudin.
INTRODUCTION

In 1979, Andreas Gruentzig reported his experience with the first 50 coronary angioplasty procedures. In those first 50 patients, antiplatelet therapy was empiric and consisted of 1.0 g of aspirin (approximately 65 mg) for 3 days and dextran during the procedure. In the 36 years since that publication, the scientific understanding of arterial thrombus formation in response to arterial injury and clinical experience with pharmacologic means to mitigate this process have grown by immeasurable proportions. Specifically, the understanding of surface receptors and ligands necessary for the transformation of platelets to their active state, as well as the surface proteins responsible for adherence to fibrin, leukocytes, and other platelets, has facilitated the development of therapies targeted to specific steps in the activation sequence. Clinical investigation and experience continually refine the circumstances under which specific therapies are best applied in order to maximize benefit and minimize risk. In contemporary coronary angioplasty, the interplay between arterial wall, platelets, plaque components, clinical presentation, stent design, stent components, and concomitant medications
HISTORICAL PERSPECTIVE

From the initial angioplasty procedure in 1977 through the introduction of coronary stents in the early 1990s, thrombosis at the site of angioplasty was recognized as a primary mediator of acute vessel closure during and immediately after the procedure. Heparin was empirically used successfully during and in the immediate periprocedural period, but only aspirin was administered at patient discharge. In the earliest experience with intracoronary stents in the early 1990s, stent thrombosis rates approached 20% and became a focus of postprocedure care. The empiric approach of universal oral anticoagulation with warfarin following stent implantation reduced the incidence of stent thrombosis to 3% to 5%, but at a significant cost of access site–related and non–access site–related bleeding complications. Some operators even suggested that the thrombotic risk of stents was too excessive to justify routine use.

In 1995, a landmark study changed stent practice and shifted pharmacologic strategy from antithrombotic to antiplatelet following percutaneous coronary intervention (PCI). After initial observations that 80% of stents were inadequately expanded when examined by intravascular ultrasound (IVUS), Colombo and colleagues elegantly demonstrated that full stent expansion with apposition to the artery wall was both necessary and sufficient for patients to be safely treated with 2 antiplatelet medications (aspirin and ticlopidine) rather than warfarin. The calculus again changed substantially with the introduction of drug-eluting stents. Although the benefits of a durable revascularization result have been well documented, the combination of delayed healing and polymer hypersensitivity made these stents more susceptible to late thrombosis and lengthened the duration of antiplatelet therapy after PCI.

Twenty years of clinical studies of coronary stent procedures have resulted in the following principles of contemporary PCI with regard to antiplatelet therapy: (1) stent thrombosis is platelet mediated and carries a high morbidity and mortality; (2) adequate platelet inhibition before, during, and after the procedure is associated with optimal clinical outcome; (3) bleeding avoidance
is as important as preventing ischemic complications; and (4) both patient and procedural factors (including stent design) determine relative risk of stent thrombosis and the intensity and duration of platelet inhibition required for the lowest rates of both ischemic and bleeding complications. In this chapter, we outline the evidence for current antiplatelet therapies during and after PCI, as well as strategies for management of antiplatelet therapies in the setting of other medications and complicating clinical circumstances.

CYCLOOXYGENASE-1 INHIBITORS: ASPIRIN

Pharmacokinetics of Aspirin

Aspirin is rapidly absorbed in the stomach and upper intestine when administered in a chewable formula or oral liquid to reach peak plasma levels in 30 to 40 minutes. In patients unable to take medication by mouth, rectal administration also results in rapid absorption. Aspirin is hydrolyzed to salicylic acid, which irreversibly inhibits the cyclooxygenase-1 (COX-1) activity of platelets within the portal circulation, and platelet inhibition is evident within 1 hour.

The half-life of aspirin is short at 15 to 20 minutes. However, the circulating platelets are irreversibly inhibited for the duration of their lifespan, which is approximately 10 days. Approximately 10% of platelets are replaced each day; hence, almost 50% of platelets continue to be inhibited at 5 to 6 days after a single loading dose.¹

Optimal Dosing of Aspirin in PCI

Aspirin has been used empirically in all angioplasty since Gruentzig’s initial report. There is a single reported angioplasty study that randomized patients to an arm that did not include aspirin treatment. Although not designed to assess the necessity of aspirin (but rather restenosis rates), the study is often quoted as being the basis for the universal use of aspirin in contemporary practice. In this study, the periprocedural events included a Q-wave myocardial infarction (MI) rate of 6.8% in the placebo arm, compared to
1.3% in the aspirin arm. Performed in the balloon angioplasty era with a small number of patients, the applicability to current practice is questionable, yet this study remains an important influence regarding the primacy of aspirin as a pharmacologic adjunct to angioplasty.

The minimum effective dose prior to PCI in patients presenting with acute coronary syndrome has not be studied prospectively. Considering available data, the current guidelines for treatment of ST-segment elevation myocardial infarction (STEMI) recommend 162 to 325 mg of non–enteric-coated aspirin given as early as possible prior to primary PCI as a Class I recommendation.² In elective PCI, guidelines suggest a loading dose of 325 mg prior to PCI in aspirin-naïve patients and 81 to 325 mg in patients on chronic aspirin therapy.³

Aspirin sensitivity/allergy is an important consideration prior to PCI because as many as 3% to 5% of patients being considered for PCI report a history of respiratory or cutaneous symptoms or reactions after aspirin ingestion. A number of aspirin desensitization protocols are available, using sequential administration of escalating doses of oral aspirin. Patients with true anaphylaxis to aspirin can be desensitized, although at increased risk. In our practice, we generally desensitize those patients with sensitivity, but in cases of true anaphylaxis or where the patient does not consent to desensitization, we have proceeded successfully with thienopyridine monotherapy.

Many well-designed randomized trials have shown that a maintenance dose of aspirin less than 100 mg is effective as secondary prevention in patients with coronary atherosclerosis.⁴,⁵ These studies, which did not include patients who underwent PCI, are insufficient to confirm that low-dose aspirin would suffice to prevent stent thrombosis. However, in the PCI-CURE trial,⁶ a post hoc analysis of the PCI cohort of the CURE (Clopidogrel in Unstable Angina to Prevent Recurrent Events) trial,⁷ 2658 patients with acute coronary syndromes undergoing PCI were stratified into 3 aspirin dose groups and followed up to 1 year. The high-dose group received more than 200 mg, and the low-dose group received less than 100 mg, with the moderate-dose group receiving doses in between. The moderate- and high-dose groups had similar rates of cardiovascular death, MI, or stroke compared to the low-dose group. From a safety standpoint, major bleeding was increased with high-dose aspirin with net adverse clinical events (death, MI, stroke, and major
bleeding) favoring low-dose aspirin over high-dose aspirin. Therefore, in this observational analysis of patients undergoing PCI, low-dose aspirin appeared to be as effective as higher doses in preventing ischemic events but was also associated with a lower rate of major bleeding and an improved net efficacy-to-safety balance.

In the CURRENT-OASIS\textsuperscript{8} study, 25,086 patients with an acute coronary syndrome who were referred for an invasive strategy were randomized to higher dose aspirin (300-325 mg daily) or lower dose aspirin (75-100 mg daily). The primary outcome was cardiovascular death, MI, or stroke at 30 days. There was no significant difference between higher dose and lower dose aspirin with regard to the primary outcome. From a safety standpoint there was no increase in major bleeding (2.3% vs 2.3%; hazard ratio [HR], 0.99 [95% confidence interval (CI), 0.84-1.17]; \( P = .9 \)) between the groups. However, the rate of minor bleeding was increased (5.0% vs 4.4%; HR, 1.13 [95% CI, 1.00-1.27]; \( P = .04 \)) and major gastrointestinal bleeding was more frequent (0.4% vs 0.2%; \( P = .04 \)) with higher dose aspirin.

Most recently, the ADAPT-DES registry\textsuperscript{9} followed 8582 patients after PCI with stent implantation who were treated with low-dose aspirin and clopidogrel and had platelet functional testing performed to detect both clopidogrel and aspirin nonresponsiveness prior to discharge. In this study, aspirin nonresponsiveness did not predict stent thrombosis events, MI, or death. However, aspirin responsiveness was associated with a higher likelihood of clinically evident bleeding. Small case series have also described successful PCI with stent placement using P2Y\textsubscript{12} inhibitors alone in patients unable to take aspirin. Finally, although thienopyridine discontinuation is frequently identified as a clinical factor strongly associated with stent thrombosis, aspirin discontinuation is less predictive. Discontinuation of aspirin in clinical trials has been reported to be as high as 18%. Taken together, these data suggest that aspirin may not be as important as previously thought in the prevention of post-PCI ischemic complications, a hypothesis that certainly deserves further study, particularly in cases of aspirin allergy or the need for oral anticoagulation.

In summary, currently available data indicate that a loading dose of 325 mg before PCI followed by low-dose aspirin after PCI (100 mg or less) is a reasonable standard. However, there is some evidence to suggest that the necessity of aspirin should be formally reexamined.
P2Y$_{12}$ RECEPTOR ANTAGONISTS: TICLOPIDINE, CLOPIDOGREL, PRASUGREL, TICAGRELOR, AND CANGRELOR

Upon arterial injury, circulating platelets are exposed to subendothelial proteins such as von Willebrand factor, vitronectin, and collagen. Platelet collagen receptors mediate more firm attachment of platelets and result in the release of platelet-dense granules, which contain, among other vasoactive components, the extracellular signaling purine nucleotide adenosine diphosphate (ADP). ADP acts locally to attract and activate other platelets and amplify the local response to injury. The primary receptor for ADP on the platelet is the P2Y$_{12}$ receptor, which is a member of a large family of purine and pyrimidine nucleotide receptors.

Thienopyridines are a group of compounds that have antithrombotic activity mediated through irreversible binding and inactivation of the P2Y$_{12}$ receptor. The first thienopyridine, tinoridine, was isolated in 1970 and has anti-inflammatory and analgesic properties; it is currently marketed in a number of countries worldwide as a nonsteroidal anti-inflammatory. Ticlopidine is a tinoridine derivative that exhibited antithrombotic properties, and was first marketed in Europe in 1978 for prevention of clotting in hemodialysis and cardiopulmonary bypass. It subsequently proved effective in patients with other clinical manifestations of atherosclerosis, such as in transient ischemic attacks (TIAs), stroke, and peripheral vascular disease, and became available in the United States in 1991. In 1995, Colombo and colleagues demonstrated that P2Y$_{12}$ inhibition with ticlopidine was an important strategy to avoid stent thrombosis, and ticlopidine became a standard of care. With wider use, hematologic dyscrasias from ticlopidine helped to accelerate the development of other, less toxic thienopyridines. Although the P2Y$_{12}$ receptor was not cloned until 2001, its existence was inferred from the effects of thienopyridines on platelet function. Due to the success of thienopyridines, nonthienopyridine P2Y$_{12}$ receptor antagonists have been developed, including those that do not irreversibly inactivate the
receptor.

There are now 4 P2Y$_{12}$ inhibitors that have clinical utility in the treatment of atherosclerotic cardiovascular disease and, in particular, have clinical data supporting their use during and after PCI.

**Clopidogrel (Plavix)**

**Pharmacokinetics of Clopidogrel**

Clopidogrel is a prodrug that is rapidly absorbed in the intestine following oral administration. However, 85% of the dose is eliminated as an inactive metabolite. Following intestinal absorption, clopidogrel is activated in the liver by 2 sequential oxidative steps. The first step results in the formation of 2-oxo-clopidogrel, which is then further metabolized by cytochrome P450 isoforms including CYP3A4/5 and CYP2C19 to generate the active metabolite. Variability in the efficiency of this second step is mediated through differences in CYP2C19 alleles, resulting in different degrees of platelet inhibition depending on genotype. The active metabolite irreversibly binds to the P2Y$_{12}$ receptor, inhibiting ADP binding of the platelet. Once clopidogrel binds to the P2Y$_{12}$ receptor, platelet function is inhibited for the lifespan of the platelet, generally 7 to 10 days.

**Dosing of Clopidogrel in PCI**

While the practice of using thienopyridines to prevent stent thrombosis after PCI was introduced by Colombo’s observations in 1995, it was not until 5 years later that PCI-CURE established the principal of thienopyridine pretreatment. Randomizing 2658 subjects with non–ST-segment elevation myocardial infarction (NSTEMI) to clopidogrel or placebo for 6 days before PCI, clopidogrel was associated with a relative risk of 0.7 compared to placebo for a composite end point of death, MI, or urgent revascularization at 30 days. ISAR-REACT showed that clopidogrel had a similar magnitude of effect as glycoprotein IIb/IIIa inhibitors in elective PCI.

The timing and dose of clopidogrel loading prior to PCI, in both elective cases and acute coronary syndromes, have been extensively studied. Muller et al$^{10}$ compared the effect of a high clopidogrel loading dose (600 mg)
versus a loading dose of 300 mg on platelet aggregation in response to ADP in patients undergoing PCI. Faster and more profound suppression of platelets was achieved following a 600-mg loading dose.\textsuperscript{10}

In the CREDO trial,\textsuperscript{11} there was no reduction in events (death, MI, or stroke), compared with placebo, when 300 mg of clopidogrel was given 3 hours prior to the procedure. However, in a prespecified subgroup analysis, patients who received 300 mg of clopidogrel at least 6 hours before PCI experienced a relative risk reduction of 38.6\% (95\% CI, –1.6\%-62.9\%; \(P = .051\)) at 28 days.

Following a load of 600 mg of clopidogrel, peak suppression of platelet activity is seen by 2 hours after administration. In 428 patients undergoing PCI, the 30-day composite rate of major adverse cardiac events was not significantly different in patients undergoing PCI within 2 hours after a loading dose of 600 mg or at a later time point.\textsuperscript{12}

The ARMYDA-2 trial was the first randomized trial to evaluate the impact of a 600-mg loading dose in comparison to the 300-mg conventional loading dose in patients undergoing PCI. Three hundred twenty-nine patients with typical exertional angina and a positive stress test or non-ST-segment elevation acute coronary syndrome (ACS) were randomized to either 300 or 600 mg of clopidogrel between 4 and 8 hours prior to PCI. The composite end point (death, MI, or target vessel revascularization) was significantly higher in patients treated with the conventional dose of clopidogrel than in patients treated with the high loading dose (12\% vs 4\%; \(P = .041\)). The incidence of MI was significantly higher in patients treated with the conventional dose (5\% vs 15\%). Bleeding complications were similar, and the difference in frequency of entry site hematoma was not statistically significant (7.1\% vs 4.7\%; \(P = .56\)). Furthermore, significantly more patients in the conventional-dose arm had elevations of cardiac biomarkers following the procedure (creatine kinase [CK]-MB, \(P = .038\); troponin I, \(P = .021\); myoglobin, \(P = .002\)). In this study, the event-free survival at 30 days significantly favored the high loading dose (\(P = .017\)). Multivariate analysis identified pretreatment with the 600-mg dose of clopidogrel and statin therapy as independent predictors of decreased risk of periprocedural MI (\(P = .044\) and \(P = .020\), respectively). Additional benefit was noted in high-dose patients who were on statin therapy before the intervention (\(P = .017\)).\textsuperscript{13} A loading dose of 900 mg was studied, but no additional benefit beyond that of
600 mg was seen.

To obtain maximum clinical benefit in clopidogrel-naïve patients, the data suggest that it is reasonable to treat patients with a 600-mg loading dose if administered at least 2 hours prior to PCI to ensure full antiplatelet activity. Benefit from a 300-mg loading dose is not expected unless administered at least 6 hours prior to PCI.

Administering a loading dose of clopidogrel routinely to patients prior to diagnostic coronary angiography may be problematic should coronary artery bypass grafting (CABG) be necessary, as there is an increased risk of bleeding and reoperation in patients undergoing bypass surgery while on clopidogrel. Current American College of Cardiology Foundation (ACCF)/American Heart Association (AHA) guidelines for CABG surgery recommend clopidogrel and ticagrelor be discontinued for at least 5 days prior to elective CABG surgery and 24 hours prior to urgent CABG surgery.\textsuperscript{14}

It is not infrequent that patients on chronic clopidogrel therapy are referred for PCI. Two studies have examined the impact of reloading of clopidogrel. The Antiplatelet Therapy for Reduction of Myocardial Damage During Angioplasty (ARMYDA-4 RELOAD) trial was conducted to evaluate safety and effectiveness of clopidogrel reloading in patients on chronic clopidogrel therapy undergoing PCI. Five hundred three patients on chronic clopidogrel therapy for greater than 10 days presenting with stable angina and ACS were randomized to receive either 600 mg of clopidogrel loading 4 to 8 hours before PCI or placebo. The primary end point of 30-day incidence of death, MI, or target vessel revascularization (TVR; major adverse cardiac events [MACEs]) was not significantly different between the reload and placebo arms (6.7\% vs 8.8\%, respectively; odds ratio [OR], 0.75 [95\% CI, 0.37-1.52]; \( P = .50 \)). In patients with stable angina, 1-month MACEs were not significantly different (\( P = .36 \)), whereas ACS patients had significant clinical benefit with reloading (\( P = .033 \)). There was no excess bleeding in the reload arm.\textsuperscript{15}

The ARMYDA-8 RELOAD-ACS study evaluated the benefit of administering a 600-mg dose of clopidogrel compared with placebo in patients with NSTEMI on chronic clopidogrel therapy for more than 10 days. The primary end point of 30-day incidence of death, MI, and TVR occurred in 4.1\% of patients in the reload arm versus 14.1\% of patients in the placebo arm (OR, 0.26 [95\% CI, 0.10-0.73]; \( P = .013 \)). The benefit in the reload arm
was driven mainly by reduction of periprocedural MI in the reload arm. There was no difference in bleeding outcomes between the 2 groups.\textsuperscript{16} Taken together, the ARMYDA-4 and ARMYDA-8 studies indicate that patients presenting with ACS while on chronic clopidogrel therapy would benefit from reloading using a 600-mg dose of clopidogrel.

Genetic variability in the metabolism of clopidogrel leads to variability in the antiplatelet effect as measured by in vitro testing and in the clinical effectiveness of clopidogrel after PCI with stenting. The GRAVITAS trial measured the degree of routine platelet inhibition in 2214 subjects and randomized half of the patients to receive high-dose clopidogrel (150 mg/d). Although the higher dose of clopidogrel did not improve outcomes, individuals with better responsiveness as measured by VerifyNow P2Y\textsubscript{12} platelet functional testing (Accriva Diagnostics, San Diego, CA) had the lowest risk of adverse events. An on-treatment VerifyNow measurement (12-24 hours after PCI) of less than 208 P2Y\textsubscript{12} reaction units was associated with a 60-day HR of 0.28 for cardiovascular death, MI, and stent thrombosis.

Similarly, Thrombolysis in Myocardial Infarction (TIMI)-38 showed that clopidogrel was associated with less severe bleeding but more evidence of post-PCI ischemic events (cardiovascular death, nonfatal MI, nonfatal stroke), including a 50\% increase in stent thrombosis, compared to prasugrel. Both of those observations are consistent with variations of genes that result in reduced conversion of clopidogrel to the active metabolite. All evidence for safety and efficacy of clopidogrel must be interpreted in the context of the individual variation in clopidogrel responsiveness.

**Prasugrel (Effient)**

**Pharmacokinetics of Prasugrel**

Prasugrel, the third thienopyridine to become available after ticlopidine and clopidogrel, is a more rapid, potent, and consistent antiplatelet agent. Prasugrel is a prodrug that is absorbed in the intestine and rapidly hydrolyzed by esterases to a thiolactone metabolite, which is then oxidized in a single cytochrome P450 (CYP)-dependent step to the active metabolite. CYP3A4/5 and CYP2B6 play a major role in this conversion, whereas CYP2C19 and CYP2C9 are less important; clinically, there is universal responsiveness to
the drug. As with clopidogrel, the active metabolite irreversibly binds to the platelet P2Y$_{12}$ receptor, thus inhibiting ADP-activated platelet activation and aggregation for the life of the platelet.

The active metabolite of prasugrel reaches peak plasma levels within 30 minutes. A dose-proportionate concentration is noted between doses of 5 and 60 mg. Prasugrel does not interact to any clinically significant extent with other drugs, including those also metabolized by the hepatic CYP isoenzymes CYP3A4, CYP2C9, CYP2C19, and CYP2B6, which are responsible for prasugrel metabolism. Therefore, prasugrel has a pharmacokinetic and pharmacodynamic profile that compares favorably with those of existing antiplatelet agents.

**Dosing of Prasugrel in PCI**

Prasugrel is more potent than clopidogrel on several fronts. In a randomized, double-blind, crossover study in patients undergoing cardiac catheterization with planned PCI, loading with 60 mg of prasugrel resulted in greater platelet inhibition than a 600-mg clopidogrel loading dose. Maintenance therapy with prasugrel 10 mg/d resulted in a greater antiplatelet effect than 150 mg/d of clopidogrel.$^{17}$ Antiplatelet effects of prasugrel have not been found to change with moderate liver disease, end-stage renal disease, diabetes, or smoking. However, in a population pharmacokinetic analysis of the Trial to Assess Improvement in Therapeutic Outcomes by Optimizing Platelet Inhibition With Prasugrel–Thrombolysis in Myocardial Infarction 38 (TRITON-TIMI 38), patients older than 75 years had 19% higher exposure to the active metabolite of prasugrel compared with patients less than 75 years old and 25% higher exposure compared with patients less than 60 years old. In addition, patients <60 kg had 30% higher exposure than patients ≥60 kg and 42% higher exposure than patients ≥85 kg.$^{18}$

The pivotal trial of the safety and efficacy of prasugrel was TRITON-TIMI 38, published in 2007.$^{19}$ In this trial, 13,608 patients with moderate- to high-risk ACS (including unstable angina, NSTEMI, and STEMI) with planned PCI and who were naïve to thienopyridine therapy were randomized to receive either a 300-mg loading dose of clopidogrel followed by 75 mg daily or a 60-mg loading dose of prasugrel followed by 10 mg daily. Patients with unstable angina/NSTEMI or STEMI treated initially with medical
therapy were randomized and treated only after the coronary anatomy was known to be suitable for PCI; patients with STEMI and planned primary PCI were randomized and treated on first contact. The primary efficacy end point was death from cardiovascular causes, nonfatal MI, or nonfatal stroke. The key safety end point was major bleeding, and patients at high risk for bleeding were excluded. Over a median duration of therapy of 14.5 months, the primary composite end point occurred in 12.1% of the patients receiving clopidogrel and 9.9% of patients receiving prasugrel (\(P < .001\)). The primary efficacy end point was driven by a 24% reduction in MI (including both fatal and nonfatal MI). There was no significant difference between the 2 treatment groups in the rate of stroke or death from cardiovascular causes not preceded by recurrent MI. The beneficial effect of prasugrel was seen across the board in patients presenting with STEMI (HR, 0.79 [95% CI, 0.65-0.97]; \(P = .02\)) and non–ST-segment elevation ACSs (HR, 0.82 [95% CI, 0.73-0.93]; \(P = .002\)). An important finding from TRITON–TIMI 38 was a significant reduction in stent thrombosis among patients receiving prasugrel. Overall, for the duration of the trial, Academic Research Consortium (ARC)-defined definite or probable stent thrombosis was reduced by 52% (1.1% vs 2.4%; HR, 0.48 [95% CI, 0.36-0.64]; \(P < .001\)), and definite (angiographic or autopsy proven) stent thrombosis was reduced by 58% (0.9% vs 2.0%; HR, 0.42 [95% CI, 0.31-0.59]; \(P < .001\)) in patients in the prasugrel arm. These findings were similar among patients receiving bare metal stents or drug-eluting stents. The reduction in stent thrombosis was also noted before and after 30 days of PCI (\(P < .0001\) and \(P = .03\), respectively).

Conversely, the increased potency of prasugrel resulted in higher rates of bleeding. The main safety end point of non–CABG-related TIMI major bleeding was observed more frequently with prasugrel than clopidogrel (2.4% vs 1.8%; HR, 1.32 [95% CI, 1.03-1.68]; \(P = .03\)); there was also an increase in non–CABG-related TIMI major or minor bleeding (5.0% vs 3.8%; HR, 1.31 [95% CI, 1.11-1.56]; \(P = .002\)) and bleeding requiring transfusion (4.0% vs 3.0%; HR, 1.34 [95% CI, 1.11-1.63]; \(P < .001\)).

Regarding non–CABG-related bleeding, the increased rate was driven predominantly by an increase in spontaneous bleeding (1.6% vs 1.1%; HR, 1.51 [95% CI, 1.09-2.08]; \(P = .01\)), commonly gastrointestinal bleeding, with no difference in intracranial bleeding. The rate of major bleeding was not significantly different between the 2 groups within the first 30 days. However, after 30 days, a significant increase in TIMI major bleeding was
observed (1.42% vs 0.97%; HR, 1.48 [95% CI, 1.04-2.09]; \( P = .03 \)). Still, the prespecified net end point of all-cause death, MI, stroke, and non-CABG TIMI major bleeding was evaluated and significantly favored the prasugrel group over the clopidogrel group (12.2% vs 13.9%; HR, 0.87 [95% CI, 0.79-0.95]; \( P = .004 \)).

Prespecified landmark analyses for efficacy were performed from randomization to day 3 and from day 3 to the end of the trial to examine individually the effects of the loading dose and the maintenance dose in patients enrolled in TRITON-TIMI 38. Significant reductions in ischemic events, including MI, stent thrombosis, and urgent TVR, were observed with the use of prasugrel, both during the first 3 days and from 3 days to the end of the trial. TIMI major non-CABG bleeding was similar to that of clopidogrel during the first 3 days but was significantly greater with the use of prasugrel from 3 days to the end of the study. Net clinical benefit significantly favored prasugrel both early and late in this trial. One criticism of TRITON-TIMI 38 was the choice of a 300-mg loading dose of clopidogrel, rather than the more effective dose of 600 mg.

A post hoc analysis of TRITON-TIMI 38 identified 3 patient groups who did not experience a net benefit from prasugrel: patients \( \geq 75 \) years old, patients weighing <60 kg, and patients with a prior history of stroke or TIA. Any 1 of these 3 factors was associated with increased bleeding, and in patients with prior stroke or TIA, there was no benefit compared to clopidogrel, but a strong trend toward increased major bleeding, including intracranial bleeding. Importantly, these findings led to prasugrel labeling instructions in the United States to indicate that the drug should not be used in these specific subgroups.

**Ticagrelor (Brilinta)**

Ticagrelor is a potent P2Y\(_{12}\) receptor antagonist that is not a thienopyridine. This drug belongs to the cyclopentyltriazolopyrimidine class. In contrast to thienopyridine agents, ticagrelor reversibly binds to the P2Y\(_{12}\) receptor and does not require metabolic activation.

**Pharmacokinetics of Ticagrelor**
Although the parent compound does not require activation for platelet inhibition, ticagrelor is metabolized primarily by the CYP3A isoenzyme into an active metabolite (AR-C124910XX). This metabolite exerts similar potency in inhibiting the P2Y\textsubscript{12} receptor and is present at about 40% of the parent concentration.

Ticagrelor is rapidly absorbed, with maximum levels achieved in 90 to 120 minutes. However, significant platelet inhibition is noted within 30 minutes of administration of a loading dose of 180 mg of ticagrelor.

Compared with clopidogrel, ticagrelor achieved 1.6 times greater platelet inhibition 1 to 2 hours after a 180-mg loading dose than that seen 8 hours after administration of a 600-mg clopidogrel loading dose. Platelet inhibition by ticagrelor continued to be significantly higher than clopidogrel at the end of 6 weeks of treatment ($P < .0001$).\textsuperscript{22} The degree of platelet inhibition is similar at 24 hours after discontinuation of clopidogrel and ticagrelor, and the antiplatelet effect seen on day 3 after the last dose of ticagrelor was similar to that seen on day 5 after clopidogrel (Fig. 16-1).\textsuperscript{22} Although there may be benefit to the rapid offset (as in patients in need of coronary artery bypass surgery), ticagrelor would be a less attractive choice in patients with poor compliance, because discontinued treatment would result in a reduction of platelet inhibition within a shorter time period, potentially increasing risk of cardiovascular events and stent thrombosis.

Excretion of ticagrelor and its active metabolite occurs through the hepatobiliary system. Severe hepatic impairment is a contraindication to use of ticagrelor, with no restriction in mild liver disease. CYP3A inhibitors, including diltiazem and ketoconazole, increase the plasma concentration of ticagrelor. Ticagrelor increases the levels of simvastatin, as it is a CYP3A substrate. Therefore caution should be used in patients on high doses of simvastatin. Similar to prasugrel, there is no alteration in efficacy of ticagrelor with any specific CYP2C19 genotype.

**Dosing of Ticagrelor in PCI**
The Dose Confirmation Study Assessing Antiplatelet Effects of AZD6140 Versus Clopidogrel in Non–ST-Segment Elevation Myocardial Infarction-2 (DISPERSE-2) trial was performed to compare the safety and initial efficacy of ticagrelor versus clopidogrel in patients with non–ST-segment elevation ACSs. Nine hundred ninety patients who were treated with standard therapy for ACS, including aspirin, were randomized in a double-blind fashion to receive ticagrelor 90 mg twice daily, ticagrelor 180 mg twice daily, or clopidogrel 300-mg loading dose plus 75 mg once daily for up to 12 weeks. Patients randomized to receive ticagrelor were also subrandomized to either a 180- or 270-mg loading dose of ticagrelor. There was no difference in the primary outcome of major and minor bleeding at 4 weeks between the ticagrelor groups and the clopidogrel group ($P = .43$ and $P = .96$, respectively). The use of a loading dose of ticagrelor did not significantly affect bleeding rates. There was no difference in any of the secondary clinical end points (all-cause death, cardiovascular death, MI, stroke, or recurrent ischemia) between the ticagrelor 90 mg and clopidogrel groups. However, there was a dose-dependent increase in the rate of reported dyspnea and asymptomatic ventricular pauses with ticagrelor.$^{24}$

The Study of Platelet Inhibition and Patient Outcomes (PLATO) was the pivotal trial evaluating the efficacy and safety of ticagrelor.$^{25}$ This multicenter, double-blind, randomized trial enrolled 18,624 patients from 43 countries with ACS with or without ST-segment elevation, who were randomized to receive either ticagrelor as a 180-mg loading dose followed by 90 mg twice daily or clopidogrel as a 300- to 600-mg loading dose followed by 75 mg daily thereafter. In contrast to TRITON-TIMI 38, which excluded patients receiving thienopyridines within 5 days and delayed study drug administration until coronary angiography was performed, the PLATO investigators administered the study drugs as early as possible within 24 hours of chest pain and included patients already treated with clopidogrel. The primary efficacy end point was a composite of death from cardiovascular causes, MI, or stroke. The major safety end point was major bleeding, which was a more inclusive than TIMI-defined major bleeding used in TRITON-TIMI 38.$^{19}$ In PLATO, major bleeding was defined as a decrease of 3.0 g/dL in the hemoglobin, transfusion of 2 units of packed red blood cells, or bleeding that led to a significant clinical disability.

The results of the study demonstrated a significant reduction in the primary composite end point in patients treated with ticagrelor compared to
clopidogrel (9.8% vs. 11.7%; HR, 0.84 [95% CI, 0.77-0.92]; \( P < .001 \)). This benefit was replicated in the 13,408 patients treated with a planned invasive strategy.

Despite the higher potency and efficacy of ticagrelor as an antiplatelet agent, no significant difference in the rates of major bleeding, as defined by the trial, was found between the ticagrelor and clopidogrel groups (11.6% vs 11.2%, respectively; \( P = .43 \)). The rate of fatal intracerebral hemorrhage was significantly greater with ticagrelor therapy, but this was offset by a higher rate of nonintracranial fatal bleeding with clopidogrel, resulting in an overall similar rate of fatal bleeding with the 2 therapies. Although there was no difference in CABG-related bleeding, non–CABG-related TIMI major bleeding was significantly more frequent with ticagrelor (HR, 1.25 [95% CI, 1.03-1.53]; \( P = .03 \)).

As noted in DISPERSE-2, dyspnea occurred more frequently in the ticagrelor group than the clopidogrel group, and Holter monitoring revealed a higher incidence of ventricular pauses in the first week in the PLATO study. The proposed mechanism of both dyspnea and ventricular pauses is ticagrelor’s interference with the normal clearance of adenosine. The ventricular pauses were rarely symptomatic, with no increased requirement of pacemaker implantation. The levels of creatinine and uric acid increased slightly more during the treatment period with ticagrelor than with clopidogrel. The exact pharmacologic mechanisms leading to these effects are unclear at the present time.

A main criticism of the PLATO trial was the lack of reduction in the primary end point seen among 1814 patients enrolled in the United States and Canada.\(^{26}\) Although no clear explanation is available, a maintenance dose of 300 mg of aspirin was used in these sites, and aspirin dose has been a referenced explanation for the regional differences. Therefore, the US Food and Drug Administration (FDA) issued a warming directing the use of less than 100 mg of aspirin as a maintenance dose when used concurrently with ticagrelor.\(^{27}\) Table 16-1 shows a comparison of oral antiplatelet agents.

| Table 16-1 Comparison of Oral Antiplatelet Agents |
Cangrelor

Pharmacokinetics of Cangrelor

Cangrelor is an adenosine triphosphate analog that, when given intravenously, is a direct-acting platelet P2Y12 inhibitor that is rapidly reversible. The antiplatelet effect of a bolus dose of cangrelor is rapid, with >95% platelet inhibition within 15 minutes of administration. The plasma half-life is approximately 3 to 5 minutes, and antiplatelet effects are maintained by a continuous infusion. Normalization of platelet aggregation occurs 60 minutes after discontinuation of the infusion.

The clinical efficacy of cangrelor was evaluated in the Cangrelor Versus Standard Therapy to Achieve Optimal Management of Platelet Inhibition (CHAMPION)-PCI28 and CHAMPION-PLATFORM29 trials, which were phase III, randomized, clinical trials comparing cangrelor with clopidogrel administered before and after PCI, respectively. Both trials were stopped prematurely by the Data and Safety Monitoring Committee after an interim review showed that neither study would show a benefit, although the trials had enrolled 93.6% and 83.8% of planned patients, respectively. The results of these parallel studies were simultaneously published in The New England Journal of Medicine in 2009.

Abbreviations: COX, cyclo-oxygenase; NSAID, nonsteroidal anti-inflammatory drug; PCI, percutaneous coronary intervention.
The CHAMPION-PCI\textsuperscript{28} study randomized 8877 patients to receive either cangrelor 30 minutes before and for 2 hours after PCI in a loading dose of 30 μg/kg body weight followed by a 4 μg/kg/min infusion, or an oral loading dose of 600 mg of clopidogrel administered 30 minutes before PCI. Cangrelor was not superior to 600 mg of clopidogrel with respect to the primary composite end point of death from any cause, MI, or ischemia-driven revascularization at 48 hours (OR, 1.05 [95% CI, 0.88-1.24]; \( P = .59 \)) or 30 days.

The CHAMPION-PLATFORM\textsuperscript{29} trial included 5362 stented patients randomized to receive either placebo or cangrelor during PCI, followed by 600 mg of clopidogrel at the end of the procedure. Results of the trial showed that the primary end point occurred in 185 (7%) of 2654 patients receiving cangrelor versus 210 (8%) of 2641 patients receiving placebo (OR, 0.87 [95% CI, 0.71-1.07]; \( P = .17 \)). Two prespecified secondary end points that were significantly reduced at 48 hours in the cangrelor group were the rate of stent thrombosis (from 0.6% to 0.2%; \( P = .02 \)) and the mortality rate from any cause (from 0.7% to 0.2%; \( P = .02 \)).

Because the initial CHAMPION trials evaluating cangrelor did not show an increased efficacy in comparison to clopidogrel, the CHAMPION-PHOENIX trial\textsuperscript{30} was designed as a double-blind, placebo-controlled trial in which the primary efficacy end point was a composite of death, MI, ischemia-driven revascularization, or stent thrombosis at 48 hours after randomization and the primary safety end point was severe bleeding at 48 hours. In contrast to the prior trials, stent thrombosis was included in the primary end point, and the definition of periprocedural MI was modified.

A total of 11,145 patients who were undergoing either urgent or elective PCI were randomized after diagnostic angiography to receive either a bolus and infusion of cangrelor or a 300- or 600-mg loading dose of clopidogrel, with the dose decided at the discretion of the provider. Cangrelor infusion was continued for at least 2 hours or the duration of the procedure. At the completion, patients who received cangrelor received 600 mg of clopidogrel.

A significant efficacy benefit was seen with the use of cangrelor in this study, with the primary efficacy end point reached in 4.7% of patients in the cangrelor group, compared to 5.9% of patients in the clopidogrel group (adjusted OR with cangrelor, 0.78 [95% CI, 0.66-0.93]; \( P = .005 \)). The rate of the primary safety end point was similar between cangrelor and clopidogrel.
However, the FDA rejected the approval of cangrelor in February of 2014, citing 2 previous negative studies and trial design difficulties of CHAMPION-PHOENIX.

In summary, although there are an increasing number of P2Y_12 inhibitors available, clopidogrel remains the most widely used. Clinical trials of dual antiplatelet therapy (DAPT) continue to focus primarily on clopidogrel, perhaps related to considerations of cost and safety profile, as well as once-a-day dosing. In clinical situations where rapidity of onset is of primary importance (such as primary PCI), prasugrel or ticagrelor may be more appropriate.

**PROTEASE-ACTIVATED RECEPTOR-1: VORAPAXAR**

Local generation of thrombin at the site of arterial injury serves to convert soluble fibrinogen into insoluble fibrin, contributing to the formation of clot. However, thrombin also acts on a variety of other targets, including the protease-activated receptor-1 (PAR-1) on platelets. In 2014, the FDA approved a selective PAR-1 antagonist, vorapaxar, as the first antiplatelet agent in this class for use in patients with coronary artery disease (CAD).

Two large phase III randomized clinical trials examined the efficacy and safety of vorapaxar—the TRACER study in patients with ACS, and TRA 2P TIMI-50 for secondary prevention in patients with stable CAD. TRACER examined whether the addition of vorapaxar to standard therapy (aspirin and clopidogrel) could reduce ischemic events in patients with non–ST-segment elevation ACS, compared with placebo, in 12,944 patients. In this study, 57.4% of patients receiving placebo and 58.1% of patients receiving vorapaxar underwent PCI. Follow-up in the study was terminated early due to an excess of bleeding events, including a significant increase in intracranial hemorrhage (0.2% with placebo vs 1.1% with vorapaxar; \( P < .001 \)), without a benefit in the primary end point. In patients undergoing PCI, there was no difference in definite/probable stent thrombosis during the follow-up period.

In patients with stable CAD, the TRA 2P TIMI-50 trial did demonstrate a reduction in the primary composite end point of cardiovascular death, MI, or
stroke at 3 years. However, came at a cost of increased Global Use of Strategies to Open Occluded Coronary Arteries (GUSTO) moderate or severe bleeding; the increase in intracranial hemorrhage in this study did not reach significance.

Although these studies raise interesting questions, for now, there appears to be no role for this medication in patients undergoing PCI.

GLYCOPROTEIN IIB/IIIA INHIBITORS

The platelet integrin receptor αIIbβ₃ (glycoprotein [GP] IIb/IIIa) plays a critical role in coagulation by mediating interactions between platelets and several other ligands, primarily fibrinogen. This receptor consists of 2 separate subunits, αIIb (GP IIb) and α₃ (GP IIIa). Following platelet activation, the IIb/IIIa receptor undergoes conformational changes, and several binding sites for fibrinogen and other ligands are exposed. In competing with fibrinogen and von Willebrand factor for GP IIb/IIIa binding, GP IIb/IIIa inhibitors (GPIs) interfere with platelet cross-linking and platelet-derived thrombus formation. Because fibrinogen binding to the activated receptor GP IIb/IIIa constitutes the final common pathway of platelet aggregation, GPIs are very effective platelet inhibitors, independent of the type of platelet agonist.

Three intravenous GP IIb/IIIa antagonists are approved for use at the current time: abciximab, eptifibatide, and tirofiban. Abciximab (ReoPro) is a large monoclonal antibody with a high binding affinity that results in a prolonged antiplatelet effect. The drug is a Fab (fragment antigen binding) fragment of a monoclonal antibody that targets the GP IIb/IIIa receptor on the platelet membrane. In contrast to the small molecular GPIs eptifibatide and tirofiban, abciximab is a noncompetitive inhibitor. Following a bolus administration, the plasma concentration of abciximab decreases rapidly with an initial half-life of less than 10 minutes and a second-phase half-life of approximately 30 minutes. However, due to the increased affinity to the GP IIb/IIIa receptor, the biologic half-life remains between 12 and 24 hours. Abciximab remains detectable in the circulation for almost 15 days. The recommended loading dose of abciximab is 0.25 mg/kg followed by an infusion of 0.125 mcg/kg/min for 12 hours with no renal dose adjustment.

Eptifibatide (Integrilin), a cyclic heptapeptide GPI, is a small-molecule
antagonist with rapid onset of action and short half-life of 2 to 2.5 hours. It reversibly inhibits platelet aggregation by preventing the binding of fibrinogen, von Willebrand factor, and other adhesive ligands to GP IIb/IIIa. Platelet aggregation inhibition is reversible following completion of the eptifibatide infusion, likely from dissociation of eptifibatide from the platelet. Recovery of platelet function occurs within 4 hours of cessation of eptifibatide.

Administration of a single 180 mcg/kg bolus combined with an infusion at 2 mcg/kg/min produces an early peak level, followed by a small decline prior to attaining steady state within 6 hours. Dose confirmation studies show that this decline is prevented, and the steady state reached faster, with a second bolus of 180 mcg/kg administered 10 minutes after the first. In patients with moderate to severe renal insufficiency (creatinine clearance <50 mL/min), the clearance of eptifibatide is reduced by approximately 50%. Hence, the recommended maintenance dose in these patients is 1 mcg/kg/min, whereas the bolus doses are unchanged.

Tirofiban (Aggrastat) is a tyrosine-derived, nonpeptide inhibitor and is a highly specific, competitive agonist for the GP IIb/IIIa receptor. It is associated with a rapid onset and a short duration of action, with a half-life of approximately 2 hours. Platelet recovery with tirofiban occurs in 4 to 8 hours of completion of infusion. Tirofiban is not approved in the United States for use during PCI but is widely used in other parts of the world. Considering that prior suboptimal results with tirofiban use in PCI were likely due to low doses (bolus of 10 mcg/kg followed by infusion of 0.15 mcg/kg/min for 18-24 hours), a high bolus dose (25 mcg/kg) is currently under study in the SAVI-PCI study. Because 75% of tirofiban clearance is renal, dose adjustment is required in renal failure.

The benefits of adding GPIs to heparin in PCI have been widely studied. However, GPIs were developed and brought to clinical use before stents were widely available. Hence, studies evaluating the efficacy of GPIs could be divided into “predominantly angioplasty studies” and “mostly stent-related studies,” with the latter being more applicable to current practice.

**Angioplasty Studies**

The first studies of GPIs were the EPIC and EPILOG studies, where addition of abciximab to heparin led to a 35% to 50% reduction in major
adverse cardiovascular events at 30 days, predominantly driven by a reduction in periprocedural MI. However, this benefit was at the cost of increased bleeding, with TIMI major bleeding being 50% higher in the GPI arm in the EPIC study. In EPILOG, bleeding was mitigated through a weight-based reduced-dose heparin strategy. Similar benefits were seen in studies examining tirofiban\(^{35}\) (18.5% vs 22.3%; \(P = .03\)) and epitifibatide\(^{36}\) (14.2% vs 15.7%; \(P = .04\)), with a significant reduction in death and nonfatal MI occurring up to 30 days after the index event. However, the issue of increased bleeding was also seen with these agents.\(^{35,36}\)

**Use of GPIs in Contemporary Practice**

**GPI Use in PCI With Stents Without Thienopyridine Preloading**

Early trials of GPIs enrolled patients not pretreated with a thienopyridine. The ESPIRIT (Enhanced Suppression of the Platelet IIb/IIIa Receptor With Integrilin)\(^{37}\) and EPISTENT (Effect of Abciximab on Angiographic Complications During Percutaneous Coronary Stenting in the Evaluation of Platelet IIb/IIIa Inhibition in Stenting Trial)\(^{38}\) trials each randomized over 2000 patients to eptifibatide versus placebo or abciximab versus placebo, respectively. Results of the ESPIRIT study demonstrated a 37% relative risk reduction (from 10.5% to 6.6%; \(P = .0015\)) in the primary composite end point of death, MI, and need for urgent TVR. There was a small but significant increase in bleeding from 0.4% to 1.3% with eptifibatide (\(P = .027\)). In EPISTENT, there was a 51% relative risk reduction of the composite primary end point of death, MI, and need for urgent revascularization in the first 30 days with abciximab in addition to heparin. Major bleeding was higher with abciximab but did not reach statistical significance. This beneficial effect persisted at 6 and 12 months.\(^{39}\)

Together, the ESPIRIT and EPISTENT trials indicate that in patients undergoing PCI without prior thienopyridine loading, GPIs reduce ischemic complications at a possible cost of increased rate of bleeding.

**GPI Use in Patients With Clopidogrel Preloading and**
Coronary Stenting

More contemporary studies performed with routine stenting and P2Y$_{12}$ therapy have been valuable in identifying the specific group of patients that would benefit from GPIs in current practice. The ISAR-REACT$^{40}$ (Intracoronary Stenting and Antithrombotic Regimen: Rapid Early Action for Coronary Treatment) trial studied 2159 low-risk patients preloaded with 600 mg of clopidogrel at least 2 hours prior to PCI; in this low-risk elective population, the addition of abciximab to heparin did not reduce ischemic complications. At 30 days, the incidence of death, MI, and urgent TVR did not differ between the groups (4.0% vs 4.0%; $P = .82$). There was no difference in bleeding in the treatment groups. Similar results were obtained in diabetic patients undergoing elective angioplasty, when compared to routine pretreatment with clopidogrel.$^{41}$

In contrast to the initial studies evaluating low-risk patients, an analysis of the CAPTURE, PURSUIT, and PRISM-PLUS data indicated a more important role for GPIs in patients with ACS. This was confirmed in the ISAR-REACT-2 study, which randomized 2022 high-risk patients with non–ST-segment elevation ACS undergoing PCI to receive either abciximab or placebo with heparin in addition to aspirin and a 600-mg loading dose of clopidogrel administered at least 2 hours prior to the procedure. Among patients with elevated troponin levels, the incidence of the primary end point of the study, which was the composite of death, MI, or urgent TVR at 30 days, was significantly reduced in the abciximab group (relative risk, 0.71 [95% CI, 0.54-0.95]; $P = .02$), with no increase in major or minor bleeding between the 2 groups.$^{42}$ The benefit seen in these high-risk patients was maintained at 1 year, with a 20% reduction in death, MI, or TVR and a 25% reduction in death or MI among patients randomized to receive abciximab.$^{43}$ The ISAR-REACT-2 study was critical in establishing the benefit of GPIs for patients receiving routine thienopyridine treatment and coronary stents, particularly in patients with ACS with high-risk features.

GPIs in Primary PCI

The use of a powerful and rapid-acting antiplatelet agent is an appealing choice in patients with STEMI, considering the large thrombus burden and highly activated platelets; additionally, the time dependency of
revascularization means that pretreatment with P2Y$_{12}$ inhibitors may not be possible. Not surprisingly, there is a large body of literature regarding the efficacy and safety of the use of GPIs in primary PCI.

The ADMIRAL trial randomized 300 patients with STEMI to either heparin or heparin plus abciximab and showed a significant reduction in a composite 30-day end point of ischemia-related events (death, reinfarction, or urgent TVR); there were too few major bleeding events to make a comparison. The CADILLAC trial randomized 2018 patients in a 2×2 factorial design to percutaneous transluminal coronary angioplasty, percutaneous transluminal coronary angioplasty plus abciximab, bare metal stent, or bare metal stent plus abciximab. The primary end point (death, reinfarction, stroke, or ischemia-driven TVR) was lowest in the stent/abciximab arm. Abciximab also reduced the rates of subacute thrombosis and urgent, ischemia-driven TVR in the first several weeks after the index procedure. BRAVE-3 randomized 800 patients to abciximab or placebo in STEMI, but detected no difference in the primary end point of infarct size; similarly, a composite secondary end point of death, reinfarction, stroke, or urgent revascularization was not different at 30 days or 1 year.

These 3 studies are a small sample of the published trials, but they highlight the difficulties with the available data, which include relatively small trials (mostly with abciximab), variable use of clopidogrel, and divergent results. Meta-analyses of a larger group of available studies have suggested that although there is no clear benefit to universal application of GPI in STEMI, there may be certain subgroups of high-risk patients who receive a mortality benefit. These studies have also consistently shown a persistent increase in bleeding with GPI use. These aggregate data are the basis of the Class IIa recommendation for GPI use in STEMI in the most recent ACCF/AHA and Society for Cardiovascular Angiography and Interventions PCI practice guidelines.

**GPI and Bivalirudin**

Although heparin and platelet inhibition with GPIs have established efficacy in preventing periprocedural ischemia, excess bleeding events remain a barrier to more routine use. Bivalirudin is a specific inhibitor of thrombin with predictable bioavailability and anticoagulant effects and has been an effective alternative to heparin in PCI since the balloon angioplasty era.
Several important studies have examined bivalirudin in the current PCI era, comparing bivalirudin to the combination of heparin and GPI. Although designed to evaluate bivalirudin, these studies have added significantly to our understanding of the current role of GPI.

The REPLACE-2 trial randomized 6000 patients undergoing elective PCI to bivalirudin and provisional GPI or heparin and planned GPI. In this study, only 7% of patients in the bivalirudin arm received GPI, and there were equivalent 30-day ischemic events in both groups. Importantly, there were significantly fewer bleeding events in the bivalirudin arm.

The ACUITY trial randomized 13,819 patients with intermediate- to high-risk non–ST-segment elevation ACS to 1 of 3 strategies: bivalirudin monotherapy, bivalirudin plus GPI, or heparin plus GPI. In this trial, only 60% of patients received a thienopyridine prior to going to the catheterization lab. The results at 30 days and 1 year showed equivalent ischemic events with bivalirudin monotherapy but significantly lower bleeding when compared to either of the arms using GPIs. ISAR-REACT-4 evaluated abciximab plus unfractionated heparin versus bivalirudin alone in 1721 patients with NSTEMI (all pretreated with clopidogrel) with similar results: no difference in ischemic end points, but increased bleeding with abciximab at 30 days. The comparable outcomes between the 2 arms persisted at 1 year.

HORIZONS-AMI repeated these comparisons in patients with STEMI. In this trial, 3602 patients (all pretreated with either 300 or 600 mg of clopidogrel) were randomized to receive heparin plus GPI or bivalirudin alone. The trial had 2 primary end points: major bleeding and net adverse clinical events (a combination of major bleeding or major adverse cardiovascular events, including death, reinfarction, TVR for ischemia, and stroke within 30 days). There was a significant reduction in the 30-day rate of net adverse clinical events in the bivalirudin group (9.2% vs 12.1%; \( P = .005 \)), mainly due to a lower rate of major bleeding (4.9% vs 8.3%; \( P < .001 \)). Treatment with bivalirudin alone, as compared with heparin plus GPIs, resulted in significantly lower 30-day rates of death from cardiac causes (1.8% vs 2.9%; \( P = .03 \)) and death from all causes (2.1% vs 3.1%; \( P = .047 \)). These benefits were preserved at 1 and 3 years. A 600-mg loading dose of
clopidogrel was an independent predictor of lower rates of ischemic events at 30 days.

The weight of evidence from the bivalirudin studies has resulted in a reduced role for GPIs in even the highest risk PCI. However, there are 2 important caveats to keep in mind before dismissing GPIs from the antiplatelet armamentarium. First, radial artery access was used in a small minority of the patients, which may result in an overstated bleeding reduction benefit of bivalirudin (because a substantial proportion of bleeding events were access site related). Second, in both ACUITY and HORIZONS, there was an increased incidence of early MACE (in the first 10 days) including definite stent thrombosis in the first 24 hours (although stent thrombosis at 30 days was similar). This tendency toward increased early stent thrombosis was also observed in the EUROMAX trial, a more contemporary study that included a majority of patients receiving either prasugrel or ticagrelor (rather than clopidogrel) and almost 48% radial access (2218 randomized to either bivalirudin monotherapy or heparin with GPI).

Finally, the most contemporary trial clinical trial of PCI for STEMI, HEAT-PPCI, summarizes the current state of GPI utilization. Enrolling 1829 patients in 2012 and 2013, the investigators used radial access in 80% of patients and rapidly acting, potent thienopyridines (prasugrel and ticagrelor) in 90% of patients. Under these circumstances with experienced operators in a tertiary center, bailout GPI use was only 13% with bivalirudin and 15% with heparin, resulting in a 30-day MACE rate of 8.7% in the bivalirudin arm and 5.7% in the heparin arm. Although there are many valid criticisms of this trial, it does provide a glimpse of the result of strictly bailout GPI. It would appear that although GPIs have a role in current PCI, they are reserved for a minority of even the most acute cases.

In our practice, we favor radial access for STEMI, with unfractionated heparin as the anticoagulant. In cases where the patient has not had adequate thienopyridine pretreatment (6 hours for clopidogrel or 1 hour for prasugrel/ticagrelor), a bolus and short-duration infusion of a GPI, such as eptifibatide, can ensure platelet inhibition until thienopyridine loading is effective. Eptifibatide is also used in patients with a large thrombus burden, with evidence for distal embolization, or in whom there is less than TIMI grade 3 flow at the conclusion of the intervention. In femoral access cases, we favor bivalirudin; similarly, a bolus with or without a short infusion of eptifibatide is used in patients that have not been pretreated with a
thienopyridine or in whom the results are suboptimal.

**DUAL ANTIPLATELET THERAPY: DURATION OF THERAPY**

Historically, the primary indication for DAPT after PCI is the avoidance of stent thrombosis. In contemporary practice, stent thrombosis rates are low; registry data from 21,009 patients receiving 31,065 stents (63.8% bare metal) between 2004 and 2007 reported a stent thrombosis rate of 2.1% at a median follow-up of 30.9 months. Interestingly, 73% of stent thromboses occurred within the first 30 days, and 88% of these patients were still taking DAPT. Although cessation of antiplatelet therapy (specifically thienopyridine therapy) remains a predictor of early stent thrombosis, clearly there are patient- and procedure-related factors that are also important.

With bare metal stents, the duration of antiplatelet therapy can be brief. In the STARS trial, 4 weeks of aspirin and ticlopidine resulted in a stent thrombosis rate of 0.5%, presumably related to adequate stent endothelialization. A low rate of subsequent stent thrombosis persists for bare metal stents, even at 3 years. The STARS data remain the basis for current guideline recommendations regarding bare metal stents.

In drug-eluting stents, the information regarding duration of antiplatelet therapy continues to evolve rapidly. In the initial SIRIUS trial evaluating the sirolimus-eluting Cypher stent (Cordis, Fremont, CA), aspirin and clopidogrel were administered for a total of 8 weeks based on animal model estimates of time to full reendothelialization. In this study of 238 patients (120 received the drug-eluting stent), there were no reported stent thrombosis events at the 6-month primary end point. By the time of FDA approval, labeling recommendations for the duration of DAPT were 3 months for the Cypher and 6 months for the Taxus stents (Boston Scientific, Marlborough, MA). Despite these prolonged treatment times, early signals appeared of higher than expected late stent thrombosis events, with associated high morbidity and mortality. Within the first year of their approval, the FDA issued a public health notification to remind physicians that off-label use of drug-eluting stents and early discontinuation of antiplatelet therapy may contribute to increased stent thrombosis rates. Within 3 years, continued
reports of stent thrombosis, as well as studies indicating that longer duration of antiplatelet therapy might reduce stent thrombosis rates, prompted the FDA to convene an advisory panel to review the data. The conclusions of this panel in early 2007 included a recommendation to extend the duration of antiplatelet therapy to 12 months for all drug-eluting stents. Although this recommendation was endorsed in the ACC/AHA practice guidelines, it was made in the absence of any supporting randomized data.

Since 2007, 3 factors have substantially altered our understanding of the need for prolonged DAPT: (1) evolution of stent design, including drug and polymer; (2) the availability of clinical tests of platelet function to assess the effects of antiplatelet medication in an individual patient; and (3) an increased appreciation that avoidance of bleeding is equal to ischemia/stent thrombosis as a measure of clinical success and long-term mortality.

Since the sirolimus-eluting and paclitaxel-eluting “first-generation” stents, stent design has changed with respect to the stent metal composition, polymer composition, and drug. A full discussion of the details of these changes is beyond the scope of this chapter, but almost all the changes have been associated with a steady reduction in stent thrombosis rates. Recent meta-analyses have indicated that second-generation drug-eluting stents are superior to first-generation DESs with regard to definite or definite/probable ARC-defined stent thrombosis, including both early and late stent thrombosis events. Thin strut stent platforms have been associated with extremely low stent thrombosis rates. In the HOST-ASSURE trial, cobalt chromium zotarolimus-eluting stents had a 1-year definite/probable stent thrombosis rate of 0.67%, and platinum chromium everolimus-eluting stents had a stent thrombosis rate of 0.36%. Further reduction in stent thrombosis rates may be possible with biodegradable polymers and/or biodegradable struts, and this is being examined in ongoing clinical trials of the newest stent designs. Interestingly, stent thrombosis events in these studies are so low that detecting differences has become exceedingly difficult. One-year follow-up of the Nobori bioabsorbable stent (Terumo, Elkton, MD) versus the everolimus-eluting stent showed noninferiority in the primary end point in almost 3000 patients, but the stent thrombosis rate was less than 1% at 1 year. Finally, continued evolution of PCI techniques and adjunctive drug therapy may also make clinical differences in stent design difficult to detect; in the recently published PROTECT study, there was no difference between a first-generation stent (sirolimus) and a second-generation stent (everolimus)
at 3 years, although there were more very late stent thrombosis events in sirolimus-eluting stents (after discontinuation of antiplatelet therapy). This study is notable for the fact that it is the only stent study to use stent thrombosis as the primary end point and that both of these stents are no longer commercially available.

As noted previously, available P2Y\textsubscript{12} inhibitors have variable metabolism and efficacy in platelet inhibition, which are largely mediated through genetic differences in metabolic enzymes. Wholesale change to those agents with more reliable platelet inhibition has been limited primarily by cost, as well as concerns for increased neurologic and bleeding complications. Both genetic differences and degree of platelet inhibition can now be detected by rapid clinical tests in individual patients. Although there was great initial enthusiasm for routine use of platelet functional testing and/or genetic testing to identify individuals with inadequate platelet inhibition, clinical trials have failed to show differences in patient outcomes with routine testing. This is best illustrated in the ADAPT-DES study,\textsuperscript{9} a registry of over 8500 patients undergoing PCI. Routine platelet functional testing after PCI and treatment with clopidogrel confirmed that inadequate platelet inhibition is strongly associated with stent thrombosis; however, adequate platelet inhibition was also strongly associated with bleeding episodes. Because both stent thrombosis and bleeding impact mortality, neither adequate nor inadequate platelet inhibition was associated with improved overall long-term outcome. Interestingly, aspirin responsiveness was only associated with bleeding; better aspirin effect was not correlated with less stent thrombosis. The important implication of platelet functional studies in terms of length of treatment is that better inhibition of platelets is associated with bleeding over time, and duration of treatment needs to balance these dual goals of avoidance of stent thrombosis and bleeding events.

Bleeding episodes at the time of PCI are powerful predictors of long-term mortality, even when the initial bleeding event is not catastrophic. Strategies for bleeding avoidance at the time of the procedure, such as use of bivalirudin or radial access, may be associated with improved long-term survival. Similarly, late bleeding episodes are also associated with increased mortality, and late bleeding is related to DAPT. The PRODIGY trial enrolled 2013 patients to be randomized to 6 or 24 months of DAPT and found no difference in ischemic outcomes (including ARC-defined stent thrombosis) but a significant increase in bleeding events, including life-threatening
bleeding, in the 24-month DAPT group.

Two large randomized studies will soon bring new data into the duration of therapy debate. The ISAR-SAFE trial is enrolling up to 6000 patients to be randomized between 6 and 12 months of clopidogrel and aspirin, with a primary composite end point (death, MI, stent thrombosis, stroke, and TIMI major bleeding) to be assessed at 15 months after the index procedure. The recently reported DAPT trial randomized 9961 patients who received either DESs or bare metal stents to 12 or 30 months of DAPT. The coprimary efficacy end points were the cumulative incidence of definite/probable stent thrombosis and a composite of death, MI, and stroke in months 12 to 30 (randomization period). The primary safety end point was GUSTO-defined moderate or severe bleeding. Importantly, a specific thienopyridine was not mandated, nor was a specific stent type.

The end points in DAPT strongly favored the longer duration of treatment. First, prolonged antiplatelet therapy was associated with a lower rate of stent thrombosis (0.4% in 24-month group vs 1.4% in 12-month group). Second, the risk of MACE (death, MI, and stroke) was also lower in the prolonged therapy group (4.3% vs 5.9%), driven primarily by a reduction in MI (2.1% vs 4.1%). A reduction in non–stent-related MI accounted for 55% of the treatment effect in this end point. Not unexpectedly, moderate to severe bleeding occurred more often in the prolonged therapy group (2.5% vs 1.6%). Although all-cause mortality was higher with prolonged therapy (2.0% vs 1.5%; HR, 1.36; \( P = .05 \)), deaths related to bleeding (11 deaths in 24-month therapy group and 3 in 12-month therapy group) did not achieve statistical significance (\( P = .06 \)). Finally, the incidence of MI and stent thrombosis increased in the first 3 months after cessation of therapy in both groups, leaving the question of duration of treatment still unanswered. However, a consideration of the DAPT conclusions must keep in mind 2 important details of the study. First, by design only, patients who made it through 12 months of therapy without a major cardiovascular or bleeding event were randomized, which was a minority of those enrolled (9961 of 25,682, or 38.7%), suggesting the final study population was skewed toward a lower risk profile. Second, 38% of randomized patients received first-generation sirolimus-eluting (Cypher) or thin strut paclitaxel-eluting (Taxus Liberte) stents, which may have higher stent thrombosis rates than current-generation everolimus and zotarolimus stents. Still, the finding that prolonged therapy with thienopyridines prevents MI, not just stent thrombosis, is important and must
be part of the discussion about the most appropriate medications for secondary prevention. The DAPT and PEGASUS-TIMI 54 trials are indicative of a growing understanding that the benefits of antiplatelet therapy after PCI extend beyond the increasingly rare issue of stent thrombosis. One of the most exciting ideas to emerge is that of antiplatelet treatment durations of less than 6 months. In 2012, the Xience everolimus-eluting stent (Abbott Vascular, Santa Clara, CA) received approval in Europe for use for only 3 months of DAPT, based on postmarketing registry data from over 10,000 patients. In 2013, the results of OPTIMIZE became available, where 3119 patients were randomized to either 3 months or 12 months of aspirin and clopidogrel after receiving a zotarolimus DES. The primary end point was a net benefit composite of both ischemic and bleeding events, and after 1 year, there was no difference between the 2 DAPT strategies. Similar results were seen in the RESET trial, which used the Endeavor zotarolimus-eluting stent (Medtronic, Edgwater, MD). Although encouraging, this stent is no longer available, having been replaced by the Resolute Integrity zotarolimus stent (Medtronic) with a more prolonged drug elution profile that more closely imitates competing stent elution profiles. The change in rate of drug elution significantly decreased the degree of intimal hyperplasia in the new stent and, as a result, may have altered thrombosis risk. There are currently several proposed or actively enrolling studies that are designed to evaluate 3 versus 6 months of treatment using current generation stent designs.

**Bioabsorbable Polymer and Scaffold**

Concerns regarding the long-term thrombogenicity of the polymer matrix, either through hypersensitivity reactions or other direct mechanisms, has led to the development of bioabsorbable polymer stent. Three studies (LEADERS, ISAR-TEST 3 and ISAR-TEST 4) have compared first-generation DESs to absorbable matrix stents in a total of 4062 patients. At 4 years, the total number of stent thrombosis events was lower in the bioabsorbable platforms, particularly with respect to very late stent thrombosis events (between 1 and 4 years). Although this seems to lend validity to the hypothesis that elimination of polymer will improve vessel healing and long-term safety, these differences may not persist when compared to second-generation DESs. Long-term results of the COMPARE 2 study (Nobori bioabsorbable stent vs everolimus DES) and EVOLVE II
(Boston Scientific Synergy stent vs everolimus-eluting stent) will hopefully give insight into this category of stent but will not specifically address the issue of length of treatment. The largest study of bioabsorbable polymer to date, LEADERS, mandated 12 months of dual therapy.

A number of concepts in totally resorbable stent platforms have reached the level of entering early clinical investigation. The device farthest along this path is the bioreabsorbable vascular everolimus-eluting scaffold; a trial is currently enrolling patients in a comparison of this device against a metal, permanent polymer everolimus-eluting stent. All trials continue to mandate 12 months of DAPT, but the potential exists for this to be tailored after the initial experience is available. To date, stent thrombosis events have been low in an overall low-risk population.

**SPECIAL CIRCUMSTANCES**

**DAPT and Anticoagulation**

In patients prescribed oral anticoagulants, the need for PCI and stent placement often presents the clinician with the obligation to consider continuing oral anticoagulation concomitantly with DAPT (triple therapy). In patients treated with warfarin, the evidence is clear that there is a substantially increased risk of severe bleeding when aspirin and clopidogrel are added after PCI. By 6 months, the relative risk of any bleeding is as high as 3.12 compared to DAPT, whereas the relative risk of major bleeding is 2.87. The recognition of this relationship may lead to relative underuse and/or decreased intensity of anticoagulation, with a resultant increase in both bleeding episodes and number of strokes while on triple therapy. A single, relatively small (573 patients) study has examined the strategy of clopidogrel alone with warfarin after PCI. When compared to triple therapy, clopidogrel was associated with a significantly lower rate of bleeding (12.0% vs 2.2%) and blood transfusion (9.5% vs 3.9%) without an increase in stroke or stent thrombosis. In patients on warfarin undergoing PCI, a clear examination of thrombosis risk with interruption of warfarin needs to be balanced against the need for a DES, and consideration must be given to shortened duration of DAPT.
In patients receiving newer, nonwarfarin oral anticoagulants, the data are scant but do suggest similar increased bleeding events when DAPT is added. Two meta-analyses have suggested a 2- to 3-fold increase in bleeding episodes, similar to warfarin.\textsuperscript{58,59} Importantly, no study has examined the effect of duration of DAPT while on new oral anticoagulants. Finally, there are no data for new oral anticoagulants when combined with P2Y\textsubscript{12} inhibitors other than clopidogrel, but one must assume bleeding rates would be even higher given the more uniform platelet inhibition with these agents and the documented increase in bleeding episodes even in the absence of oral anticoagulants.

**DAPT and Noncardiac Surgery**

As many as 23\% of patients undergoing PCI with stent placement will have noncardiac surgery within 48 months of their stent procedure. Current guidelines (last revised in 2007) recommend delaying surgery until after 12 months of DAPT have been completed or, if necessary, until the year following PCI, continuing DAPT through the perioperative period. These recommendations (Class IIa, Level of Evidence C) are based on the observation of high stent thrombosis rates when surgery is performed early after the stent procedure and the assumption that complete reendothelialization of the stented segment will be associated with the lowest probability of stent thrombosis and cardiac events at the time of surgery.

The largest observational study provides evidence from 28,029 patients who had noncardiac surgery within 24 months of coronary stenting (52.4\% bare metal).\textsuperscript{60} This study did not specifically examine stent thrombosis, but rather repeat revascularization and MI without death, repeat revascularization/MI with death, and death. The overall MACE rate was 4.7\%, but was 5.1\% before the publication of the 2007 guidelines and 3.5\% for operations performed after 2007. Interestingly DESs were slightly less associated with MACE (OR of 0.91 compared to bare metal stent), although obviously, only bare metal stents were available in the earliest part of the study, when event rates were highest. There appeared to be no association between the occurrence of MACE and antiplatelet therapy cessation. Interestingly, clinical variables such as emergency surgery, recent MI, and a high revised cardiac risk index score were among the most powerful predictors of MACE. With regard to stent-specific variables, a shorter period
of time between the stent procedure and surgical procedure was predictive of MACE. These findings are largely similar to other, smaller registries and would suggest a reevaluation of the 2007 guidelines.

CONCLUSION

Antiplatelet therapy in patients undergoing PCI is a therapeutic challenge that is continuously, and rapidly, evolving. Recognition of factors that place patients at greatest risk for ischemic complications, rapid progress in stent design, and availability of new antiplatelet therapies have pushed stent thrombosis rates to all-time lows. Long-respected cornerstones of therapy, such as universal use of aspirin, may be less relevant. Recognition of the short- and long-term consequences of peri-PCI bleeding episodes has raised bleeding avoidance to equal ischemia prevention as dual therapeutic objectives of therapy following stent placement. The rapid refinement of therapy in the first 10 years of DESs gives great hope that our antiplatelet therapy can be tailored, using shortened duration and more rapidly acting, consistently effective medications to further reduce bleeding events and eliminate stent thrombosis.

**MULTIPLE CHOICE QUESTIONS**

1. Ticlopidine was the first P2Y$_{12}$ inhibitor to be used clinically for dual antiplatelet therapy after stent placement. Ticlopidine was quickly replaced by clopidogrel, however, because of which of the following disadvantages or side effects?
   A. Twice-daily dosing
   B. High incidence of gastrointestinal upset
   C. Neutropenia/thrombocytopenia
   D. All of the above

2. The TRITON-TIMI 38 trial compared prasugrel to clopidogrel in patients with acute coronary syndrome (ACS) receiving drug-eluting stents. Which of the following subgroups was identified in a post hoc analysis as patients who did **not** benefit from prasugrel because of an excess of bleeding complications?
   A. Patients over the age of 75
   B. Patients over 80 kg in weight
   C. Patients with a prior transient ischemic attack (TIA)
   D. A and C
   E. B and C
   F. A, B, and C

3. Which of the following antiplatelet medications achieves its therapeutic effect by interfering with the functioning of the P2Y$_{12}$ receptor on
platelets?
A. Vorapaxar
B. Aspirin
C. Ticagrelor
D. Cangrelor
E. Abciximab
F. C and D
G. A, C, and E

4. The results of the HORIZONS-AMI trial compared bivalirudin monotherapy to heparin and glycoprotein IIb/IIIa inhibitors in patients undergoing primary percutaneous coronary intervention (PCI) for ST-segment elevation myocardial infarction (STEMI). The results of this study indicated which of the following?
A. That glycoprotein IIb/IIIa inhibitors maintain a strong advantage in this patient group
B. That drug-eluting stents should not be used in primary PCI
C. That bivalirudin reduced bleeding events compared to heparin and glycoprotein IIb/IIIa inhibitor
D. That femoral access is the best means of arterial access in STEMI
E. C and D

5. Which factor(s) impacts any calculation of the duration of dual antiplatelet therapy after drug-eluting stent placement?
A. Stent design
B. Stent polymer
C. Stent diameter and length
D. Risk of bleeding for a specific patient, including other medications
E. All of the above

ANSWERS

1. D

Ticlopidine 250 mg twice a day (along with aspirin) was the antiplatelet therapy used in the first clinical study to prove that antiplatelet therapy was superior to anticoagulation (ie, warfarin) in patients who received stents.
However, there were a significant proportion (8%-10%) of patients who suffered nausea and diarrhea while taking ticlopidine. More serious bone marrow suppression was less frequent. Clopidogrel was better tolerated, did not cause bone marrow suppression, and was dosed once daily—all significant advantages.

2. D

Patients in the TRITON-TIMI 38 trial benefitted from more reliable protection from ischemic events provided by prasugrel compared to clopidogrel, although at a cost of more frequent serious bleeding events. For the majority of patients in the trial, the net effect was still benefit, even when considering bleeding. Post hoc analysis identified 3 groups in whom the bleeding was equal to ischemia prevention, and so there was no benefit: patients older than 75, patients with body weight less than or equal to 60 kg, and patients with a prior TIA or stroke. These findings led to labeling instructions that indicate that use of this medication should be restricted in patients who meet these criteria.

3. F

Platelets may be activated through a number of surface receptors: the thrombin receptor (PAR-1), adenosine diphosphate (ADP) receptors (including P2Y\(_{12}\)), the thromboxane A\(_2\) (TP) receptor, and collagen receptors. Interference with the receptors and/or receptor agonists of the activation sequence is the primary mechanism of antiplatelet therapy. Vorapaxar is an antagonist of the thrombin receptor; aspirin inhibits formation of thromboxane A\(_2\); and clopidogrel, cangrelor, prasugrel, and ticagrelor are P2Y\(_{12}\) antagonists. Abciximab, eptifibatide, and tirofiban exert their effect by blocking the ability of activated platelets to bind to fibrinogen, thus preventing platelets from adhering to clots and other platelets.

4. C

HORIZONS-AMI randomized patients to 1 of 2 anticoagulation strategies for primary PCI: either the direct thrombin inhibitor bivalirudin or heparin combined with a glycoprotein IIb/IIIa inhibitor. The results of the study indicated that there was a lower overall mortality, a lower cardiac mortality,
and a lower reinfarction rate at 3 years in the bivalirudin arm. These results may have been mediated, at least in part, by a lower rate of major bleeding in patients receiving bivalirudin.

A second randomization within HORIZONS-AMI compared bare metal stents to paclitaxel-eluting stents; in this analysis, the drug-eluting stent was associated with lower rates of target vessel revascularization without any safety concerns.

The vast majority of patients in HORIZONS had their procedure by femoral access; there was no meaningful comparison between access methods in the trial design or in post hoc analysis.

5. E

The duration of antiplatelet therapy is a treatment parameter that is difficult to generalize because there are so many factors that can be important for any individual patient. First-generation drug-eluting stents were initially plagued by late and very late stent thrombosis, which in turn favored a very long duration of antiplatelet therapy. Changes in stent design and polymer composition have made the stents less prone to thrombosis, and duration of antiplatelet therapy has shortened accordingly. In addition to stent factors, procedural factors, including stent size and length or bifurcation stenting, raise the risk for stent thrombosis and may favor longer dual antiplatelet therapy duration. Patient factors, such as the need for anticoagulation or prior major gastrointestinal bleeding, renal disease, or liver disease, raise the bleeding risk and may favor shorter dual antiplatelet therapy duration. In any individual patient, the clinician must balance ischemic risk and bleeding risk when deciding how long to continue antiplatelet therapy after stent placement.
INTRODUCTION

The recognition of the proximate role of coronary thrombosis secondary to plaque rupture or erosion as the underlining cause of ST-segment elevation acute myocardial infarction (AMI) opened the door to the development of pharmacologic and mechanical interventions that have saved countless lives from a disease process that previously had few options and carried a high mortality rate. Thrombolytic agents were the first to provide substantial and sustained improvements in the morbidity and mortality of AMI. Summarized in this chapter are the key trials of thrombolytic agents and adjuncts to fibrinolysis along with recommendations for their application in AMI.

BACKGROUND

The discovery that hemolytic streptococci produce a thrombolytic substance is attributed to a 1933 report by Dr. William Smith Tillett. However, it would be another 50 years before streptokinase was systemically evaluated in the treatment of AMI. Although sporadic use of streptokinase in AMI was reported during that interval, concerns regarding antigenicity, hemodynamic effects, efficacy, dosing, timing, and even method of delivery restricted acceptance. In 1986, the landmark Gruppo Italiano per la Sperimentazione
della Streptochinasi nell’ Infarto Miocardico (GISSI) study was published demonstrating a marked improvement in AMI survival with treatment. The GISSI study evaluated 11,806 patients presenting with an AMI within 12 hours of symptom onset. Patients were randomized to treatment with streptokinase or placebo, with both groups otherwise receiving standard of care. There was a significant reduction in 30-day and 1-year mortality compared with placebo (10.7% vs 13.0% and 17.2% vs 19.0%, respectively). It was observed that the more rapidly a patient received streptokinase from symptom onset, the greater the mortality benefit. The results were confirmed by the Second International Study of Infarct Survival Collaborative Group (ISIS-2) trial (see below), resulting in the acceptance of streptokinase as first-line treatment of AMI.

THROMBOLYTIC AGENTS

With the therapeutic benefits of streptokinase well established, pharmaceutical research and development turned to identifying agents with greater specificity for fibrin and with fewer side effects. There are currently four US Food and Drug Administration (FDA)-approved thrombolytic agents for the use in the United States: streptokinase, alteplase, reteplase, and tenecteplase (Table 17-1). The three fibrin-specific agents are discussed in the following sections.

Table 17-1 Comparison of the Available Thrombolytics
Alteplase (tPA) is a recombinant tissue plasminogen activator. It promotes fibrinolysis by converting plasminogen to plasmin. The efficacy and safety of tPA were evaluated and compared with streptokinase in the Global Utilization of Streptokinase and Tissue Plasminogen Activator for Occluded Coronary Arteries (GUSTO)-I trial published in 1993. The investigators randomized 41,021 patients presenting with an AMI into 1 of 4 treatment regimens: (1) streptokinase 1.5 million units over a 60-minute period, with subcutaneous heparin at 12,500 units twice daily, beginning 4 hours after the start of thrombolytic therapy; (2) streptokinase 1.5 million units over a 60-minute period, with an intravenous heparin bolus dose of 5000 units and infusion of 1000 units per hour adjusted for an activated partial thromboplastin time between 60 and 85 seconds; (3) accelerated tPA in a bolus dose of 15 mg, followed by a 0.75 mg/kg of body weight infusion over 30 minutes (not to exceed 50 mg), followed by 0.5 mg/kg over the subsequent 60 minutes (not to exceed 35 mg), with the same intravenous bolus.
heparin regimen as arm 2; and (4) the combination of intravenous tPA as a 1.0 mg/kg infusion over 60 minutes (not to exceed 90 mg, with 10% given in a bolus dose) and streptokinase (1.0 million units over 60 minutes) given simultaneously but through separate intravenous catheters, along with intravenous heparin. The results demonstrated a statistically significant reduction in mortality at 24 hours and at 30 days with accelerated tPA and intravenous heparin compared with streptokinase (10 lives saved per 1000 patients treated). However, there was an increased risk of hemorrhagic stroke in the accelerated tPA arm compared with streptokinase (2 hemorrhagic strokes per 1000 patients treated). Despite the increased risk of intracranial bleeding, tPA was easier to use, lacked the antigenicity of streptokinase, and had an overall mortality benefit. As a result, tPA rapidly became the preferred agent for the treatment of AMI.

**Reteplase**

Reteplase (rPA) is a deletion mutant of recombinant plasminogen activator. The key differences are that it lacks the kringle-1, finger, and growth factor portions of wild-type tPA. These differences result in the same specificity for fibrin but decreased affinity, with a longer half-life, making it suitable for bolus administration. The pilot evaluations of rPA compared with tPA were the Reteplase Angiographic Phase II Interventional Dose-Finding Study (RAPID)-I and RAPID-II. These studies demonstrated a slight increase in the rate of artery patency by coronary angiography at 90 minutes without an increase in the risk of bleeding. However, the key registration trial, GUSTO-III, demonstrated essentially no differences in mortality or bleeding between rPA and tPA. The primary advantage of rPA is thus easier administration (as a double bolus) compared with the bolus plus infusion regimen of tPA.

**Tenecteplase**

Tenecteplase (TNK) is a genetically altered variant of tPA with three amino acid substitutions. The result is a more fibrin-specific lytic, with a longer half-life and greater resistance to plasminogen activator inhibitor 1 (PAI-1). This allows TNK to be administered as a single bolus. The key registration trial of TNK was the Assessment of the Safety and Efficacy of a New Thrombolytic Study (ASSENT)-2 head-to-head comparison with tPA. As
with GUSTO-III, the results of the study demonstrated no difference in 30-day mortality or intracranial hemorrhage. Of note, there were statistically significantly fewer nonintracranial bleeding events and a lower need for transfusions; these observations were attributed to the increased fibrin specificity of TNK. Given the ease of administration, equivalent efficacy, and slightly improved bleeding profile, TNK now enjoys the largest share of the thrombolytic market for AMI in the United States.

**ADJUNCTIVE THERAPY**

While the seminal trials of fibrinolysis in AMI incorporated heparin anticoagulation, there still remained a significant risk of reinfarction and subsequent angina, heart failure, or death attributable to vessel reclosure within 30 days of randomization. As a result, investigators have evaluated a series of adjunct therapies to the thrombolytic agents to reduce the incidence of coronary artery rethrombosis and its consequences.

**Low-Molecular-Weight Heparin**

Low-molecular-weight heparin (LMWH) is an attractive alternative to unfractionated heparin (UFH) for several reasons. The action of LMWH is to inhibit the coagulation cascade at an earlier point in the cascade than heparin. LMWH also proportionally inhibits the activity of factor Xa versus factor IIa to a greater extent than UFH. Theoretically, this reduces thrombin generation and provides for a more even and reliable anticoagulant effect. Additionally, in the absence of renal dysfunction, there is little need for monitoring. In the Enoxaparin Versus Unfractionated Heparin With Fibrinolysis for ST-Elevation Myocardial Infarction–Thrombolysis in Myocardial Infarction (ExTRACT TIMI)-25 trial, the investigators compared enoxaparin and UFH as adjunctive therapy for fibrinolysis in AMI. The choice of thrombolytic agent (streptokinase, tPA, rPA, or TNK) was left to the discretion of the treating physician. In the trial, 20,506 patients were randomized in a 1:1 fashion to either LMWH or UFH based on the thrombolytic they received. The results demonstrated a significant reduction in the primary end point of death or nonfatal myocardial infarction with LMWH compared with UFH (9.9% vs 12.0%; \( P < .001 \)). Additionally, there was a significant reduction in
the secondary end point of death, nonfatal reinfarction, or need for urgent revascularization (11.7% vs 14.5%; \( P < .0001 \)). The benefits came at a cost of increased risk of major bleeding (2.1% vs 1.4%; \( P < .001 \)) at 30 days. Of note, enoxaparin was continued to the end of the index hospitalization, whereas UFH was continued for 48 hours, suggesting a possible explanation for the observation of increased bleeding.

**Fondaparinux**

Fondaparinux is an anti-Xa inhibitor with a half-life of 16 to 24 hours. The seminal trial of fondaparinux in ST-segment elevation myocardial infarction was the Effects of Fondaparinux on Mortality and Reinfarction in Patients With Acute ST Elevation Myocardial Infarction–Organization to Assess Strategies in Acute Ischemic Syndromes (OASIS)-6 trial. In OASIS-6, 12,092 patients presenting with an AMI were randomized to receive fondaparinux 2.5 mg daily for up to 8 days versus usual care (placebo or UFH). Of these patients, 2692 received thrombolytic therapy and fondaparinux, whereas 2744 received thrombolytic therapy with usual care.\(^{12}\) Rate of death or reinfarction at 30 days was lower in those treated with fondaparinux versus UFH/placebo (9.7% vs 11.2%; \( P < .008 \)), with a trend toward lower bleeding events. Of note, fondaparinux alone as an anticoagulant is not recommended in patients undergoing percutaneous coronary intervention (PCI) secondary to the observation of guide catheter thrombosis in OASIS-6.

**Bivalirudin**

Bivalirudin is a short-acting (half-life ~25 minutes) direct thrombin inhibitor that acts on both clot-bound and unbound thrombin.\(^{13}\) It is highly specific and does not result in platelet activation. It also partially inhibits platelets via blocking the binding of thrombin to the platelet protease activated receptor (PAR)-1. As an adjunct to thrombolytic therapy, bivalirudin was studied in the Hirulog Early Reperfusion Occlusion (HERO)-2 trial, which enrolled 17,073 patients presenting with an AMI to receive bivalirudin or UFH with standard-dose streptokinase.\(^{14}\) The trial demonstrated no significant difference in mortality at 30 days (10.8% vs 10.9%, respectively; \( P = .85 \)). There was a statistically significant increase in mild to moderate bleeding but
not severe or intracranial bleeding with bivalirudin treatment. Given the lack of mortality benefit and increased bleeding profile, bivalirudin is not recommended for routine use in the initial treatment of AMI after thrombolysis except in patients with a history of heparin-induced thrombocytopenia.

**Platelet Glycoprotein IIb/IIIa Inhibitors**

The platelet glycoprotein IIb/IIIa receptor inhibitors are a potent group of medications whose effect is directed at blocking platelet aggregation. The final common pathway of platelet activity is a conformational change in the glycoprotein IIb/IIIa receptor allowing for cross-linkage with other platelets via dimeric adhesion molecules. This process stabilizes thrombus and contributes to resistance to fibrinolysis and to artery reocclusion. A series of studies have been performed evaluating the efficacy of glycoprotein IIb/IIIa receptor blockade with thrombolytic therapy. Small dose-finding studies such as the Integrilin to Minimize Platelet Aggregation and Coronary Thrombosis–Acute Myocardial Infarction (IMPACT-AMI) trial of eptifibatide with tPA demonstrated improved patency rates when compared with placebo, prompting several large phase III studies. Among these, the GUSTO-V trial was a large multicenter, randomized, open-label trial that randomized 16,588 patients to standard-dose rPA or half-dose rPA plus full-dose abciximab. Both treatment arms also received UFH and aspirin. The study failed to produce a significant difference in the primary end point or mortality at 30 days. Although secondary end points including reinfarction, recurrent ischemia, and the need for “bailout” revascularization were significantly reduced, this was offset by an approximate doubling in nonintracranial bleeding and other measures of bleeding. Given the lack of mortality benefit and the increase in bleeding complications, routine use of glycoprotein IIb/IIIa inhibitors in combination with thrombolytic therapy is not recommended.

**Aspirin**

Aspirin is a reversible cyclooxygenase-2 (COX-2) inhibitor with well-documented cardiovascular benefits. It was first studied in a large randomized fashion in the setting of AMI in the ISIS-2 study published in
In ISIS-2, 17,187 patients with suspected AMI were randomized to receive one of the following regimens: aspirin alone, streptokinase alone, both aspirin and streptokinase, or placebo. With respect to aspirin, the observed mortality with aspirin alone (10.7% at 5 weeks) approached the benefit observed with streptokinase alone (10.4%). In addition, the combination of aspirin and streptokinase had a significant additive benefit (an additional 2.4% absolute risk reduction in mortality on top of the benefit seen with streptokinase). As a result, aspirin is a recommended adjunct in all patients who receive thrombolytic therapy.

**Clopidogrel**

Clopidogrel is an oral agent that blocks the adenosine diphosphate P2Y$_{12}$ receptor, resulting in inhibition of platelet activation. It is an irreversible prodrug that requires metabolism by the CYP2C19 enzyme for activation. Two large trials have evaluated the efficacy and safety of clopidogrel as an adjunct to thrombolytic therapy. The Clopidogrel as Adjunctive Reperfusion Therapy–Thrombolysis in Myocardial Infarction (CLARITY TIMI)-28 trial, published in 2005, evaluated the efficacy of a 300-mg loading dose followed by 75 mg daily of clopidogrel compared with placebo in 3491 patients presenting with an AMI and receiving thrombolytic therapy. The choice of thrombolytic agent was at the discretion of the treating physician, and aspirin and heparin were also administered. The primary efficacy end point was a composite of an occluded infarct-related artery (defined as Thrombolysis in Myocardial Infarction [TIMI] flow grade 0 or 1) at angiography, death, or recurrent myocardial infarction before angiography. The results demonstrated a statistically significant reduction in the primary end point at initial angiography and at 30 days (14.1% vs 11.6%; $P = .03$). There was no significant difference between the clopidogrel arm and placebo in TIMI major or minor bleeding. These results were reinforced by the COMMIT study (Addition of Clopidogrel to Aspirin in 45,852 Patients With Acute Myocardial Infarction: Randomized Placebo-Controlled Trial, part of the Clopidogrel and Metoprolol in Myocardial Infarction Trial/Second Chinese Cardiac Study). In this study, 45,852 patients in China were randomized to clopidogrel versus matching placebo. The results demonstrated a significant reduction in the primary end point of death, reinfarction, or stroke (9.2% vs 10.1%; $P = .002$) with use of clopidogrel versus placebo without a significant
increase in bleeding.\textsuperscript{17}

**SUMMARY OF CURRENT GUIDELINES**

Current AMI management guidelines were published in 2013.\textsuperscript{18} The use of thrombolytic therapy has gradually decreased over the past decade, being supplanted by primary PCI. Nonetheless, thrombolytic therapy is still the treatment of choice in perhaps 20% of AMI patients. A clear understanding of indications for thrombolytic therapy versus transfer for immediate PCI is critical. In the AMI guidelines, the decision to administer thrombolytic therapy (in the absence of a contraindication; \textit{Table 17-2}) is framed by 2 considerations: (1) time from the onset of symptoms to first medical contact (FMC), and (2) time from FMC to anticipated time of PCI. The greatest benefit of reperfusion occurs within 1 to 3 hours from symptom onset. As the time from symptom onset to the administration of thrombolytic therapy increases, there is a concomitant decrease in benefit with an associated increase in risk (\textit{Fig. 17-1}). In the current guidelines, it is a Class I recommendation, with Level of Evidence A, to administer thrombolytic therapy to patients when there is an anticipated delay to primary PCI of greater than 120 minutes. In other words, if the anticipated time from FMC to first balloon is anticipated to be greater than 120 minutes, then thrombolytic therapy should be given. If thrombolytic therapy is decided upon, then the goal is to administer the thrombolytic agent (the door-to-needle time) in less than 30 minutes. Given these time frames, when the difference in anticipated time between the 2 reperfusion strategies is less than 90 minutes, the preferred strategy is to transfer to a PCI center.
FIGURE 17-1 Projected reduction in mortality with reperfusion in acute ST-segment elevation myocardial infarction (curve), with recommendations for reperfusion strategy by time from onset of symptoms. The efficacy of fibrinolytic therapy declines rapidly over the first few hours following vessel occlusion. Nonetheless, when a delay to primary percutaneous coronary intervention (PCI) of >120 minutes is anticipated, fibrinolytic therapy should be given (absent contraindication). *Primary PCI (but not fibrinolytic therapy) is recommended when there is evidence for ongoing ischemia and a large area of myocardium at risk or hemodynamic instability, even when >12 hours has elapsed since the onset of symptoms. (Concepts adapted from Gersh BJ, Stone GW, White HD, Holmes DR Jr. Pharmacological facilitation of primary percutaneous coronary intervention for acute myocardial infarction: is the slope of the curve the shape of the future? JAMA. 2005;293:979-986.)

Table 17-2 Absolute and Relative Contraindications for Thrombolytic Therapy

<table>
<thead>
<tr>
<th>Absolute Contraindications</th>
</tr>
</thead>
<tbody>
<tr>
<td>1. Any prior intracranial hemorrhage</td>
</tr>
<tr>
<td>2. Known cerebral vascular lesion or intracranial neoplasm</td>
</tr>
<tr>
<td>3. Ischemic stroke within 3 months except if within 4.5 hours</td>
</tr>
<tr>
<td>4. Suspected aortic dissection</td>
</tr>
<tr>
<td>5. Active bleeding or bleeding diathesis (excluding menses)</td>
</tr>
<tr>
<td>6. Significant closed-head or facial trauma within 3 months</td>
</tr>
<tr>
<td>7. Intracranial or spinal surgery within 2 months</td>
</tr>
<tr>
<td>8. Severe uncontrolled hypertension that is unresponsive to emergency treatment</td>
</tr>
</tbody>
</table>
9. If using streptokinase, previous administration within 6 months

**Relative Contraindications**

1. History or chronic, severe, or poorly controlled hypertension
2. Significant hypertension on presentation (systolic blood pressure >180 mm Hg or diastolic blood pressure >110 mm Hg)
3. History of prior ischemic stroke >3 months
4. Dementia
5. Known intracranial pathology that is not an absolute contraindication
6. Traumatic or prolonged (>10 minutes) cardiopulmonary resuscitation
7. Major surgery less than 3 weeks
8. Noncompressible vascular punctures
9. Pregnancy
10. Active peptic ulcer
11. Oral anticoagulant therapy

In patients whose time of onset to FMC is greater than 12 hours, the diminished efficacy coupled with the risks of fibrinolysis preclude treatment with thrombolytic agents, and thrombolytic therapy is generally not recommended. However, in symptomatic patients with persistent ST-segment elevations who are hemodynamically unstable and where PCI is unavailable, thrombolytic therapy should be considered. The current guidelines give this group of patients who present in the 12- to 24-hour time frame and have a large area of myocardium at risk a Class IIa, Level of Evidence C recommendation.

**Adjunctive Therapy**

It is a class I recommendation that both anticoagulant and antiplatelet therapies be administered in conjunction with thrombolytic agents in AMI (Tables 17-3 and 17-4). Absent contraindication, both aspirin and clopidogrel (dual antiplatelet therapy) are recommended. Only 1 anticoagulant is to be administered, with the choice of agent depending on local practice and expected time to referral to the catheterization laboratory for definitive revascularization. In general, anticoagulation is to be discontinued at the time of revascularization to reduce bleeding following intervention.

**MULTIPLE CHOICE QUESTIONS**

1. Which of the following most strongly suggests the failure of fibrinolytic therapy to achieve reperfusion?
   - A. >50% residual ST-segment elevation
   - B. Occurrence of ventricular tachycardia or ventricular fibrillation
   - C. Cardiogenic shock
   - D. Lack of complete relief of chest discomfort

2. Which of the following approaches is associated with the greatest
reduction in mortality in the patient <75 years of age who fails to reperfuse within 90 to 120 minutes following fibrinolytic therapy?
A. Administration of a second dose of fibrinolytic therapy  
B. Administration of a platelet glycoprotein IIb/IIIa inhibitor  
C. Transfer of the patient to a percutaneous coronary intervention (PCI)-capable hospital for rescue PCI  
D. Administration of enoxaparin by intravenous (IV) bolus and subcutaneous injection

3. The time window of benefit of primary PCI in patients with cardiogenic shock extends to what duration?
A. 24 hours from symptom onset  
B. 48 hours from symptom onset  
C. 24 hours from the onset of shock  
D. 48 hours from the onset of shock

4. Compared with implantation of a bare metal stent (BMS) during primary PCI for STEMI, the rate of which of the following is reduced with implantation of a drug-eluting stent (DES)?
A. Death  
B. Myocardial infarction  
C. Bleeding  
D. Target vessel revascularization

5. In the patient receiving a BMS during primary PCI for STEMI, what is the recommended duration of dual antiplatelet therapy (absent contraindication)?
A. 1 month  
B. 3 months  
C. 6 months  
D. 1 year

6. Based on clinical trials including INFUSE-AMI, TASTE, and TOTAL, what is the recommendation for the use of aspiration thrombectomy in primary PCI during acute STEMI?
A. Aspiration thrombectomy should never be used.  
B. Aspiration thrombectomy should be evaluated on a case-by-case
C. Aspiration thrombectomy should be used only when there is a large thrombus.
D. Aspiration thrombectomy should be performed only when the infarct lesion is in the left main, proximal left anterior descending, proximal left circumflex, or proximal right coronary artery.

ANSWERS

1. A
A number of factors have been identified as being predictive of successful coronary reperfusion with fibrinolytic therapy, including the reduction and/or relief of chest pain, resolution of ST-segment elevation, and the presence of reperfusion arrhythmias. Conversely, >50% residual ST-segment elevation, ongoing chest discomfort, and the absence of reperfusion arrhythmias are indicative of reperfusion failure. The presence of cardiogenic shock is correlated with the amount of myocardium at jeopardy. Complete relief of chest discomfort does not always occur with coronary reperfusion.

2. C
The REACT study demonstrated the superiority of a strategy of immediate transfer of the patient for primary PCI compared with repeat fibrinolysis or conservative therapy. Several studies, including the GUSTO-V and FINESSE trials, evaluated glycoprotein IIb/IIIa therapy in conjunction with fibrinolysis in ST-segment elevation myocardial infarction (STEMI), but not as rescue therapy. Furthermore, these trials were negative. Enoxaparin, including dose adjustment based on age, proved superior to heparin as an adjunct to fibrinolytic therapy in the ExTRACT-TIMI 25 study when given in conjunction with the fibrinolytic agent, not in the context of reperfusion failure.

3. B
Patients with shock complicating acute STEMI are a very-high-risk subgroup, with in-hospital mortality of 40% to 80% in reported series. In the SHOCK trial, the benefit of emergency revascularization was apparent across
a very wide time window, extending up to 54 hours after the onset of symptoms and 18 hours after shock onset.

4. D
The benefit of DES compared with BMS in STEMI patients is mainly in reducing restenosis (in-stent restenosis, target lesion revascularization, and target vessel revascularization, along with the need for repeat revascularization), while not affecting rates of recurrent myocardial infarction or death. Critically, stent thrombosis does not appear to be increased with DES compared with BMS in trials of second-generation stents. Bleeding is actually increased in patients receiving a DES due late bleeding associated with prolonged dual antiplatelet therapy.

5. D
The duration of P2Y$_{12}$ treatment following stent implantation during primary PCI for STEMI is determined by the presenting syndrome (acute STEMI) rather than the type of stent (BMS vs DES). Current guidelines recommend 1 year of treatment.

6. B
The current recommendation is that aspiration thrombectomy should be evaluated on a case-by-case basis, rather than being considered as a universally applicable strategy. Importantly, subgroup analyses of aspiration thrombectomy in patients with a large thrombus burden did not show an advantage. There was also no specific advantage in the INFUSE-AMI study, which selectively enrolled patients with a large anterior myocardial infarction.
Despite the prolific increase in new technology in interventional cardiology, x-ray imaging combined with radiographic contrast media continues to be the mainstay in imaging technology. Visualization of vascular structures using x-rays requires the use of a radiographic contrast medium in order to distinguish them from surrounding tissues, which aside from bones, absorb x-rays poorly. Iodinated radiographic contrast agents have been used for this purpose since the 1950s. Since then, just as digitalization and evolution of imaging equipment technology have made significant strides in improving image quality and reducing exposure to ionizing radiation, refinements in the design of and judicious use of iodinated contrast has improved patient safety and reduced adverse outcomes.

**PHARMACOLOGY**

The iodine atom, with its relatively high atomic weight, attenuates x-rays and is used in most intravascular contrast agents today. Iodine’s K shell binding energy of 33.2 keV is ideal for x-ray photon absorption. Covalent bonding of 3 iodine atoms to a benzene ring at the 2, 4, and 6 position—the basic structure of all iodinated contrast agents (Fig. 18-1)—allows iodine to be delivered intravascularly, free of the side effects of free iodine, and also increases the effective molecular concentration of iodine, improving the ability to attenuate x-rays.\(^1\) An iodine concentration of 320 to 370 mg/mL is
optimal for angiographic studies. Although all iodinated contrast agents use this basic benzene ring structure, the number of rings per molecule (monomers or dimers) and the side chains at the 1, 3, and 5 positions give each of them unique chemical properties.²

![Chemical structures of contrast agents](image_url)

**FIGURE 18-1** Schematic of iodinated benzene monomers and dimers used in radiographic contrast media.

Contrast agents are classified based on whether they are monomers or dimers, ionic or nonionic, and high, low, or iso-osmolar (Table 18-1). Ionic
agents have 2 osmotically active particles per molecule, whereas nonionic agents have 1 osmotically active particle per molecule. High-osmolar agents are generally 4 to 6 times the osmolarity of blood, low-osmolar agents are 1.5 to 3 times the osmolarity of blood, and iso-osmolar agents are usually the same osmolarity of blood.

Table 18-1 Iodinated Intravascular Contrast Media
These iodinated contrast agents are generally hydrophilic and quickly
distribute throughout the extravascular space but do not cross lipid membranes and, therefore, remain extracellular. There is minimal protein binding. The circulatory half-life is approximately 1 to 2 hours with primarily renal excretion via glomerular filtration. Ionic, high-osmolar contrast agents have calcium-chelating properties as they are preserved in ethylene diamine tetra-acetic acid (EDTA), which contributes to their hemodynamic and electrophysiologic side effects such as bradyarrhythmias and ventricular fibrillation. Therefore, calcium was added to contrast formulations to reduce these adverse effects.

**ADMINISTRATION**

During interventional cardiology procedures, contrast is generally injected directly into the vascular structures of interest using catheters during fluoroscopy, allowing x-ray visualization of the lumen of the vessel. Administration rates are determined by the flow rates of the vascular structure being visualized (generally ranging from 1-30 mL/s). The intravascular injections are usually performed through 4- to 8-Fr (1.3-2.6 mm) diameter catheters, ranging from 10 to 120 mm in length. Viscosity of the different contrast agents varies and can limit the maximum delivery rate through these relatively narrow, long tubes, with increasing viscosity in the low- and iso-osmolar agents. Warming high-viscosity contrast agents, particularly iso-osmolar agents (iodixanol), to body temperature lowers viscosity and optimizes their injectability.

**Optimal Contrast Use**

In recent years, interventionalists have become conscious of contrast volume use to prevent contrast nephropathy. Minimizing contrast volume while maintaining good imaging is the key and includes the following measures:

1. Estimation of contrast volume to be used
2. Small manifold syringes
3. 50:50 diluted contrast
4. Small diagnostic catheters (4 and 5 Fr)
5. Small-caliber guiding catheters (5 and 6 Fr)
6. Biplane imaging  
7. Zooming for image magnification  
8. Ultrasound imaging with intravascular ultrasound (IVUS) in optimizing percutaneous coronary intervention (PCI) procedures  
9. Marker wires for lesion length and device position  
10. Markers on IVUS catheters  
11. Mechanized contrast injectors delivering prefixed contrast amount

**Contrast Volume Estimation**

The maximal acceptable contrast dose (MACD) minimizes the chance of contrast nephropathy is calculated as follows\(^4-6\):

\[
5 \text{ mL} \times \text{Body weight (in kg)/Serum creatinine (mg/dL)}
\]

Ratios of contrast volume used: MACD > 1 predict acute kidney injury. Complex coronary interventions, such as the opening of chronic total occlusions, require large contrast volumes, often approaching the MACD. The importance of these volume estimations have now extended to complex structural heart disease intervention, including transcatheter aortic valve replacement, perivalvular leaks plugging, complex congenital abnormality treatment, and endografts for abdominal and thoracic aneurysms, where large volumes of contrast are often used.

**PHYSIOLOGIC EFFECTS**

Hemodynamic effects of intraventricular contrast administration include a mild and transient decrease in ventricular function and increase in ventricular filling pressures, effects that are greater with high-osmolar than with low- or iso-osmolar agents. Contrast administration also increases intravascular volume, again more profoundly with high-osmolar than low- or iso-osmolar agents. These effects may be important in patients with heart failure, and contrast ventriculograms, in particular, should be performed with caution. Another hemodynamic effect of intra-arterial contrast administration is transient arteriolar vasodilation, resulting in decreased vascular resistance, increased blood flow, and potentially decreased systemic pressure.\(^1,2\)

Electrophysiologic effects of intracoronary contrast administration include
transient changes on the surface electrocardiogram such as QRS prolongation, axis shift, ST-segment depression, PR prolongation, and QT prolongation. Bradyarrhythmias, such as sinus bradycardia and asystole, may also occur. These arrhythmias are more common following injection of the right coronary artery and may reflect a vagal response as well as a direct effect on the sinoatrial node. Such bradyarrhythmias are often transient but, when necessary, generally respond to coughing or to intravenous (IV) atropine. Contrast also lowers the myocardial ventricular fibrillation threshold. All of these electrophysiologic effects are more common with the high-osmolar agents than the low- or iso-osmolar agents. Furthermore, the bradycardia and ventricular fibrillation potential are exacerbated by concomitant ischemia. For example, during an acute inferior ST-segment elevation myocardial infarction, reflow following restoration of coronary flow can cause asystole and heart block, and repetitive contrast injection can worsen the arrhythmia.1,2,7

Bench testing demonstrated that ionic agents were less likely to cause thrombosis than nonionic agents because these agents bind to the anion binding site of thrombin. There was also less platelet degranulation and aggregation and less thrombus formation.8-12 Finally, there was more thrombus deposition on guide wires and guiding catheters by electron microscopy with nonionic iopamidol versus ionic ioxaglate.13 Initial clinical studies also suggested less thrombotic effects with ionic agents. In acute coronary syndromes (ACSs), there was less urgent recatheterization procedures following PCI performed with ionic ioxaglate (17.8% vs 8.1%).14 Nonrandomized studies, such as the Evaluation of c7E3 Fab in the Prevention of Ischemic Complications (EPIC) trial, demonstrated greater abrupt closure and Q-wave myocardial infarction with nonionic agents.15 In the Global Use of Strategies to Open Occluded Coronary Arteries in Acute Coronary Syndromes (GUSTO) IIB trial,16 there was less refractory ischemia with ionic agents, and fewer ischemic events were noted in the Randomized Efficacy Study of Tirofiban for Outcomes and Restenosis (RESTORE) study with ionic agents.17 There was a reduction in stent thrombosis and 12-month major adverse cardiac events (MACE) with ionic ioxaglate with early-generation stents as reported by Scheller et al.18

However, later clinical trials have not uniformly supported reduced thrombotic events with ionic contrast agents. In the randomized, controlled
Contrast Media Utilization in High-Risk Percutaneous Transluminal Coronary Angioplasty (COURT) trial,\textsuperscript{19} in-hospital MACE occurred less with nonionic, iso-osmolar iodixanol versus ionic, low-osmolar ioxaglate (5.4\% vs 9.5\%, respectively; \( P = .027 \)). No difference between ionic and nonionic agents was observed in a primary PCI study after adjustment for baseline characteristic differences.\textsuperscript{20} No difference in MACE was also noted in the Visipaque in Percutaneous Coronary Angioplasty (VIP) randomized controlled trial comparing nonionic iodixanol and ionic ioxaglate.\textsuperscript{21} Finally, in the randomized Visipaque Versus Isovue in Cardiac Catheterization (VICC) trial comparing iopamidol versus iodixanol, in patients primarily undergoing PCI, there was no significant difference in the occurrence of myocardial infarction between 2 and 30 days after PCI.\textsuperscript{22}

Currently, there is insufficient evidence to support a clinical advantage of nonionic agents such as iodixanol over ionic agents such as ioxaglate. Thrombotic complications during contrast angiography, regardless of the agent used, are generally avoided by:

- Frequent catheter flushing with heparinized saline
- Avoiding contrast stasis with blood in manifold syringes or tubing\textsuperscript{23}
- Avoiding prolonged coronary engagement with catheters without frequent flushing or anticoagulating the patient
- Additive use of heparin or other anticoagulant (other than fondaparinux\textsuperscript{24}) if procedure is prolonged and/or involves intracoronary devices

### ADVERSE REACTIONS

Adverse reactions due to radiographic contrast media are generally due to their cardiovascular physiologic effects, other chemotoxic effects, or immune-mediated hypersensitivity. However, clinically, it is also practical to classify contrast reactions based on the time of occurrence, with \textit{immediate reactions} occurring within 1 hour of administration and \textit{delayed reactions} occurring greater than 1 hour after administration (Table 18-2).

**Table 18-2 Most Common and Significant Adverse Contrast Reactions**
Immediate Reactions

Immediate reactions that are due to radiographic contrast media’s physiologic and chemotoxic effects are generally dependent on dose and infusion rate. Symptoms include warmth, flushing, nausea, emesis, burning, and/or pain. These reactions are usually transient and self-limited. Sometimes a vagal syndrome may occur, including lightheadedness, hypotension, and bradycardia, and will reverse with IV fluid administration and atropine. Overall, randomized trials and large registry surveys show that the incidence of such mild to moderate immediate adverse reactions is significantly reduced with the use of nonionic and low- or iso-osmolar contrast media as compared to high-osmolarity agents (9%-14% vs 29%-40%).25-27

Immediate hypersensitivity reactions (IHRs) are generally independent of dose and infusion rate. Seventy percent of these reactions occur within 5 minutes of contrast media administration, and 96% occur within 20 minutes.27-30 Clinical manifestations can include pruritus, urticaria, angioedema, abdominal pain, diarrhea, bronchospasm, wheezing, laryngeal edema, stridor, and hypotension. The syndrome can appear identical to a type 1 hypersensitivity anaphylactic reaction. Mild IHRs (pruritus, urticaria) have
been estimated to occur in 0.7% to 3.1% of patients receiving nonionic radiographic contrast media, whereas severe reactions (respiratory failure, hypotension) have been reported in 0.02% to 0.04% of patients, with fatalities occurring in 1 to 3 per 100,000. Large registry studies show that high-osmolar radiographic contrast media are associated with a higher rate of IHRs (mild, 5%-13%; severe, 0.04%-0.22%).

The mechanism of IHRs is not completely understood but appears to involve complement activation and bradykinin formation, resulting in mast cell and basophil activation with histamine and tryptase release. Evidence of immunoglobulin E (IgE) mediation has not been identified in most patients, and reactions often occur without any prior exposure, suggesting a non–IgE-related mechanism. Direct compliment activation and/or a direct membrane effect of the contrast media due to its osmolarity or chemical structure are therefore likely causes of IHRs. However, in some patients with severe IHRs, positive skin tests and basophil activations tests have been found, suggesting a possible IgE-mediated reaction may also play a role. Testing has shown that iodine is rarely, if ever, the cause of IHRs.

Diagnosis of IHRs is usually made based on the clinical presentation. In diagnostically difficult situations, the occurrence of an IHR may be confirmed by blood samples for histamine and tryptase analysis drawn as soon as possible after the reaction as well as during convalescence for comparison. The utility of allergy skin testing after recovery is controversial.

Risk factors for IHRs include a prior IHR as well as asthma and atopy. Shellfish or seafood allergies are not independent risk factors for IHRs, nor is contact dermatitis to povidone-iodine skin disinfectant. Prevention of recurrent IHRs is of paramount importance. In patients with a history of prior reaction, the recurrence rate without prophylaxis is in the range of 16% to 44%. Prevention starts with the use of a low- or iso-osmolar contrast. Using a different agent in patients with a prior reaction may be beneficial, although cross-reactivity between agents does occur. In addition, adequate pretreatment of patients with prior reactions using steroids and antihistamines reduces the recurrence rate substantially. A regimen of 50 mg of prednisone administered 13 hours, 7 hours, and 1 hour before the procedure, as well as 50 mg of diphenhydramine administered 1 hour before the procedure, reduced the risk of recurrent anaphylactoid reaction to
A regimen of prednisolone 32 mg given 6 to 24 hours and 2 hours prior to contrast administration also reduced the risk of anaphylactoid reaction. However, a single dose of prednisolone 32 mg 2 hours before contrast administration was not effective at lowering the risk of anaphylactoid reactions. Because H₂ receptors have a significant role in the vasodilatory response to histamine release and H₂ blockers have been shown to be effective in the treatment of refractory IgE-mediated anaphylaxis, administration of H₂ blockers (eg, cimetidine) should also be considered. There are minimal data on the “pretreatment” of patients with prior contrast reactions undergoing emergency PCI. One group has suggested that IV steroids (eg, 80-125 mg of methylprednisolone, 100 mg of hydrocortisone sodium succinate), as well as oral or IV diphenhydramine and IV cimetidine, may be useful in preventing reactions. Because severe reactions may still develop despite prophylaxis, the potential benefits of any procedure using contrast media must be carefully weighed against the residual risk of IHR. Pretreatment of unselected patients without risk factors for IHRs has not been shown to be beneficial. Pretreatment of unselected patients without risk factors for IHRs has not been shown to be beneficial.

Treatment of severe IHRs, such as those associated with hypotension and respiratory failure, should be similar to that of anaphylaxis and include maintenance of the airway and breathing and circulatory support. Epinephrine (0.1 mg IV with repeated doses as needed), oxygen, IV fluids, and antihistamines (diphenhydramine 25-50 mg IV) are essential in patients with hypotension and/or airway compromise. Prochlorperazine or ondansetron may be given for nausea and vomiting. Glucocorticoids administered during emergency management are not known to impact acute symptoms, but may be beneficial in preventing or reducing the severity of delayed symptoms. Intubation may be required, with supportive medications potentially necessary for up to 72 hours. Treatment of mild IHRs (urticaria only) should include antihistamines with or without steroids, as well as consideration of immediate interruption of the administration of the contrast. After treatment, the affected patient should be closely observed for symptom progression or recurrence.

**Delayed Reactions**

Delayed reactions include nephrotoxicity, hyperthyroidism, and delayed
hypersensitivity reactions (DHRs). For an extensive discussion of contrast-induced nephrotoxicity, see Chapter 19.

DHRs manifest primarily as skin exanthemas, usually macular or maculopapular. Less common delayed skin manifestations include urticaria, angioedema, symmetrical drug-related intertriginous and flexural exanthema, drug-related eosinophilia with systemic symptoms, erythema multiform minor, fixed drug eruption, and rarely, Stevens-Johnson syndrome, toxic epidermal necrolysis, graft-versus-host reaction, and vasculitis. These reactions usually start within 3 days of contrast exposure but may present after up to 10 days.\(^3\)\(^0\) They are estimated to occur in 1% to 3% of patients.\(^4\)\(^9\) The mechanisms of most DHRs are believed to be T-cell–mediated type 4 hypersensitivity reactions.\(^4\)\(^9\) Evidence supporting this mechanism includes the fact that the maculopapular exanthemas resemble other drug-induced T-cell–mediated hypersensitivity reactions; the onset is 2 to 10 days after first exposure and 1 to 2 days after reexposure (consistent with a sensitization phase), and the histopathology reveals perivascular infiltrates of CD4\(^+\) and CD8\(^+\) T cells plus eosinophils.\(^5\)\(^0\),\(^5\)\(^1\) This pathogenesis likely explains why patients treated with interleukin-2, a potent T-cell stimulator, are at higher risk.\(^5\)\(^2\) As with IHRs, iodine is rarely, if ever, the eliciting agent.\(^3\)\(^6\)

Diagnosis of DHRs is usually based on the clinical features and scenario. The maculopapular rashes often include erythema, swelling, and pruritus (Fig. 18-2). Differential diagnosis often includes reactions to other recently newly introduced medications, such as thienopyridine antiplatelet agents. If the differential diagnosis extends beyond a drug reaction, a skin biopsy may be useful.\(^3\)\(^0\) Hematology and clinical chemistry need only be considered in the case of more severe exanthemas to exclude systemic involvement.\(^2\)\(^9\)

Skin testing can be considered 2 to 6 months after the reaction, particularly if there is a question of the offending drug or consideration of repeat contrast administration. While skin testing may have a high specificity, it only has a moderate sensitivity.38,53

The main risk factor for DHRs is a prior DHR, but patients with a strong history of atopy may also be susceptible.30,53 Some, but not all, studies have suggested that nonionic, iso-osmolar contrast agents (eg, iodixanol) more commonly cause these reactions than other contrast agents (by 3- to 4-fold).54 Sun exposure following contrast exposure may exacerbate the development of DHRs.55 Prevention should consist of avoiding the culprit contrast medium. If other contrast media are identified by skin testing, they should also be avoided. Skin testing does have a negative predictive value but does not guarantee tolerance.30 Steroid prophylaxis can be given to prevent delayed reactions with some, but not complete, success.56,57

The most common maculopapular rashes are generally transient and self-limited, resolving within 3 to 7 days after onset. Treatment of these is usually based on symptoms and may include antihistamines (diphenhydramine 25-50 mg every 6 hours by mouth) as well as consideration of topical
corticosteroids and antipruritics. More severe reactions require consultation with a dermatologist.

Hyperthyroidism

The use of iodinated contrast has been linked with thyroid dysfunction, both hyperthyroidism and, to a lesser degree, hypothyroidism. The incidence has not been well defined, but has been reported in the 0.05% to 5% range. The mechanism is likely related to the exposure to a large supraphysiologic bolus of iodine, which serves as substrate for thyroxine production or, alternatively, triggers a pathologic thyroid inhibitory effect. Patients with diagnosed or subclinical hyperthyroid conditions (eg, Graves disease, nontoxic diffuse or multinodular goiter), particularly when age is >65 years or when patients are from iodine-deficient areas, are predisposed to iodinated contrast–induced hyperthyroidism. Likewise, hypothyroidism may occur, particularly in patients with prior thyroiditis, with thyroid ablation, or on chronic dialysis. Contrast-induced hyperthyroidism can be difficult to manage and should trigger referral to an endocrinologist, whereas contrast-induced hypothyroidism is usually self-limited and can be treated with temporary levothyroxine replacement therapy. Although some have recommended prophylaxis against iodinated contrast–induced thyroid dysfunction in high-risk patients using perchlorate and thiamazole, these drugs may have significant side effects, and this practice has not been widely adopted.

CARDIOGENIC SHOCK

Cardiogenic shock and associated hypotension can result in multiorgan failure and acute kidney injury (AKI). The additive effect of contrast use exacerbates AKI. In the SHOCK (Should We Emergently Revascularize Occluded Coronaries for Cardiogenic Shock?) trial, AKI developed in 24% of patients with initial medical therapy versus 13% in the early revascularization arm. AKI exacerbates the bleeding complications of PCI, prolongs hospitalization, and is associated with increased hospital mortality. Although contrast use is a bystander in the complex syndrome associated with shock, judicious contrast use and early revascularization contribute to
improved survival.

**GLUCOPHAGE**

Diabetes causes endothelial dysfunction and decreased production of nitric oxide. Contrast-induced vasoconstriction and lack of a vasodilatory response result in decreased renal blood flow. Glucophage or metformin is excreted unchanged in the kidneys. With renal insufficiency, which may be exacerbated by contrast use, glucophage accumulates in tissues and can cause lactic acidosis. Contrast-induced lactic acidosis is rare at 3 per 100,000 patient-years, with a mortality of 1.5 per 100,000 patient-years.

**General Guidelines**

- In a patient with serum creatinine >2.0 mg/dL, glucophage should be discontinued permanently.
- With normal renal function, contrast studies can be performed without holding glucophage before the procedure. Glucophage can be resumed in 48 hours if serum creatinine levels are in the normal range.

With emergent procedures, contrast studies need not be delayed; hydration should be continued and serial creatinine levels obtained.

**NONIODINATED CONTRAST AGENTS**

**Gadolinium**

Gadolinium, a rare, natural, heavy metal, is used extensively in magnetic resonance imaging (MRI). It is used in radiographic imaging in patients with severe iodine allergy. In the recommended concentration of 0.4 mmol/kg body weight, only small doses can be injected in the coronary circulation, and image quality is inferior to iodinated contrast, but is still diagnostic. The viscosity of the agent can cause cardiac arrhythmias, in particular ventricular fibrillation. This adverse effect is enhanced by catheter dampening of the coronary artery. Repeat injections are not recommended, and hence, there is a
lack of usefulness in coronary intervention procedures. Gadolinium does not prevent contrast-induced nephropathy. It is well tolerated in patients with serum creatinine levels of <2.0 mg/dL but can worsen renal function in patients with creatinine levels >2.0 mg/dL. In patients with renal insufficiency (estimated glomerular filtration rate <30 mL/min) and end-stage renal disease, the heavy metal accumulates in body tissues, causing nephrogenic systemic fibrosis.

**Carbon Dioxide**

Carbon dioxide, given via an injector, in the vasculature is absorbed over a 2-minute period by the blood, where it is converted into sodium bicarbonate and excreted by the lungs as carbon dioxide. It produces radiologic contrast and neither causes an allergic reaction nor nephrotoxicity. The image quality is less than iodinated contrast and requires enhancement by digital subtraction angiography.

Carbon dioxide imaging is used in below-the-diaphragm visceral, renal, and lower extremity angiography, renal stent placement, and endovascular aortic repair for abdominal aortic aneurysms. Delivery of carbon dioxide is through special injectors and connecting tubes, free of air contamination. Generally, 20 to 40 mL of carbon dioxide is injected through 3- to 4-Fr catheters. It is not used in coronary or pulmonary angiography because it produces a “vapor lock” that resolves over a 2-minute period of absorption of the gas, and in the coronary circulation, this may cause myocardial ischemia similar to coronary air embolism. In the pulmonary circulation, this vapor lock is similar to pulmonary air embolism, resulting in hypotension.67-70

**CONCLUSION**

Iodinated radiographic contrast media are essential for the angiography necessary to guide the practice of interventional cardiology today. Low- and iso-osmolar agents are very well tolerated in measured doses in most patients. The interventional cardiologist’s awareness of the physiologic effects and adverse reactions occasionally caused by these agents, including their prevention and treatment, helps to protect vulnerable patients.

MULTIPLE CHOICE QUESTIONS

1. Cardiovascular physiologic effects of radiographic contrast media include which of the following?
   A. Arteriolar vasodilation
   B. Electrocardiogram (ECG) QRS prolongation
   C. Ventricular hypercontractility
   D. A, B, and C
   E. A and B

2. Dose- and/or infusion rate–dependent adverse reactions that occur immediately after radiographic contrast media administration include all the following except:
   A. Nausea and emesis
   B. Burning and/or pain
   C. Pruritus
   D. Flushing
   E. Warmth

3. Risk factors for immediate hypersensitivity reactions (IHRs) include which of the following?
   A. Shellfish reaction
   B. Contact dermatitis to povidone-iodine
   C. Asthma
   D. Seafood allergy

4. Delayed hypersensitivity reactions can manifest as all the following except:
   A. Macular skin exanthemas
   B. Angioedema
   C. Urticaria
   D. Hematuria
   E. Erythema multiform minor

5. Interventions that may prevent hypersensitivity reactions include which of the following?
A. Minimizing contrast media dose
B. Prednisone
C. Aminophylline
D. Intravenous epinephrine

ANSWERS

1. E
Hemodynamic effects of intraventricular contrast administration include a mild and transient decrease in ventricular function and increase in ventricular filling pressures. Another hemodynamic effect of intra-arterial contrast administration is transient arteriolar vasodilation, resulting in decreased vascular resistance, increased blood flow, and potentially decreased systemic pressure. Electrophysiologic effects of intracoronary contrast administration include transient changes on the surface electrocardiogram such as QRS prolongation, axis shift, ST-segment depression, P-R prolongation, and QT prolongation. Bradyarrhythmias, such as sinus bradycardia and asystole, may also occur. All these electrophysiologic effects are more common with the high-osmolar agents than the low- or iso-osmolar agents.

2. C
Immediate reactions that are due to radiographic contrast media’s physiologic and chemotoxic effects are generally dependent on dose and infusion rate. Symptoms include warmth, flushing, nausea, emesis, burning, and/or pain. These reactions are usually transient and self-limited. However, immediate hypersensitivity reactions are generally independent of dose and infusion rate. Seventy percent of these reactions occur within 5 minutes of contrast media administration, and 96% occur within 20 minutes. Clinical manifestations can include pruritus, urticaria, angioedema, abdominal pain, diarrhea, bronchospasm, wheezing, laryngeal edema, stridor, and hypotension.

3. C
Risk factors for IHRs include a prior IHR as well as asthma and atopy. Shellfish or seafood allergies are not independent risk factors for IHRs, nor is
prior contact dermatitis to povidone-iodine skin disinfectant.

4. D

Delayed hypersensitivity reactions manifest primarily as skin exanthemas, usually macular or maculopapular. Less common delayed skin manifestations include urticaria, angioedema, symmetrical drug-related intertriginous and flexural exanthema, drug-related eosinophilia with systemic symptoms, erythema multiform minor, fixed drug eruption, and rarely, Stevens-Johnson syndrome, toxic epidermal necrolysis, graft-versus-host reaction, and vasculitis. These reactions usually start within 3 days of contrast exposure but may present after up to 10 days. They are estimated to occur in 1% to 3% of patients.

5. B

Prevention starts with the use of a low- or iso-osmolar contrast. Using a different agent in patients with a prior reaction may be beneficial, although cross-reactivity between agents does occur. In addition, adequate pretreatment of patients with prior reactions using steroids and antihistamines reduces the recurrence rate substantially. A regimen of 50 mg of prednisone administered 13 hours, 7 hours, and 1 hour before the procedure, as well as 50 mg of diphenhydramine administered 1 hour before the procedure, reduced the risk of recurrent anaphylactoid reaction to around 0.5%. A regimen of prednisolone 32 mg given 6 to 24 hours and 2 hours prior to contrast administration also reduced the risk of anaphylactoid reaction. However, a single dose of prednisolone 32 mg 2 hours before contrast administration was not effective at lowering the risk of anaphylactoid reactions. Because H₂ receptors have a significant role in the vasodilatory response to histamine release and H₂ blockers have been shown to be effective in the treatment of refractory IgE-mediated anaphylaxis, administration of H₂ blockers (eg, cimetidine) should also be considered. Aminophylline would not be anticipated to prevent immediate hypersensitivity reactions. IV epinephrine may be used to treat immediate hypersensitivity reactions after they occur. Hypersensitivity reactions are not dose or infusion rate dependent.
Renal Complications of Contrast Media

Anand Prasad
Peter A. McCullough

HISTORICAL PERSPECTIVE

Radiocontrast was first described to cause nephrotoxicity in the 1960s.\textsuperscript{1,2} Contrast-induced nephropathy (CIN), now termed \textit{contrast-induced acute kidney injury} (CI-AKI), is likely to increase in frequency over the next 10 to 15 years. This rise is largely due to increasing use of radiocontrast studies in patients who are older, sicker, or have attendant comorbidities such as diabetes mellitus, renal failure, cardiac failure, and volume depletion.\textsuperscript{3} CI-AKI is currently described as the third most common cause of hospital acquired renal failure, accounting for approximately 11\% of cases.\textsuperscript{4} The incidence of CI-AKI reported in the literature has ranged between 1\% and 45\%, largely depending on the comorbidities of the study population, the clinical scenario in which the contrast is given, and the parameters used to define CI-AKI.\textsuperscript{5} With more than a million radiocontrast procedures performed annually in the United States, the incidence of CI-AKI is approximately 150,000 cases per year. At least 1\% of these episodes require dialysis therapy (in half of patients, it will be permanent) with prolongation of hospital stay to an average of 17 days, with an additional cost of approximately $32 million annually. For episodes that do not require dialysis, the average prolongation of the hospital stay is 2 days (at $500 per day), and
this translates to an added cost of $148 million annually.\textsuperscript{6,7} The incidence and costs are higher in critically ill patients, who have associated comorbidities such as hypotension, hypovolemia, diabetes, and congestive heart failure.

This chapter will first examine the important renal complications of contrast media. This will be followed by an evaluation of laboratory investigations that provide insights into the pathogenesis of this disorder. The last section deals with 2 important clinical issues: (1) the use of low-osmolality radiocontrast agents specifically to reduce the incidence of CI-AKI and (2) adjunctive methods currently used to prevent the development of CI-AKI.

**THE CARDIORENAL INTERSECTION**

The obesity pandemic is a central driver of the dysmetabolic syndrome, hypertension, and diabetes. It is thus anticipated that there will soon occur a secondary epidemic of combined chronic kidney disease (CKD) and cardiovascular disease (CVD).\textsuperscript{8} Among patients with diabetes for 25 years or more, the prevalence of diabetic nephropathy in type 1 and type 2 diabetes is 57\% and 48\%, respectively. Approximately half of all cases of end-stage renal disease (ESRD) are due to diabetic nephropathy, with most of these cases driven by obesity-related type 2 diabetes and hypertension.\textsuperscript{9} With the graying of America and cardiovascular care shifting toward the elderly, the imperative thus exists to understand the relationship between decreasing levels of renal function as a major adverse prognostic factor in cardiac patients. AKI after contrast exposure as the most proximal renal event is predictable and highlights an opportunity for preventive measures outlined later in this chapter.

**SMALL RISES IN CREATININE ARE LINKED TO POOR LONG-TERM OUTCOMES**

The overall prevalence of CI-AKI, defined as a transient rise in serum creatinine (Cr) $\geq$0.3 mg/dL above the baseline, occurs in approximately 7\%
of patients undergoing percutaneous coronary intervention (PCI) (Fig. 19-1).\textsuperscript{10} Fortunately, rates of CI-AKI leading to dialysis are quite low (0.5%-2.0%). However, the occurrence of CI-AKI is associated with catastrophic outcomes, including a 36% in-hospital mortality rate and a 2-year survival of only 19%.\textsuperscript{10} Transient rises in Cr are directly related to longer intensive care unit and hospital ward stays (3 and 4 additional days, respectively) after cardiac bypass surgery.\textsuperscript{11} Recently, it has been shown that even transient elevations in Cr translate to differences in adjusted long-term outcomes including mortality, ESRD, and all-cause hospitalization after diagnostic catheterization or PCI (Fig. 19-2).\textsuperscript{12,13} In addition to a heavy degree of confounding by older age, diabetes, and other factors, a secondary explanation is that when renal function declines, the associated abnormal vascular pathobiology accelerates, and hence, the progression of other diseases, including CVD, accelerates.

\textbf{FIGURE 19-1} Incidence of contrast-induced acute kidney injury from the American College of Cardiology National Cardiovascular Data Registry, as defined by the Acute Kidney Injury Network (AKIN) definitions (analogous to Kidney Disease Improving Global Outcomes criteria): stage 1, ≥0.3 mg/dL absolute or 1.5- to 2.0-fold relative increase in serum creatinine (Cr); stage 2, >2- to 3-fold increase in serum Cr; and stage 3, >3-fold increase in serum Cr or serum Cr >4.0 mg/dL with an acute increase of >0.5 mg/dL. Dialysis was an in-hospital outcome identified using a predefined National Cardiovascular Data Registry data element for acute or worsening renal failure, necessitating new renal dialysis. Associations between acute kidney injury and cardiovascular and renal outcomes after coronary angiography. *Circulation*. 2011;123(4):409-416.)

The limitations of our understanding of the epidemiology of CI-AKI should be emphasized. The literature has been impacted by inconsistent definitions of AKI based on temporal changes in the serum Cr level. This variation makes comparison of different populations and studies challenging. Earlier studies, including some that established risk prediction models for AKI in the context of cardiac procedures, used an increase in serum Cr of >0.5 mg/dL or a relative 1.5- to 3-fold increase (coupled with assessment of urine output) as the definition of CI-AKI. These criteria established in 2004 by the Acute Dialysis Quality Initiative are referred to as the RIFLE criteria (risk, injury, failure, loss, ESRD).

The RIFLE definition correlates with progression to CKD and mortality. In 2007, these definitions were further modified by the Acute Kidney Injury Network (AKIN). The AKIN criteria included a more sensitive definition of acute Cr change, using a relative increase of >0.3 mg/dL. Although this latter definition may identify more cases of AKI, the differential impact on outcome prediction versus the RIFLE criteria remains modest at best. Lastly, the Kidney Disease Improving
Global Outcomes (KDIGO) criteria combined elements of both RIFLE and AKIN but kept the 0.3 mg/dL cutoff for AKI.\(^\text{17}\)

More problematic for the study of CI-AKI is the reliance on the serum Cr as the biomarker of renal damage. Increases in serum Cr, regardless of the definitions used, require serial measures and are temporally delayed from the acute injury. Serum Cr also provides no information as to the anatomic location or mechanism of injury. In this regard, novel biomarkers of glomerular and tubular injury offer promise as more sensitive and specific measures of AKI. Most relevant in the context of contrast administration are serum cystatin C, which provides a sensitive approximation of glomerular function, and urinary tubular markers such as neutrophil gelatinase-associated lipocalin (NGAL), liver-type fatty acid binding protein (LFABP), and kidney injury molecule-1 (KIM-1). Beyond the scope of this discussion are additional numerous molecules and signaling markers that are actively being investigated as alternatives to the serum Cr for the detection of CI-AKI.\(^\text{18}\)

### RISK FACTORS FOR CONTRAST-INDUCED ACUTE KIDNEY INJURY

Mild, transient decreases in glomerular filtration rate (GFR) occur after contrast administration in almost all patients and are usually subclinical.\(^\text{19}\)

There is a brief increase in renal blood flow followed by prolonged vasoconstriction within the kidneys after contrast exposure. The development of clinically significant CI-AKI can be predicted based on the presence or absence of specific risk factors (Table 19-1). A multivariable analysis of prospective trials has shown that baseline renal impairment, diabetes mellitus, congestive heart failure, and higher doses of contrast media increase the risk of CI-AKI.\(^\text{20,21}\)

Other risk factors include reduced effective arterial volume (eg, due to dehydration, nephrosis, cirrhosis) or concurrent use of potentially nephrotoxic drugs such as nonsteroidal anti-inflammatory agents and aminoglycosides. Multiple myeloma has been suggested as a potential risk factor for CI-AKI, but a large retrospective study failed to demonstrate an increased risk in these patients.\(^\text{22}\)

Of all these risk factors, preexisting renal impairment appears to be the single most important; patients with diabetes mellitus and renal impairment, however, have a substantially higher risk of
CI-AKI than patients with renal impairment alone.\textsuperscript{23,24}

A growing population of individuals at risk for CI-AKI are those with symptomatic peripheral arterial disease (PAD). PAD impacts 8 to 12 million Americans and is a rising epidemic, driven by the aging of the population and increasing rates of diabetes. Management of symptomatic PAD, spanning the spectrum from claudication to critical limb ischemia, has evolved in the past decade to an endovascular first approach. Within the context of peripheral angiography, the specific risk factors for CI-AKI remain poorly defined. Extrapolating from the coronary experience, concerns related to total contrast volume, atheroembolism, and volume status remain key components of risk assessment and prevention. Pooled data would suggest the incidence of CI-AKI is approximately 10% to 15%.\textsuperscript{25}

CLINICAL FEATURES
The vast majority of patients who develop CI-AKI are asymptomatic, contributing to the lack of universal awareness of this complication. CI-AKI manifests usually as a decrease in GFR without hematuria and is typically nonoliguric. Nonoliguric AKI is generally more common in patients initially having a lower serum Cr prior to receiving contrast. In oliguric AKI, the time course of the oliguria and the rise in serum Cr depend on the preprocedure baseline serum Cr. Patients with normal renal function or mild renal functional impairment prior to receiving radiocontrast agents usually have oliguria lasting 2 to 5 days, with recovery to baseline renal function by day 7. Dialysis is infrequently required.\textsuperscript{24,26} Some degree of residual renal impairment has been reported in as many as 30\% of those affected by CI-AKI.\textsuperscript{24} Other comorbidities such as sustained hypotension, hypovolemia, atheroembolism, and the concurrent use of nephrotoxic medications can also contribute to CI-AKI after coronary angiography and intervention. The occurrence of CI-AKI usually prolongs the hospital stay.\textsuperscript{27} Finally, mortality is increased in patients who develop CI-AKI. In a retrospective study, Levy et al.\textsuperscript{28} compared the outcomes of hospitalized patients with CI-AKI to a control group of patients matched for age, baseline serum Cr, and type of diagnostic procedure who did not develop CI-AKI. The mortality in the CI-AKI group was 34\% compared with 7\% in the control group ($P < .001$; odds ratio, 5.5), even after controlling for baseline factors and in-hospital comorbidities.\textsuperscript{28}

The antidiabetic agent metformin may lead to the development of lactic acidosis in the setting of CI-AKI. This complication is rare and occurs only if the contrast administration results in significant renal failure and the patient continues to take metformin. In a recent review of this subject, no conclusive evidence was found to indicate that the use of contrast precipitated metformin-induced lactic acidosis in patients with serum Cr <1.5 mg/dL or 130 μmol/L at baseline. The complication was almost always observed in non–insulin-dependent diabetic patients with decreased renal function before injection of contrast media. Thus, while there is no justification to discontinue metformin before the day of the contrast-requiring procedure, it is recommended that patients not take this drug for 48 hours or so after contrast administration and resume taking the drug only if there are no signs of nephrotoxicity. This is especially true for patients in high-risk subgroups, described earlier.\textsuperscript{29}
DIAGNOSIS OF CONTRAST-INDUCED ACUTE KIDNEY INJURY

CI-AKI usually develops within 24 to 72 hours following a radiocontrast study. In 2012, the KDIGO guidelines defined CI-AKI as a rise in serum Cr of ≥0.3 mg/dL within 48 hours of contrast exposure or a rise in serum Cr ≥1.5 times the baseline within a week of exposure or urine volume <0.5 mL/kg/h for a 6-hour period after contrast administration. Because the urine output is commonly influenced by intravenous fluids and diuretics, most patients are diagnosed with CI-AKI based on the serum Cr. One interesting feature of oliguric CI-AKI is the presence of a low fractional excretion of sodium during the initial stages, despite the absence of clinical evidence of volume depletion. The urinalysis microscopic exam demonstrates renal tubular epithelial cell casts or coarsely granular brown casts, but may occasionally be negative. Even in the absence of a rise in serum Cr, radiocontrast agents may still alter the urinary sediment, showing epithelial cells, epithelial cell casts, granular or muddy brown coarsely granular casts, and occasional crystals. Hence, routine urinalysis is not particularly specific and is not recommended after contrast procedures.

A persistent nephrogram 24 to 48 hours after the contrast study has been reported to be a sensitive indicator of the presence of renal failure (83% of patients with renal failure had a positive nephrogram) with high specificity (93% of patients without renal failure lacked the persistent nephrogram). The persistent nephrogram has been related to an abnormal and persistent intrarenal vasoconstriction after contrast exposure.

PATHOPHYSIOLOGY

There are 3 core elements that are intertwined in the pathophysiology of CI-AKI: (1) direct toxicity of iodinated contrast to nephrons; (2) micro-showers of atheroemboli to the kidneys; and (3) contrast- and atheroemboli-induced intrarenal vasoconstriction. Direct toxicity to nephrons with iodinated contrast has been demonstrated and appears to be related to the osmolality of the contrast. Hence, low ionic or nonionic and low-osmolar or iso-osmolar contrast agents have been shown to be less nephrotoxic in vitro. Micro-
showers of cholesterol emboli are thought to occur in up to 50% of percutaneous interventions where a guiding catheter is passed through the aorta. Most of these showers are clinically silent. However, in approximately 1% of high-risk cases, an acute cholesterol emboli syndrome can develop manifested by AKI, mesenteric ischemia, decreased microcirculation to the extremities, and in some cases, embolic stroke. Because AKI occurs after coronary artery bypass surgery with nearly the same risk predictors as in patients undergoing contrast procedures, it is thought that atheroembolism may be a common pathogenic feature of both causes of renal failure. Finally, intrarenal vasoconstriction as a pathologic vascular response to contrast media and (perhaps) to cholesterol emboli is a third mechanism leading to hypoxic/ischemic injury to the kidney. Hypoxia triggers activation of the renal sympathetic nervous system and results in a reduction in renal blood flow, especially in the outer medulla (Fig. 19-3). It is important to note that animal studies do not demonstrate agreement regarding the direct vasoconstrictive and/or vasodilatory effects of contrast on the kidney. In humans with vascular disease, endothelial dysfunction, and glomerular injury, it is believed that contrast and the multifactorial insult of renal hypoxia provokes a vasoconstrictive response and, hence, mediates in part an ischemic injury. The most important predictor of CI-AKI is underlying renal dysfunction. The “remnant nephron” theory postulates that after sufficient chronic kidney damage has occurred and the estimated GFR (eGFR) is reduced to <60 mL/min/1.73 m², the remaining nephrons must pick up the remaining filtration load, have increased oxygen demands, and are thus more susceptible to ischemic and oxidative injury.
Pathophysiology of contrast-induced nephropathy (CIN) involves acute ischemia to the outer medulla, the most vulnerable part of the kidney, due to direct cellular toxicity and sustained intrarenal vasoconstriction and reduction in renal blood flow. This process is worsened by multiple factors including hypoxia, anemia, and systemic hypoperfusion. (Adapted from Brezis M, Rosen S. Hypoxia of the renal medulla—its implications for disease. *N Engl J Med*. 1995;332(10):647-655. Copyright © 1995 Massachusetts Medical Society. Reprinted with permission from Massachusetts Medical Society.)

It is important to distinguish CI-AKI from cholesterol emboli syndrome (CES) or atheroembolic renal disease. The incidence of CES following coronary angiography has been reported to be 1.4% in a recent study. Scolari et al. retrospectively reported that 15 of 16,223 vascular procedures were complicated with CES, which had an incidence of 0.09%. In contrast, an autopsy study reported that the overall prevalence of CES was 25% to 30% of patients after cardiac catheterization. Ramirez et al. noted cholesterol emboli at autopsy in 30% of patients who died within 6 months after undergoing aortography and 25.5% of patients who died within 6 months after undergoing coronary angiography. In contrast, the incidence of cholesterol embolism was 4.3% in age-matched controls who had not
undergone a previous invasive vascular procedure. The cholesterol emboli in the control group may have resulted from spontaneous erosion of atheromatous plaques or from previous anticoagulant or thrombolytic therapy. In patients with CES occurring after angiographic and vascular surgical procedures, the interval from the inciting event to the onset of renal symptoms may vary greatly. Some patients have immediate clinical features, but in others, the onset can be more insidious, with a delay of weeks or months between the precipitating event and clinical features. In 17 patients who developed atheroembolization after an arteriographic procedure, Frock et al found the mean interval between the inciting event and diagnosis of atheroembolic renal disease to be 5.3 weeks. Contrast media–associated nephrotoxicity immediately follows the radiographic study. There is an increase in Cr level a few days after the procedure (usually within 72 hours); peak Cr level elevation occurs approximately 1 week after exposure and returns to baseline within 10 to 14 days. Conversely, atheroembolic renal damage frequently has a delayed onset (days to weeks) and a protracted course; the outcome is often poor, resulting in progressive renal failure requiring dialysis. When a fulminant disease develops rapidly after angiography, the concomitant cutaneous, neurologic, and gastrointestinal complications usually accompany renal atheroembolic disease. The recent development of transcatheter aortic valve replacement, which is performed in patients with high levels of comorbidities including CKD, has brought interest to the combination of embolic and chemotoxic injury with this procedure. During predilation of the aortic valve or balloon aortic valvuloplasty, it is possible that showers of cholesterol, calcium hydroxyapatite, and fibrotic material are received into the renal arterial bed. This, in addition to higher contrast volumes than in diagnostic angiography or PCI, is believed to be part of the explanation for the high rates of more severe cases of CI-AKI. A systematic review found 13 studies with more than 1900 patients reporting rates of CI-AKI defined by the Valve Academic Research Consortium (VARC) criteria, which correspond to the KDIGO definition presented previously, that ranged from 8.3% to 57% of the patients. The following factors were associated with CI-AKI: blood transfusion; transapical access; higher preoperative Cr concentration; peripheral vascular disease; hypertension; and procedural bleeding events. Not unexpectedly, the 30-day mortality rate in patients with CI-AKI ranged from 13.3% to 44.4% and was
2-6-fold higher than in patients without CI-AKI. Interestingly, the amount of contrast agent used (typically >200 mL) was not associated with the occurrence of CI-AKI in most, but not all, studies.

RENAL PROTECTION FOR PATIENTS UNDERGOING CONTRAST PROCEDURES

Renal protection for CKD patients at risk (eGFR <60 mL/min/1.73 m²) can be thought of in 3 separate spheres: (1) long-term cardiorenal protection, (2) removal of renal toxins, and (3) prevention measures carried out before contrast exposure. Long-term cardiorenal protection involves 2 important concepts. The first concept is blood pressure control in CKD to a target of approximately 125/75 mm Hg. The second concept is to use an agent that blocks the renin-angiotensin system, such as an angiotensin-converting enzyme inhibitor (ACEI) or an angiotensin receptor blocker (ARB), but not both used together. Of note, either agent will cause a chronic rise in Cr >25% above the baseline in approximately 10% of cardiovascular patients. Even with an increase in Cr, the benefits of ACEI/ARB agents with respect to a reduction in new cases of ESRD, CHF, or cardiovascular death appear compelling. It has been sufficiently shown that these benefits extend to nondiabetics and to African Americans with CKD.

Removal of toxins largely refers to the discontinuation of nonsteroidal anti-inflammatory agents, aminoglycosides, and cyclosporin. These agents all complicate contrast procedures and increase the risk of CI-AKI. Prevention measures done prior to contrast exposure include volume expansion, approaches to reduce the direct cellular toxicity of the contrast, and measures to reduce the intrarenal vasoconstriction, which occurs uniquely in CKD patients when exposed to iodinated contrast.

PREDICTION OF CONTRAST-INDUCED ACUTE KIDNEY INJURY
CKD is defined through a range of eGFR values, and the class of CKD at baseline is strongly associated with the frequency of CI-AKI and the risk of dialysis, as shown Figure 19-4. Most studies of cardiovascular outcomes have associated the development of CI-AKI, restenosis, recurrent myocardial infarction, diastolic/systolic heart failure, and cardiovascular death with an eGFR below 60 mL/min/1.73 m², which roughly corresponds to a serum Cr of >1.5 mg/dL in the general population. Because Cr is a crude indicator of renal function and often underestimates renal dysfunction in women and the elderly, calculated measures of eGFR or Cr clearance (CrCl) by the Cockcroft-Gault equation or by the Modification of Diet in Renal Disease (MDRD) equations, now available on the Web, personal digital assistants, and hand-held plastic estimators are the preferred methods of estimating renal function. The 4-variable MDRD equation for CrCl is the preferred method because it does not rely on body weight. This equation is given below:

\[
\text{CrCl} = \frac{141 \times \text{eGFR} \times \text{body weight (kg)}}{72.5 \times \text{serum Cr (mg/dL)}}
\]

186.3*(serum Cr^{-1.154})*(age^{-0.203}); calculated values are multiplied by 0.742 for women and by 1.21 for African Americans

In addition, microalbuminuria (defined as random urine albumin/Cr ratio of 30-300 mg/g) at any level of eGFR is considered to represent CKD and has been thought to occur as the result of endothelial dysfunction in the glomeruli. It is critical to understand that the risk of CI-AKI is related in a curvilinear fashion to the eGFR, as shown in Figure 19-4. Multivariate prediction scoring schemes have been developed and indicate that patients with multiple risk factors can have a very high, if not certain, expectation for the development of CI-AKI after contrast exposure during coronary angiography or PCI (Fig. 19-5). For example, a hypotensive, critically ill patient with heart failure, anemia, diabetes, and an eGFR <60 mL/min/1.73 m² faces an estimated 57.3% risk of CI-AKI and a 12.6% risk of needing dialysis with a contrast procedure (derived from Fig. 19-5).
FIGURE 19-5 Risk prediction scheme for the development of contrast-induced acute kidney injury and for serious renal failure requiring dialysis after coronary angiography or percutaneous coronary intervention. Anemia, baseline hematocrit value <39% for men and <36% for women; CHF, congestive heart failure functional class III/IV and/or history of pulmonary edema; CIN, contrast-induced nephropathy; eGFR, estimated glomerular filtration rate; hypotension, systolic blood pressure <80 mm Hg for at least 1 hour requiring inotropic support with medications or intra-aortic balloon pump (IABP) within 24 hours periprocedurally. (Reproduced with permission from Mehran R, Aymong ED, Nikolsky E, et al. A simple risk score for prediction of contrast-induced nephropathy after percutaneous coronary intervention: development and initial validation. J Am Coll Cardiol. 2004;44(7):1393-1399. Copyright © 2004, with permission from American College of Cardiology Foundation.)

PREVENTIVE STRATEGIES

For patients with significant CKD, that is, a baseline eGFR <60 mL/min/1.73 m² or other evidence of renal disease such as proteinuria, a CI-AKI prevention strategy should be employed. In general, at an eGFR of 30 mL/min/1.73 m², the expected rate of CI-AKI is 30% to 40%, and the rate of AKI requiring dialysis is approximately 2% to 8%; with transcatheter aortic valve replacement, the rates could be doubled. These rates may be even higher and can be accurately predicted from multiple risk factors, as shown in Figure 19-5, in the setting of the cardiac catheterization laboratory. There are 4 basic concepts in CI-AKI prevention: (1) intravascular volume expansion; (2) choice and quantity of contrast; (3) pre-, intra-, and postprocedural end-organ protection with pharmacotherapy; and (4) postprocedural monitoring and expectant care.

Volume supplementation with intravenous (IV) normal saline or isotonic sodium bicarbonate solution remains key, starting 3 to 12 hours prior to the procedure at a rate of 1 to 2 mL/kg/h. A simple IV rate to remember from clinical trials of IV volume expansion is 100 to 150 mL/h. In those at risk, at least 300 to 500 mL of IV fluid should be received before contrast is administered. If there are any concerns regarding volume overload or heart failure, a right heart catheterization may be considered for management during and after the case. A urine output of 150 mL/h should be the target infusion rate after the procedure. Importantly, if patients have diuresis of more than 150 mL/h, they should have replacement of extra losses with more
IV fluid. In general, this strategy calls for IV fluid orders of 150 mL/h for at least 6 hours after the procedure. When adequate urine flow rates were achieved in a clinical trial setting, there was a 50% reduction in the rate of CI-AKI observed.\(^{68}\)

A small but growing line of data point to the benefits of a hemodynamically tailored volume expansion protocol approach. The Prevention of Contrast Renal Injury with Different Hydration Strategies (POSEIDON) trial randomized 396 patients to volume expansion guided by the left ventricular end-diastolic pressure (LVEDP) or by conventional weight-based isotonic saline volume expansion.\(^{69}\) The results demonstrated a significant reduction in CI-AKI in the LVEDP-guided group (6.7% vs 16.3%; \(P = .005\)). Similar in concept, Qian et al\(^{70}\) examined the role of central venous pressure (CVP)-guided volume expansion versus conventional IV fluid orders in patients with heart failure and CKD undergoing invasive angiography. The findings demonstrated a lower incidence of AKI in the CVP-guided group (15.9% vs 29.5%; \(P = .006\)). In the latter 2 trials, tailored volume expansion was not associated with the development pulmonary edema. Thus, it appears that CI-AKI is responsive to volume expansion, and via the mechanism of enhanced renal tubular transit of contrast, this clinical maneuver is associated with lower rates of CI-AKI.

Using lower osmolality contrast agents and limiting the amount of contrast administered are associated with lower rates of CI-AKI. This has now been confirmed in 2 large-scale, double-blind, randomized controlled trials. In the Iohexol Cooperative Study (n = 1196), iohexol (Omnipaque) was found to be superior to high-osmolality contrast (diatrizoate meglumine [Hypaque-76]) in patients with diabetes and baseline CKD.\(^{24}\) In the recently completed Nephrotoxicity in High-Risk Patients Study of Iso-Osmolar and Low-Osmolar Non-Ionic Contrast Media Study (NEPHRIC), iodixanol (Visipaque), a nonionic, iso-osmolar contrast agent was proven to be superior to iohexol with lower rates of CI-AKI observed.\(^{71}\) A meta-analysis of head-to-head randomized trials has found that iso-osmolar iodixanol is associated with lower rates of prespecified CI-AKI than low-osmolar agents (Fig. 19-6); however, these differences are limited to the intra-arterial administration of iodinated contrast and not IV injections.\(^{72}\)
FIGURE 19-6 Forest plot of clinical trials with contrast-induced acute kidney injury (CI-AKI) as a prespecified outcome that compared iso-osmolar iodixanol (IOCM) versus low-osmolar contrast agents (LOCM). This plot demonstrates a 53.8% relative risk (RR) reduction in CI-AKI with iodixanol. CI-AKI is defined as ≥0.5 mg/dL increase in serum creatinine from baseline. CI, confidence interval. (Reproduced with permission from McCullough PA, Brown JR. Effects of intra-arterial and intravenous iso-osmolar contrast medium (iodixanol) on the risk of contrast-induced acute kidney injury: a meta-analysis. Cardiorenal Med. 2011;1(4): 220-234. Copyright © 2011 Karger Publishers, Basel, Switzerland.)

Although it is logically desirable to limit the amount of contrast to the smallest volume possible, there is disagreement as to whether there is a “safe” contrast limit.\textsuperscript{73} This is mainly due to the fact that the lower the eGFR, the smaller is the amount of contrast needed to cause CI-AKI. In general, it is desirable to limit contrast to <100 mL for any procedure or no more than 2 times the eGFR in contrast volume.\textsuperscript{10,59} If staged procedures are planned, it is desirable to have >10 days between the first and second contrast exposure if CI-AKI has occurred on the first contrast exposure.\textsuperscript{74}

There have been over 40 randomized trials testing various strategies in the prevention of CI-AKI. The majority of trials have been small and underpowered and did not find the preventive strategy to be better than placebo. A few lessons have been learned from these trials: (1) diuretics in the form of loop diuretics or mannitol can actually worsen CI-AKI if there is inadequate volume replacement for the diuresis that follows; (2) low-dose or
“renal dose” dopamine and fenoldopam did not provide renal protection, presumably because of counterbalancing forces of intrarenal vasodilatation via the dopamine-1 receptor versus the vasoconstrictive effects on the dopamine-2, α, and β receptors; and (3) nephrotoxic agents including nonsteroidal anti-inflammatory agents, aminoglycosides, and cyclosporine should not be administered in the periprocedural period.

Although there are currently no approved agents for the prevention of CI-AKI, smaller studies of oral or IV N-acetylcysteine (NAC), a cytoprotective agent against oxidative injury, have not been validated in larger scale trials, which have found neutral results compared to placebo. If NAC is going to be used for emergent or urgent procedures involving radiocontrast, a dose of 1 g orally 1 hour before and 4 hours after radiocontrast exposure may be given. In one trial of NAC, patients with mild to moderate CKD undergoing PCI were randomized to receive NAC plus IV fluid or IV fluid alone. An NAC infusion (150 mg/kg) was given IV before contrast exposure and was continued (50 mg/kg) over the following 4 hours. Thus, in a 70-kg patient, the cumulative NAC dose was 14,000 mg—a significantly higher dosage than that used in previous studies (~2400 mg). In the 2 groups, the contrast volumes were 238 mL and 222 mL, and CI-AKI occurred in 5% and 21% of cases, respectively (P = .045). The Veterans Administration Clinical Trials Investigators will be conducting a very large (n = ~9000), randomized, placebo-controlled trial of NAC in a factorial with IV volume expansion with saline or bicarbonate with the primary outcome being CI-AKI. The outcomes from the trial are needed to firmly make a recommendation for the routine use of NAC.

As indicated earlier, there have been many small trials of other strategies including aminophylline, endothelin receptor antagonists, ascorbic acid, dopamine, fenoldopam, and a variety of other agents, all of which have been either neutral or of equivocal benefit. There have been 8 clinical trials involving the use of aminophylline or theophylline in the prevention of CI-AKI, of which 2 studies did not show any protective effect and 6 showed a positive effect in prevention of CI-AKI. A recent meta-analysis of studies employing theophylline or aminophylline for prevention of CI-AKI identified a statistically significant favorable effect on the decline in kidney function. However, the authors note the translation of this effect to clinically meaningful benefit (reduced need for dialysis or in-hospital mortality)
remains to be proven.\textsuperscript{87} Because endogenous adenosine activates intrarenal adenosine receptors causing vasoconstriction, the adenosine antagonism provided by aminophylline may have a favorable effect on renal blood flow. Therefore, aminophylline is considered optional as a preventive strategy and certainly can be continued in pulmonary patients who are already taking the drug.

Prophylactic continuous hemofiltration has been proposed as an interventional strategy to prevent CI-AKI in advanced CKD patients.\textsuperscript{88} Hemofiltration works to (1) guarantee preprocedure IV fluid infusion, (2) provide hemodynamic stability before and after procedure, and (3) provide a blood milieu lower in uremic toxins, thus allowing remnant nephrons to work more efficiently. A recent trial of hemofiltration before and after contrast exposure in patients with advanced CKD (mean Cr, 3.0 mg/dL) resulted in lower CI-AKI rates compared to a control group (5\% vs 50\%; \(P \lt .001\)) (Fig. 19-7). Temporary hemodialysis was required in 25\% of the control patients and in 3\% of the patients in the hemofiltration group.\textsuperscript{88} This trial needs replication. However, at the time of this writing, for patients with severe CKD, prophylactic hemofiltration as done in the trial in an intensive care unit setting 4 to 6 hours before the coronary procedure and for 18 to 24 hours after the procedure is a reasonable option. The hemofiltration circuit requires a Y-shaped 12-Fr double-lumen catheter placed in a femoral vein. Blood is driven through the circuit at a rate of 100 mL/min. The flow of isotonic replacement fluid is set at a rate of 1000 mL/h and is exactly matched with the rate of ultrafiltrate production so that no net fluid loss results. A heparin bolus of 5000 IU is required before hemofiltration, and heparin is continued at a rate of 500 to 1000 IU per hour through the inflow side of the circuit. In most centers, this process will be managed by nephrologists and their dialysis staff.
FIGURE 19-7 The lines represent changes in creatinine (Cr), blood urea nitrogen (BUN), and urine output in 114 patients randomized to prophylactic hemofiltration versus control. Changes from baseline in the Cr and BUN concentrations were significant ($P < .01$) before the procedure and on days 1, 2, and 3 in the hemofiltration group and at day 2, day 3, and discharge in the control group; the difference between the 2 groups was significant beginning on day 1. Control urine output rates differed

It is important to realize that treatment before the procedure is critical and that preemptive dialysis after contrast exposure has not been shown to prevent CI-AKI. Vogt et al. evaluated prophylactic hemodialysis started soon after the administration of the contrast agent and continued for an average of 3 hours. The rationale for the study was to remove the contrast agent efficiently by hemodialysis, thus reducing the concentration of contrast agent to which the kidneys would be exposed. However, this strategy did not show any beneficial effect as compared with saline treatment alone, and patients who were treated with hemodialysis were more likely to have a decline in renal function and to require additional hemodialysis treatment.

A possible explanation for the difference in results with postprocedure hemodialysis compared with periprocedural continuous hemofiltration is that hemodialysis may induce hypovolemia and consequently may worsen renal ischemic injury, delay recovery of renal function, and result in a need for prolonged treatment. On the other hand, hemofiltration is associated with hemodynamic stability and, by preserving the volume of circulating blood, safeguards against renal hypoperfusion. This effect is particularly useful when coronary procedures are performed in patients with critical conditions such as myocardial infarction or acute cardiovascular events such as pulmonary edema or severe left ventricular dysfunction. In addition to hemodynamic stability, hemofiltration provides controlled high-volume hydration and removal of contrast agent from the circulation, with a resultant reduction in the kidneys’ exposure to the agent. It can also be speculated that in addition to high-volume controlled hydration, the removal of mediators of contrast media–induced toxicity by convective filtration and adsorption to the filter membrane may play a significant role.

Once CI-AKI has been recognized, there is no specific treatment, and management involves supportive treatment of AKI, including dialysis treatment as needed. Most operators believe that, given the seriousness of CI-AKI as a complication, the relative safety of the strategies used, and the evolution of clinical trials shaping our practice, the combination of intensive
IV fluid administration (saline or possibly sodium bicarbonate) and use of iodixanol in as low a volume as reasonable is a prudent approach to minimize CI-AKI and the risk of AKI requiring dialysis.

Postprocedural monitoring is an issue in the modern era of short stays and outpatient procedures. In general, high-risk patients in the hospital should have IV volume expansion started 3 to 13 hours before the procedure and continued for at least 6 hours afterward (Fig. 19-8). A serum Cr should be measured 24 hours after the procedure. For outpatients, particularly those with eGFR <60 mL/h, either an overnight stay or discharge to home with 24- to 48-hour follow-up and Cr measurement is advised. It has been demonstrated that individuals who develop severe CI-AKI have a rise in Cr >0.5 mg/dL in the first 24 to 48 hours after the procedure. Hence, for those who have not had this degree of Cr elevation, and otherwise have had uneventful courses, discharge to home may be considered.

**FIGURE 19-8** Suggested algorithm for patients undergoing coronary angiography and intervention. All patients should have the estimated glomerular filtration rate (eGFR) calculated and have an assessment for contrast-induced acute kidney injury (CI-AKI) risk based on validated multivariate scoring schemes. ACS, acute coronary syndrome; AKI, acute kidney injury; Cr, creatinine; CrCl, creatinine clearance; DM,
diabetes mellitus; NSAIDs, nonsteroidal anti-inflammatory drugs; TAVR, transcatheter aortic valve replacement.

In summary, for CI-AKI risk assessment and prevention, the action items as shown in Figure 19-8 are advised. It is important that in the consent process CI-AKI risks are discussed. For patients with eGFR <30 mL/min/1.73 m$^2$, the possibility of dialysis should be mentioned. Finally, in patients with eGFR <20 mL/min/1.73 m$^2$, nephrology consultation is advised with possible planning for dialysis after the procedure.

CONCLUSION

CIN is an important cause of AKI and death in critically ill patients. The presence of multiple risk factors can anticipate up to an approximate 50% probability of CI-AKI in specific patients. Risk prediction and preventive measures are mandatory. Once AKI occurs, even with dialysis and expectant management, high rates of in-hospital and long-term mortality can be expected.

**MULTIPLE CHOICE QUESTIONS**

1. Which of the following statements is true about contrast-induced acute kidney injury (CI-AKI)?
   A. It is the most common cause of hospital-acquired renal failure.  
   B. The incidence of CI-AKI is well defined in the literature and is
approximately 20%.
C. One percent of episodes of CI-AKI require dialysis.
D. Episodes of CI-AKI not requiring dialysis add, on average, 7 days to the hospitalization.

2. Which of the following statements is true about transient rises in serum creatinine following contrast administration?
   A. Changes >0.1 mg/dL are considered significant.
   B. A rise of >0.3 mg/dL in serum creatinine occurs in approximately 7% of patients undergoing percutaneous coronary intervention (PCI).
   C. Transient rises in serum creatinine have not been associated with adverse long-term outcomes.
   D. Definitions of CI-AKI have had consistent criteria with respect to acute changes in serum creatinine.

3. Which of the following statements is true about biomarkers for CI-AKI?
   A. Tubular markers for AKI, including liver-type fatty acid binding protein, kidney injury molecule-1, and neutrophil gelatinase-associated lipocalin, have improved sensitivity for renal injury as compared to serum creatinine.
   B. Serum creatinine changes provide rapid detection of renal injury following contrast administration.
   C. Cystatin C is a tubular marker that is upregulated during AKI.
   D. Changes in urine creatinine levels are more reliable than serum creatinine for AKI.

4. Which of the following occurs after contrast administration?
   A. Prolonged renal vascular vasodilation
   B. A brief increase in renal blood flow followed by prolonged vasoconstriction
   C. No acute changes in renal perfusion
   D. An acute decline in renal vein renin levels

5. Which of the following statements is true about management and prevention of CI-AKI?
   A. Metformin-induced lactic acidosis is most common in non–insulin-dependent diabetics with underlying renal dysfunction.
B. Volume expansion is important only prior to contrast administration.
C. Use of N-acetylcysteine has been definitively shown to prevent CI-AKI in most patients.
D. The use of fenoldopam has been reliably shown to reduce the incidence of CI-AKI.

Contemporary Patient Sedation and Anesthesia in the Cardiovascular Catheterization Laboratory

Igor O. Zhukov
Kathryn E. Glas
Deborah Dunn
Vasilis Babaliaros

Sedation for patients undergoing procedures in the cardiac catheterization laboratory (CCL) can be managed by the primary physician with nursing staff or by a dedicated anesthesiology team. The choice of sedation and/or anesthetic techniques is dependent on institutional policies, patient and physician preference, and the type of procedure being performed. This discussion will focus on interventional procedures in the CCL and not hybrid operating room procedures that add an additional layer of complexity and more often than not will be staffed with an anesthesia team.

CCL sedation offers patient comfort (analgesia and anxiolysis) during invasive procedures requiring patients to hold still, potentially for long periods, without resorting to general anesthesia. In pediatric populations and uncooperative adults, either deep sedation or general anesthesia, provided by an anesthesiology care provider, is typically warranted. General anesthesia may also be warranted for patients who cannot lie flat due to cardiac or pulmonary pathology or joint pain. General anesthesia is also frequently used for patients requiring transesophageal echocardiography as part of their procedure.
At times, these sedation practices may result in cardiac or respiratory depression; these must be rapidly recognized and appropriately managed to avoid the risk of hypoxic brain damage, cardiac arrest, or death. Conversely, inadequate sedation/analgesia may result in undue discomfort, patient injury due to lack of cooperation, or adverse physiologic or psychological response to stress.¹

In general, patients managed with moderate sedation will have a shorter recovery period prior to return to their hospital room or discharge home. There may also be a shorter room turnover time for patients managed with sedation versus general anesthesia. Patients receiving general anesthesia must be recovered in a unit staffed with nurses trained in recovery of postanesthesia patients. If this unit is distant from the interventional area, room turnover will be delayed during transport of patients and transfer of care to the recovery team. Moderate sedation administered by a nurse under the supervision of the cardiologist may decrease the resource utilization and total institutional cost for the procedure by avoiding usage of these additional resources.

DEFINITION OF SEDATION

Sedation (minimal, moderate, or deep) and general anesthesia are defined points on an otherwise continuous scale of sedation defined by anesthesiologists (Table 20-1). At the origin of this scale, the individual is fully awake and conscious; at the opposite end, he or she is unarousable, apneic, and possibly hemodynamically unstable.

Table 20-1 Levels of Sedation and Anesthesia and Accompanying Physiologic Parameters²
- Minimal sedation (anxiolysis): A drug-induced state during which patients respond normally to verbal commands. Although cognitive function and coordination may be impaired, ventilatory and cardiovascular functions are unaffected.

- Moderate sedation/analgesia (conscious sedation): A drug-induced depression of consciousness during which patients respond purposefully (reflex withdrawal from a painful stimulus does not constitute a purposeful response) to verbal commands, either alone or accompanied by light tactile stimulation. No interventions are required to maintain a patent airway, and spontaneous ventilation is adequate. Cardiovascular function is usually maintained.

- Deep sedation/analgesia: A drug-induced depression of consciousness during which patients cannot be easily aroused but respond purposefully (again, reflex withdrawal from a painful stimulus does not constitute a purposeful response) following repeated or painful stimulation. The ability to independently maintain ventilatory function may be impaired. Patients may require assistance in maintaining a patent airway, and spontaneous ventilation may be inadequate. Cardiovascular function is usually maintained.

- General anesthesia: A drug-induced loss of consciousness during which patients are not arousable, even by painful stimulation. The ability to independently maintain ventilatory function is often impaired. Patients often require assistance in maintaining a patent airway, and positive-pressure ventilation may be required due to depressed spontaneous ventilation or drug-induced depression of neuromuscular function. Cardiovascular function may be impaired.
Because sedation is a continuum, it is not always possible to predict how an individual patient will respond to a given sedation strategy. Consequently, practitioners intending to produce a given level of sedation should be able to care for and rescue the patient whose level of sedation becomes deeper than initially intended. Individuals administering moderate sedation/analgesia (conscious sedation) should be able to rescue patients who enter the state of deep sedation/analgesia; those administering deep sedation/analgesia should be able to manage the situation where the patient enters the state of general anesthesia.

Each hospital is normally accredited by the specific credentialing body regarding the types of practitioners who can provide sedation outside of the operating room, as well as which levels of sedation are allowed. These policies are not universal across institutions but will provide both guidance and limitations of the sedation practice and establish minimum standards of care. Additionally, there may be provisions regarding provider recertification, equipment use, and other elements particular to a given hospital.

**PREOPERATIVE ASSESSMENT**

A thorough history and physical examination are the first steps in selecting the proper sedation technique for the specific patient and the procedure. Special emphasis should be given to the history of previous anesthetic problems, medication and contrast dye allergies, and tolerance to alcohol and recreational drugs, as these may alter the sedation approach. It is also advisable to inquire about rare but potentially critical complications such as family history of malignant hyperthermia, use of medications with potential for serious adverse reactions such as long-term amiodarone, cancer chemotherapy with bleomycin or doxorubicin, and severe or debilitating illness.¹

Physical examination should address, at a minimum, pulmonary and cardiovascular status as well as assessment of the airway. The most common airway assessment tool is the Mallampati³ score, which assigns grades I to IV based on soft palate and uvula visualization with the patient’s mouth opened (Fig. 20-1). Patients with scores of III and IV, as well as those with receding mandibles (defined as having <3 fingerbreadths distance between the chin and the hyoid bone), obese patients, or patients with full beards, may be more
difficult to ventilate and may present a challenge should endotracheal intubation become necessary. Finally, a review of past anesthetic records may clarify the degree of difficulty in managing the patient’s airway when the physical exam is nonreassuring or if the patient has a history of airway surgery.

**FIGURE 20-1 The Mallampati score for airway assessment.** (Reproduced from Mallampati et al. A clinical sign to predict difficult tracheal intubation: a prospective study. *Can Anesth Soc J.* 1985;32.4:429-434, with permission of Springer.)
Based on the results of the history and physical examination, a given patient can be classified as 1 of the 6 American Society of Anesthesiologists (ASA) classes (Table 20-2). The ASA classification stratifies the complexity of the patient’s comorbidities in order to develop the sedation management strategy, predict outcome expectations, and assist with resource management. Additionally, the ASA status is often included in the research data as an overall means of intraoperative complication risk assessment.¹ For patients receiving sedation, a minimum 6-hour fasting period is recommended, with the exception of clear fluids, which can be continued to within 3 hours of the procedure. The fasting time should be increased in patients with known delayed gastric emptying to mitigate aspiration risk.¹ ⁴

Treatment with metoclopramide or a nonparticulate antacid may benefit some patients with delayed gastric emptying or increased gastric acid secretion, but indiscriminate use in all patients is not recommended.⁴

PERSONNEL AND EQUIPMENT

The ASA taskforce recommends that a designated individual, other than the
practitioner performing the procedure, should be present to monitor the patient throughout a procedure that is performed with sedation/analgesia; during deep sedation, this individual should have no other responsibilities. However, during moderate sedation, this person may assist with minor, interruptible tasks once the patient’s level of sedation/analgesia and vital signs have stabilized, provided that adequate monitoring for the patient’s level of sedation is maintained.

Individuals responsible for patients receiving sedation/analgesia should understand the pharmacology of the administered agents, as well as the role of pharmacologic antagonists for opioids and benzodiazepines. Individuals monitoring patients receiving sedation/analgesia should be trained to recognize the associated complications. At least 1 individual capable of establishing an advanced airway and positive-pressure ventilation as well as means for summoning additional assistance should be available whenever sedation/analgesia is administered. It is recommended that an individual with advanced life support skills be immediately available (within 5 minutes) for moderate sedation and within the procedure room for deep sedation.

Pharmacologic antagonists and appropriately sized equipment for establishing an advanced airway and providing positive-pressure ventilation with supplemental oxygen should be present whenever sedation/analgesia is administered. Suction, advanced airway equipment, and resuscitation medications should be immediately available and in good working order (Table 20-3). A functional defibrillator should be immediately available when deep sedation is administered or when moderate sedation is administered to the patient with cardiovascular disease.1

</tbody>
</table>
• Sterile gauze pads
• Intravenous catheters [24-22 gauge]
• Intravenous tubing [pediatric “microdrip” (60 drops/mL)]
• Intravenous fluid
• Assorted needles for drug aspiration, intramuscular injection
  • [Intraosseous bone marrow needle]
• Appropriately sized syringes [1-mL syringes]
• Tape

Basic airway management equipment
• Source of compressed oxygen (tank with regulator or pipeline supply with flowmeter)
• Source of suction
• Suction catheters [pediatric suction catheters]
• Yankauer-type suction
• Face masks [infant/child]
• Self-inflating breathing bag-valve set [pediatric]
• Oral and nasal airways [infant/child-sized]
• Lubricant

Advanced airway management equipment (for practitioners with intubation skills)
• Laryngeal mask airways [pediatric]
• Laryngoscope handles (tested)
• Laryngoscope blades [pediatric]
• Endotracheal tubes
  • Cuffed 6.0, 7.0, 8.0 mm internal diameter (ID)
  • [Uncuffed 2.5, 3.0, 3.5, 4.0, 4.5, 5.0, 5.5, 6.0 mm ID]
• Stylet (appropriately sized for endotracheal tubes)

Pharmacologic antagonists
• Naloxone
• Flumazenil

Emergency medications
• Epinephrine
• Ephedrine
• Vasopressin
• Atropine
• Nitroglycerin (tablets or spray)
• Amiodarone
• Lidocaine
• Glucose 50% [10% or 25%]
• Diphenhydramine
• Hydrocortisone, methylprednisolone, or dexamethasone
• Diazepam or midazolam

Supplemental oxygen should be considered for moderate sedation and should be administered during deep sedation unless specifically contraindicated for a particular patient or procedure. Supplemental oxygen should be administered if hypoxemia is anticipated or is encountered during sedation/analgesia.

PATIENT MONITORING

The standards for intraoperative monitoring of patients undergoing procedures under general anesthesia are, for the most part, applicable to the sedation setting.

Oxygenation monitoring is accomplished by pulse oximetry, which is rapid, quantitative, and reliable. It uses a minimum of 2 wavelengths of light to detect concentrations of oxyhemoglobin and deoxyhemoglobin and displays an empirically derived numeric value of percent hemoglobin saturation. When coupled with a variable pitch audio output, this monitor provides a continuous background of information about both the patient’s heart rate and blood oxygenation, and it is one of the essential monitors recommended by ASA during general anesthesia and deep sedation.¹,⁵

Ventilation monitoring is dramatically different between the sedation in the CCL and an in the operating room equipped with the anesthesia machine. Usually the CCL environment lacks the mechanical ventilation devices that monitor tidal volumes, circuit integrity, and airway pressures and analyze inhaled and exhaled gas continuously. However, most modern patient monitors have the capacity for capnogram capture; the use of capnography is recommended by the ASA for all cases where sedation is used, unless precluded or invalidated by the nature of the patient, procedure, or
equipment. The capnography unit can be programmed to alert the practitioner in the event that patient’s respiratory rate is too low, indicating the potential for hypoventilation, as well as in case of the total absence of carbon dioxide, which can be caused by apnea, oxygen delivery/sampling line disconnection from the patient, or cardiovascular collapse.

It is a common misconception that pulse oximetry provides enough data to not require capnography; this assumption is quite dangerous because the patient may maintain a normal pulse oximetry profile while being totally apneic for a significant amount of time. Once the hypoxia ensues, sometimes minutes after the cessation of ventilation, the patient will require a much more involved resuscitation and may possibly require positive-pressure ventilation to restore homeostasis. However, if an appropriate intervention, such as airway repositioning, patient stimulation to breathe, or administration of sedative antagonist, is performed at the time of capnography tracing loss, the procedure can usually continue with minimal interruption.

Patients with depressed, but not totally suppressed, ventilation may also display normal pulse oximetry reading but can develop severe hypercarbia and respiratory acidosis, producing symptoms of somnolence, restlessness, or cardiovascular disturbances. If one suspects inadequate ventilation, an arterial blood gas may be necessary to rule out hypoventilation and respiratory acidosis.

*Circulation monitoring* is accomplished with several modalities; continuous electrocardiography monitoring is recommended for the duration of the procedure because it is reliable, simple, and noninvasive. When used appropriately, it allows a reliable monitoring of cardiac ischemia and will alert to cardiac rhythm disturbances quicker than other monitoring modalities. The most commonly monitored leads are II and V₅, which together provide 80% sensitivity for myocardial ischemia. Modern telemetry machines are capable of monitoring 5 or more leads, automatically alerting the provider if ST-segment morphology change is detected.

It is also recommended by the ASA that a blood pressure assessment be performed at least every 5 minutes when using an automated blood pressure cuff or a sphygmomanometer and a stethoscope. For patients with an arterial line in place for blood pressure monitoring or the arterial access for the procedure, it is still recommended to place a noninvasive blood pressure cuff because these require no calibration and thus are not subject to calibration errors. Additionally, arterial lines may fail due to thrombosis or malposition.
Meanwhile, arterial sheath pressure transducers may have to be disconnected in the course of the procedure for the transit of catheters or devices; usually, these events are the ones that require more thorough blood pressure monitoring. The blood pressure cuff should fit snugly around the patient’s limb and must be sized appropriately so that the inflatable part covers at least 80% of the limb’s circumference.5

The ASA also made the following statement pertaining to patients undergoing general anesthesia: “[A] secondary circulatory function assessment [should be performed] by at least one of the following: palpation of a pulse, auscultation of heart sounds, monitoring of a tracing of intra-arterial pressure, ultrasound peripheral pulse monitoring, or pulse plethysmography or oximetry for an additional layer of safety.” This may be applicable to deep sedation cases, and this requirement is easily satisfied because CCL patients will commonly have the pulse oximetry data.

Temperature monitoring is applicable in general anesthetic cases where the patient’s control of homeostatic functions, such as vasoconstriction and shivering, is impaired. It is reasonable to consider monitoring patient’s body temperature during procedures that are prolonged or require levels of sedation that preclude the patient from alerting the provider that he or she is getting cold. Prevention of hypothermia with forced air heating blankets and minimization of the patient’s exposure should be a part of the procedure plan if there is a potential for hypothermia due to exposure of the large areas of patient’s body for prolonged periods of time of if there is an anticipated infusion of a large volume of intravenous fluids.

SEDATION PROCEDURE OVERVIEW

After confirming the patient’s identity and the type of procedure, as well as confirming informed consent, the patient may be premedicated if it is indicated and is a part of the sedation plan. Usually the premedication is an anxiolytic, unless the patient has underlying pain that needs to be treated. An intravenous line may be established prior to premedication, or afterward if nonintravenous premedication is chosen. Often premedication may be omitted, and the patient may arrive to the CCL fully conscious if he or she is not anxious or uncooperative.1

The choice of intravenous line gauge lies with the sedation provider, but
these flexible catheters often range between 18 and 22 gauge and are 1 to 2 inches in length, unless an indication for larger-bore access exists.

After application of selected monitors, described earlier, a combination of sedative and analgesic agents may be administered as appropriate for the procedure being performed and the condition of the patient. Ideally, each component should be administered individually to achieve the desired effect (eg, additional analgesic medication to relieve pain or additional sedative medication to decrease awareness or anxiety). The propensity for sedative and analgesic agents to synergistically cause respiratory depression and airway obstruction emphasizes the need to appropriately reduce the dose of each component as well as the importance of continuous monitoring of the respiratory function. Intravenous sedative/analgesic medications should be given in small, incremental doses that are titrated to the desired effect of analgesia and sedation. Sufficient time must be allowed between doses to assess the effect of the preceding dose prior to the subsequent drug administration. This time interval becomes more critical when the medications are administered by nonintravenous routes (eg, oral, rectal, intramuscular, transmucosal), since medication absorption by routes other than intravenous may be unpredictable. The administration of repeat doses of oral medications to supplement sedation/analgesia is not recommended.1,6

SEDATIVES

Benzodiazepines

Benzodiazepines enhance the effect of the neurotransmitter γ-aminobutyric acid (GABA) at the GABAA receptor, resulting in sedative, hypnotic, anxiolytic, euphoric, anticonvulsant, and muscle-relaxing properties, as well as an amnestic effect.

Benzodiazepines are the most commonly used sedative agents due to their anxiolytic properties, with midazolam being the most frequent choice. Midazolam has a quick onset (1-2 minutes) and short duration of action (typically 15-30 minutes), and it provides better amnesia than other benzodiazepines. Of all the intravenous sedatives, midazolam produces the least amount of discomfort on injection, a property not shared by other
Diazepam (onset 1-5 minutes; terminal half-life \( t_{1/2} \) 30-60 hours) and lorazepam (onset 15-20 minutes; \( t_{1/2} \) 14 hours) can also be used if a longer acting sedative is required. Diazepam is painful on injection and may cause phlebitis; it also has an active metabolite, desmethyldiazepam, with a half-life of 30 to 100 hours. Both diazepam and lorazepam may result in longer recovery and delayed dismissal. Benzodiazepines should be avoided in pregnancy, especially in the first trimester, because of known risk of birth defects. Elderly individuals have an increased risk for delirium and confusion with benzodiazepine administration, and these should be used sparingly. Small initial doses of midazolam for frail or elderly individuals who do not receive benzodiazepines routinely should be used, with incremental subsequent doses repeated until the appropriate levels of anxiolysis and sedation are achieved. Benzodiazepines can be largely avoided by the use of topical anesthetic, low-dose analgesics, and reassurance by the treatment team in a select group of patients during short, minimally uncomfortable procedures. Many institutions also have dosage limits above which consultation with an anesthesia provider is indicated regardless of the intended sedation level.

Benzodiazepines can produce paradoxical excitation in less than 1% of the population. Patients with psychiatric disorders and those taking other psychoactive substances both medically and recreationally should be monitored more closely, and the risk of administration of benzodiazepines should be carefully weighed.

Overdose of benzodiazepines generally results in excessive somnolence, inability to maintain the airway, and depressed ventilation. Supportive measures and cessation of the offending agent administration are often sufficient for the patient to recover.

Flumazenil is a specific competitive benzodiazepine receptor antagonist that can be used to reverse sedative effects of all benzodiazepines. Flumazenil doses of approximately 0.1 to 0.2 mg produce partial antagonism, whereas higher doses of 0.4 to 1 mg usually produce complete antagonism in patients who have received the usual sedating doses of benzodiazepines. These small incremental doses can be administered every minute until a desired reversal effect is attained. The use of flumazenil may be complicated by its short duration of action (distribution half-life of 4-11 min, \( t_{1/2} \) of 40-80 minutes), leading to the patient slipping back into an overly sedated state when the
effect of flumazenil diminishes; repeat doses may be required.

Chronic benzodiazepine administration is a relative contraindication to flumazenil as these patients may experience seizures due to rapid withdrawal of GABA stimulation. Patients with heavy alcohol use also fall in the relative contraindication category due to potential risk of precipitating delirium tremens.

**Opioids**

Opioids are frequently used as adjuncts to benzodiazepines to provide analgesia for the uncomfortable portions of the procedure, such as establishment of vascular access, use of electrocautery, or defibrillation. Opioids and benzodiazepines are synergistic in their respiratory depressant effects, and caution is warranted when administering them simultaneously.

Fentanyl is the most commonly used opioid due to almost instantaneous onset of action, short duration of action (intravenous, 30-60 minutes; intramuscular, 1-2 hours), and more favorable hemodynamic profile than morphine or meperidine due to minimal histamine release. Fentanyl is estimated to be 50 to 100 times more potent that morphine at equal doses. The typical intravenous bolus dose for an adult ranges from 25 to 100 μg and may be repeated until a desired effect is achieved.

Fentanyl, like other opioids, will cause respiratory depression, and this effect may last beyond the duration of analgesia, necessitating careful postprocedure monitoring and patient counseling before discharge. Opioids increase the incidence of nausea, and their use must be weighed against potentially longer recovery to discharge.

Administration of large doses or rapid administration of fentanyl may cause chest wall rigidity, which can transiently make ventilation of the patient nearly impossible. This can be confused with bronchospasm or laryngospasm, but the temporal proximity of fentanyl injection to the appearance of symptoms should help the practitioner to decipher the etiology. A larger dose than is used in sedation practice is usually the culprit, but doses as low as 50 to 100 μg were implicated in several case reports. Treatment may consist of opioid reversal with naloxone, and in extreme cases, an induction of general anesthesia, administration of a muscle relaxant, and tracheal intubation may be required.
The symptoms of opioid overdose that warrant opioid reversal are generally excessive sedation and/or respiratory depression. Classically, the patient with relative opioid excess will take breaths on command but will have blunted response to respiratory acidosis and hypercarbia. Withdrawing the offending agent and allowing for the patient to recover are often all that is necessary. A specific opioid antagonist, naloxone, can be used in extreme overdose incidents.

Naloxone is a competitive antagonist at the μ-opioid receptor with a rapid onset (usually less than a minute if administered intravenously) and an approximate duration of action of 45 minutes. Similarly to flumazenil, the short duration of action can result in recurrence of overdose symptoms when a longer acting opioid was used.

Naloxone will cause immediate withdrawal symptoms in patients who are chronically treated with opioids, and it must be used with caution, if at all, in the opioid-dependent patients. The usual naloxone dose for total opioid reversal is 0.2 to 2 mg; it can be administered intravenously, intramuscularly, via endotracheal tube, or even intranasally, although the onset by intravenous route is the fastest. The starting dose of naloxone for partial opioid reversal should be 0.05 to 0.4 mg intravenously repeated every minute until respiratory rate is >12 breaths per minute.

Side effects of naloxone may include hypertension, tachycardia, flash pulmonary edema, nausea, vomiting, diaphoresis, and withdrawal symptoms. An extended period of patient monitoring is recommended if the reversal agent was used.8

Propofol

Propofol is an intravenous sedative-hypnotic that is not typically used by nonanesthesia personnel in spontaneously ventilated patients due to high risk of apnea associated with dose titration and the subsequent need for airway management. Many states have laws preventing the administration of propofol by nonanesthesiologists, unless the patient is intubated and mechanically ventilated. The advantage of propofol for the purpose of sedation, despite its higher cost, is the rapid sedation onset and recovery, with fewer lingering sedation-related side effects and no increase in cardiopulmonary complications compared with the benzodiazepine-narcotic combination. Propofol is also least likely to cause nausea and has antiemetic
properties when given in small doses to a postoperative patient, a practice that is considered off-label. Anticipated propofol use in the catheterization lab requires coordinated scheduling with the anesthesiology services, thus increasing scheduling complexity.

Propofol is a nonbarbiturate sedative with minimal analgesic effect, rapid (40 seconds) onset, and short duration of action, lasting between 2 and 5 minutes after a 2-mg/kg intravenous bolus. Propofol’s action is produced at the GABA$_A$ receptor, where it increases the duration of channel opening, similarly to the mechanism of action of barbiturates and benzodiazepines. It is rapidly redistributed from the central nervous system, which accounts for its short duration of action despite the half-life of 1 to 3 hours. Sedation with propofol for a prolonged period of time increases the half-life to several days due to saturation of propofol redistribution sites. This phenomenon is known as context-sensitive half-life and is not unique to propofol, as many other drugs rely on redistribution as the primary means of terminating their effect.\(^8\)

Propofol is contraindicated in individuals who have allergies to egg or soy products and glycerol, as the formulation contains 10% soybean oil, 1.2% egg phospholipid emulsion, and 2.25% glycerol. This formulation causes pain on injection, especially if injected rapidly and into a small vessel. A new aqueous-based formulation of the prodrug, fospropofol, is being investigated because it may be less painful during injection.

Propofol dosing for sedation is ideally accomplished with a 0.1 to 0.5 mg/kg initial bolus to rapidly achieve the drug concentration in the bloodstream immediately prior to the stimulating part of the procedure such as procedural vascular access, as well as the infusion of 25 to 75 μg/kg/min for the maintenance of sedating effect. Elderly and severely debilitated patients or those receiving additional sedatives or hypnotics should receive a lower initial dose, and the infusion should commence at 5 to 10 μg/kg/min and be titrated carefully.

There is no specific antidote for propofol overdose; the treatment consists of supportive measures, intubation, mechanical ventilation, cardiovascular support with inotropes and vasopressors, and allowing patient’s metabolism to resolve the overdose.

Various studies comparing cost-effectiveness of propofol-based sedation to the conventional strategies demonstrated increased, decreased, or equivalent cost. Evaluation of the utility and cost-effectiveness of propofol-
based sedation in the given setting is necessary to determine whether the increase in cost and the need for the anesthesiologist’s or anesthetist’s involvement are offset by the potentially faster recovery and dismissal and increased patient satisfaction scores.\textsuperscript{10,11}

**Ketamine**

Ketamine is a phencyclidine derivative analgesic and a dissociative anesthetic, better known for its use in the emergency department for procedural sedation. The profound analgesic effect of ketamine is employed during short but painful procedures without the need for a general anesthetic; it is also widely used in veterinary medicine.

Ketamine acts on the $N$-methyl-$D$-aspartate receptor in the central nervous system causing a dissociative state in which the patient’s respiration and cardiovascular status remain unchanged but the memory and pain perception are impaired.

The initial dose of ketamine for sedation is 1 to 2 mg/kg intravenous bolus. There appears to be a minimum dose threshold for the dissociative effect, and sedation is not increased with additional dosing. A single intravenous dose of ketamine will maintain analgesia and sedation for 5 to 10 minutes, and the patient may typically be dismissed within 1 to 2 hours of the administration. During ketamine sedation, the response to painful stimuli may be absent, which would be consistent with general anesthesia (see Table 20-1), yet ventilation will be maintained at a level comparable to minimal or moderate sedation. This threshold nature of ketamine, with all-or-none effect, may result in difficulty when estimating the depth of sedation.\textsuperscript{8,12}

A unique niche for ketamine is in patients with pericardial tamponade, where spontaneous ventilation, avoidance of further cardiac chamber compression, and maintenance of the cardiovascular tone are preferred while the pericardiocentesis is performed. Given the potential for complications during open pericardiocentesis, it may be prudent for a cardiac anesthesiologist to lead the sedation efforts. After prepping and draping the patient and having the sterile field ready for the procedure, a small premedication dose of midazolam (0.5-2 mg) followed by an induction dose of ketamine (2-4 mg/kg intravenous) will render the patient sufficiently sedated for the procedure. Repeat doses of ketamine at 0.5 to 1 mg/kg may be necessary to maintain the sedation while the procedure is under way.
Ketamine may cause hallucinations, vivid dreams, and out-of-body experiences, some of which may be quite unpleasant. An amnestic dose of benzodiazepine as a premedication prior to ketamine administration may diminish these objectionable recollections. A transient increase in intracerebral and intraocular pressure after induction is common; nausea and vomiting occur with incidence of approximately 8%, limiting ketamine utility in routine cases.

Another side effect of ketamine is hypersalivation, which may play an important role if the advanced airway management is required; this can be mitigated with administration of an anticholinergic medication such as glycopyrrolate 0.2 mg intravenously.

Absolute contraindications to ketamine are central nervous system mass lesions leading to deterioration with increasing intracerebral pressure, glaucoma or a ruptured eye globe, and hyperthyroidism or pheochromocytoma/paraganglioma, which are exacerbated by ketamine’s sympathomimetic effect.12

**Etomidate**

Etomidate is an intravenous anesthetic with an imidazole molecular structure. It possesses amnestic and anesthetic, but not analgesic, properties and is traditionally used as a general anesthesia induction agent, as well as for short procedural sedation. Etomidate acts on the GABA$_A$ receptor, similarly to benzodiazepines, barbiturates, and propofol.

A typical general anesthesia induction dose is 0.2 to 0.6 mg/kg intravenously with 30- to 60-second onset and 5- to 10-minute duration. Etomidate terminates its action via redistribution from the target tissue, and its elimination half-life is approximately 75 minutes. With the administration of etomidate, the patient’s cardiovascular status is usually maintained, and the intracerebral pressure is lowered, resulting in increased cerebral perfusion pressure; this feature is unique to etomidate and is not shared by other intravenous agents. Ventilation is maintained with sedative doses of etomidate but may become impaired once general anesthesia level is achieved.8

Etomidate is one of the drugs of choice for inducing a general anesthesia in patients with impaired cardiac function, such as critical mitral or aortic
stenosis, or severely depressed ejection fraction, because any decrease in cardiac contractility or vascular tone may be poorly tolerated. Similarly to ketamine, etomidate can be useful in patients with cardiac tamponade for similar reasons.

Etomidate causes pain during injection, a property shared with propofol, and amnestic premedication may lessen or eliminate the patient’s recollection of the burning at the intravenous site on induction. Additionally, etomidate reversibly inhibits 11-β-hydroxylase, an enzyme responsible for cortisol production.

Etomidate-induced adrenal suppression may last up to 72 hours, thus making the drug unsuitable for repeated or continuous sedation. In a recent analysis of over 2600 patients receiving etomidate or propofol during noncardiac surgery, there was an observation of increased mortality (odds ratio, 2.5), cardiac morbidity (odds ratio, 1.5), and length of hospital stay. These findings are based on a retrospective study, and thus, an argument can be made that patients receiving etomidate were more unstable, therefore prompting the use of etomidate. Nonetheless, etomidate should probably be reserved for patients with a clear indication for its hemodynamic-preserving properties and not used for routine sedation.

**Dexmedetomidine (Precedex)**

Dexmedetomidine is a fairly novel (approved for use in 1999) sedative with an unusual target receptor. It is an α₂-agonist in the central nervous system. Elimination half-life is biphasic, with a 6-minute redistribution half-time and 2-hour t₁/₂. Both liver and kidneys are involved in its elimination.

Dexmedetomidine has anxiolytic and hypnotic effects and is used for intensive care unit sedation as well as procedural sedation. It also decreases sympathetic tone, which may be beneficial to counteract the increased sympathetic activation caused by an uncomfortable procedure. The slow onset of drug action necessitates the use of a loading dose (0.5-1 μg/kg over 5-10 minutes) with subsequent maintenance infusion of 0.5 to 1.4 μg/kg/h. There is minimal to no respiratory depression when the drug is used as prescribed, and the patient may be awoken from the sedation by verbal or tactile stimulation, indicative of the moderate sedation. Ideally, dexmedetomidine infusion is started in advance of the uncomfortable parts of
the procedure, so that a plane of sedation can be attained. This baseline anxiolysis and anesthesia is then supplemented by small boluses of rapid and short-acting analgesic as needed.

Another use for dexmedetomidine is a sedative for a fast-track extubation of a patient who needs a more gradual wean from ventilatory support following a procedure under general anesthesia. This is accomplished by titrating down the infusion rate to 0.2 to 0.5 μg/kg/h and waiting for patient emergence, at which point the patient may be weaned off the ventilator support while experiencing the benefit of mild anxiolysis through the low-dose infusion.

It is worth noting that peripheral α2 receptor activation may produce hypotension and bradycardia as a result of the presynaptic inhibition of the sympathetic nervous system. The responses to activation of the receptors in other areas include decreased salivation, decreased bowel motility, contraction of vascular and other smooth muscle, inhibition of renin release, increased glomerular filtration, increased secretion of sodium and water by kidneys, decreased intraocular pressure, and decreased insulin release from the pancreas, all of which are of less importance in the CCL.14

SPECIAL CONSIDERATIONS FOR MANAGEMENT OF SEDATION IN THE CARDIAC CATHETERIZATION LABORATORY

The CCL has been the primary location for percutaneous therapy of coronary and peripheral arterial disease. Percutaneous therapies for patients with structural, congenital, and valvular heart disease have significantly increased over the last decade and can also be performed in the CCL. Transfemoral transcatheter aortic valve replacement (TAVR) has only recently transitioned from the hybrid operating room (OR) with general anesthesia to the CCL, using nurse-driven moderate sedation and hemodynamic support. Currently, the TAVR procedure in the CCL requires 4 team members fulfilling specific roles. A registered nurse (RN) is solely devoted to handling respiratory management, hemodynamic support, and patient comfort. A registered
cardiovascular interventional specialist (RCIS) or RN is required to monitor and co-circulate. A certified RCIS or RN is required to scrub for valve preparation.

The TAVR patient population has unique needs related specifically to their age, comorbidities, and concurrent procedure. Thus, pharmaceutical and associated care must be individualized. Timely administration of medication at key points during the procedure (eg, femoral access, artery dilation, valve manipulation and valve placement, and/or closure) is important to maintain patient comfort while also reducing the total amount of medications needed to evoke a moderate sedative state. Patients typically receive supplemental oxygen via nasal cannula at 2 to 4 L/min. Due to the high percentage of frail patients with arthritic complications, patient comfort measures are made to facilitate a positive experience and circumvent any procedural delay due to positional complaints. To reduce pain secondary to prolonged positioning, support is placed under knees and ankles. Normothermia is accomplished by an external convective warming system, an under body blanket, and minimization of patient exposure during procedure preparation.

Maintaining adequate patient comfort and minimizing sedation result in stable hemodynamics and the ability to assess the patient for acute neurologic events. The circulating nurse is also in charge of administrating intravenous fluids and hemodynamic agents during the TAVR procedure. If the pre-TAVR left ventricular end-diastolic pressure is <15 mm Hg, a fluid bolus of balanced salt solution (250-500 mL) should be given to prevent fluctuations in blood pressure during the subsequent procedure. Immediately after valve deployment, patients with hypertrophic ventricles may require 250- to 1000-mL fluid boluses to maintain adequate preload and blood pressure. Small doses of background sympathomimetics may be required to support patient hemodynamics, particularly prior to balloon aortic valvuloplasty and during valve placement. Patients with low systolic blood pressure (<100 mm Hg) who are euvolemic should be treated with vasoactive agents (eg, norepinephrine at 0.025-0.1 μg/kg/min; Table 20-4) prior to rapid pacing. These background agents facilitate smoother recovery of hemodynamic status while at the same time reducing the total amount of agents required to recover the patient. As the procedure progresses with further manipulation of the stenotic aortic valve, vasopressor support can be titrated to effect. Adequate systolic blood pressure is mandatory to maintain sufficient coronary perfusion and prevent subendocardial ischemia. After the
deployment of the valve, vasopressors should be weaned gradually as the patient’s hemodynamics return to normal.

Not all patients are candidates for TAVR with conscious sedation. Patients requiring alternative access points (eg, transapical, transaortic, transcarotid, femoral cut down, retroperitoneal access for vascular conduit, transcaval) should have general anesthesia and a hybrid OR environment. Individuals with high tolerance for opioids or benzodiazepines, inability to lie flat for the duration of the procedure, severe obstructive sleep apnea, severe dementia with inability to cooperate, or poor acoustic windows for TTE should be considered for general anesthesia.

Patients undergoing general anesthesia will require longer recovery periods than those with moderate sedation; however, many patients can be extubated immediately after the conclusion of the TAVR procedure. The use of general anesthesia does not preclude patients from leaving the procedure room spontaneously ventilating, with transfer to a floor bed after a standard recovery period. Patients undergoing transapical/transaortic procedures or with severe sleep apnea are typically recovered in an intensive care setting with gradual weaning of mechanical ventilation.

By offering moderate sedation procedures in the CCL and general anesthetic in the hybrid OR, we are able to provide excellent outcomes at both locations while serving a greater number of TAVR patients overall. This hybrid practice should be considered in any center where hybrid room
availability or anesthesia staffing is at a premium.

Transfemoral TAVR can be successfully performed with moderate sedation in the CCL or with general anesthesia in the OR. Successful management of these patients requires additional equipment and personnel, whether a specially trained nurse is administering the sedation with midazolam and fentanyl, or an anesthesia team is providing deep sedation or general anesthesia with propofol, dexmedetomidine, volatile anesthetic, or a combination thereof. As of September 2014, our center has performed >250 TAVR procedures with moderate conscious sedation, and 95% of our patients with transfemoral access undergo the procedure awake in the CCL. Our initial experience comparing 140 patients with different levels of sedation demonstrated equivalent safety, a shorter length of stay, decreased resource utilization, and lower cost when using moderate sedation in the CCL.¹⁵

MULTIPLE CHOICE QUESTIONS

1. What sedation plane is described by responsiveness to verbal command accompanied by tactile stimulation, unaffected respirations, and cardiovascular stimulation?
   A. Minimal sedation/anxiolysis
   B. Moderate sedation
   C. Deep sedation
   D. General anesthesia
   E. Awake state

2. During a preoperative examination, a patient’s mouth was examined, and only a small part of the uvula and soft palate were visible. Which Mallampati score should be assigned?
   A. I
   B. II
   C. III
   D. IV

3. Which benzodiazepine has the shortest half-life and is the most practical in the setting of short procedural sedation?
   A. Midazolam
   B. Diazepam
   C. Lorazepam
   D. Flumazenil

4. Which sedating agent has as its target site a central α-receptor?
   A. Propofol
   B. Ketamine
   C. Dexmedetomidine
   D. Etomidate
   E. Midazolam

5. A patient with which of the following conditions is most appropriate for transcatheter aortic valve replacement (TAVR) under moderate sedation?
   A. Hypertension, obesity with body mass index of 53, heart failure,
orthopnea, obstructive sleep apnea
B. Diabetes, hypertension, dyslipidemia, esophageal stricture due to lye ingestion
C. Chronic obstructive pulmonary disease, aortoiliac occlusive disease
D. History of chronic back pain, claustrophobia, and panic attacks

ANSWERS

1. B

Minimal sedation (anxiolysis) is a drug-induced state during which patients respond normally to verbal commands. Although cognitive function and coordination may be impaired, ventilatory and cardiovascular functions are unaffected. Moderate sedation/analgesia (conscious sedation) is a drug-induced depression of consciousness during which patients respond purposefully to verbal commands, either alone or accompanied by light tactile stimulation. No interventions are required to maintain a patent airway, and spontaneous ventilation is adequate. Cardiovascular function is usually maintained. Deep sedation/analgesia is a drug-induced depression of consciousness during which patients cannot be easily aroused but respond purposefully following repeated or painful stimulation. The ability to independently maintain ventilatory function may be impaired. Patients may require assistance in maintaining a patent airway, and spontaneous ventilation may be inadequate. Cardiovascular function is usually maintained. General anesthesia is a drug-induced loss of consciousness during which patients are not arousable, even by painful stimulation. The ability to independently maintain ventilatory function is often impaired. Patients often require assistance in maintaining a patent airway, and positive-pressure ventilation may be required due to depressed spontaneous ventilation or drug-induced depression of neuromuscular function. Cardiovascular function may be impaired.

2. C

Mallampati score is one of the tools that allow screening for potentially challenging airways.
- Class I: Soft palate, uvula, fauces, pillars visible
- Class II: Soft palate, uvula, fauces visible
- Class III: Soft palate, base of uvula visible
- Class IV: Only hard palate visible

3. A

The elimination half-life of midazolam is estimated to be approximately 3 hours, much shorter than the diazepam half-life of 30 to 60 hours and lorazepam half-life of 14 hours. That, coupled with rapid distribution of midazolam from the action site, accounts for rapid onset and offset of sedation. Flumazenil is a benzodiazepine antagonist that is not used for sedation routinely. Its half-life is short (4- to 11-minute redistribution and 40- to 80-minute elimination), which explains the occasional need to repeat reversal treatment, especially for overdose of a long-acting benzodiazepine.

4. C

Benzodiazepines, propofol, and etomidate all produce their sedating effect via the γ-aminobutyric acid receptor. Ketamine acts via an N-methyl-D-
aspartate receptor. Dexmedetomidine is a selective $\alpha_2$-agonist in the central nervous system, similarly to clonidine.

5. B

Patient B has a contraindication to transesophageal echocardiography probe placement and no indicated contraindication to sedation in the abbreviated medical history. The procedure can be done in the cath lab with sedation and transthoracic echocardiography. Patient A may have poor transthoracic echocardiography windows and inability to lay flat for prolonged periods of time, making TAVR under sedation potentially challenging. Patient C may require alternative access (transapical, transaortic, transcaval) to place her transcatheter valve, given her peripheral vascular disease. Patients in whom femoral cut down is required are also suboptimal candidates for TAVR under moderate sedation. Patient D will most likely be unable to tolerate prolonged sedation and immobility. While there is no clear-cut guideline about a patient’s psychosocial dysfunction impacting sedation, this patient would be better served with either deep sedation or general anesthesia in a hybrid operating room and under the care of an anesthesiologist.

Prior to Gruentzig’s seminal development of balloon angioplasty, coronary arteriograms were largely used to discriminate patients with and without coronary artery disease and to select those who should be referred for coronary bypass surgery. In the modern era, the cardiac interventionalist must be supremely competent in performing, interpreting, and understanding the studies that define the coronary anatomy and cardiac function. The unique demands of decision making for interventional cardiology require a new understanding of the principles and procedures that enable percutaneous coronary revascularization to be performed. To this end, acquiring high-quality diagnostic cardiac angiographic studies is critical. This chapter will review special considerations of coronary and left ventricular angiography.

INDICATIONS FOR CORONARY ARTERIOGRAPHY

In the 2014 ACC/AHA/AATS/PCNA/SCAI/STS Focused Update of the Guideline for the Diagnosis and Management of Patients With Stable Ischemic Heart Disease: A Report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines,¹
the indications for coronary arteriography are summarized as below:

1. Patients with stable angina or asymptomatic individuals with high-risk criteria on noninvasive testing.
2. Patients resuscitated from sudden cardiac death or having threatening ventricular arrhythmias.
3. Patients with unstable coronary syndromes of all varieties, including acute myocardial infarction as a preamble to primary angioplasty and those who developed complications of acute infarction.
4. Patients with ischemia at low levels of exercise in the recovery phase of myocardial infarction.
5. Patients with suspected or known coronary artery disease undergoing preoperative evaluation.
6. Patients undergoing heart valve replacement or in those patients in whom there is a need to establish the etiology of congestive heart failure. Table 21-1 lists indications and contraindications for cardiac catheterization and coronary angiography.

### Table 21-1B Contraindications to Cardiac Catheterization

- **Absolute Contraindications**
  - Inadequate equipment or catheterization facility
- **Relative Contraindications**
  - Acute gastrointestinal bleeding or anemia
  - Anticoagulation (or known, uncontrolled bleeding diathesis)
  - Electrolyte imbalance
  - Infection and fever
  - Medication intoxication (eg, digitalis, phenothiazine)
  - Pregnancy
  - Recent cerebrovascular accident (<1 month)
  - Renal failure
  - Uncontrolled congestive heart failure, high blood pressure, arrhythmias
  - Uncooperative patient

### CLINICAL ASSESSMENT PRIOR TO CORONARY ANGIOGRAPHY

The physician should not proceed to coronary angiography without the proper workup. The subtle clinical presentations of myocardial ischemia require diligent interpretation of the patient’s complaints. The judgment of a well-trained and knowledgeable physician skilled at taking an accurate history is critical to appropriate diagnosis and treatment. A superficial history identifying chest pain of any type is not a license to perform coronary arteriography. To establish the indications for coronary arteriography, results of the medical history, the electrocardiogram, and various other indices of myocardial ischemia are needed. Understanding the relationship of increased metabolic demands on fixed lesions and understanding the pathophysiology of acute coronary syndromes is fundamental to the practice of treating patients with ischemic heart disease. Depending on the clinical findings,
stress testing during exercise or at-rest (pharmacologic) stress testing with nuclear perfusion studies or echocardiographic imaging may be needed. Interventionsal cardiologists should not let their skills in interpreting these studies lapse and should not simply read the reports. The location and extent of ischemic defects, as well as the level of exercise performed, are important in determining the relative benefit of revascularization.

Noninvasive diagnostic imaging of the coronary arteries with electron beam computed tomography or multi-slice computed tomography can identify the presence of coronary artery disease. The detection of a large amount of calcium in the coronary arteries in young individuals heralds the presence of atherosclerosis, but does not confirm obstructive disease. Multi-slice computed tomography is accurate in identifying calcification in coronary arteries, the course of vessels, and a degree of coronary obstruction. In the future, such technology may supplant diagnostic coronary arteriography; however, at this time, coronary arteriography remains the standard for selecting patients for coronary interventions and for the planning and performance of the interventional procedure.

COMPONENT PROCEDURES OF CORONARY ANGIOGRAPHY

Coronary angiography and ventriculography is accomplished by a series of linked procedures beginning with vascular access and moving to angiographic catheter passage and engagement of coronary arteries and image acquisition through appropriate imaging angulations to display the critical features of the diseased artery. With the basic information of the angiograms, the interventional procedure can proceed as detailed elsewhere. Following the intervention, vascular hemostasis is performed for the particular method through a number of vascular closure devices.

Vascular Access

Vascular access for coronary angiography is performed from either the femoral or the radial artery. In the United States, the most popular approach has been femoral access, while the radial approach is favored outside the
United States. (The brachial artery should be reserved as access of last resort when the other arteries cannot be cannulated.) The radial approach has gained acceptance in the United States of late because of the increased safety associated with reduced access site bleeding. Any debate about which vascular access is better can be summarized in one sentence: Femoral access is quicker and easier, but with more complications, while radial access is more difficult and takes more skill and time, but has fewer complications. It should be noted that neither femoral nor radial access technique can be used exclusively, due to complicated anatomy and patient-specific factors. Hence, operators are required to learn and employ both access methods. We currently recommend radial access as the default approach. The new generation of cath lab operators should be able to do procedures from both approaches with the same facility and safety.

**Radial Artery Catheterization**

Compared to the femoral artery, the superficial location of the radial artery permits easy access, is not located near significant veins or nerves, and enables secure control of bleeding. In patients with a normal Allen’s test confirming a patent dual blood supply to the hand, concerns about radial artery occlusion are negligible. Importantly, patient satisfaction is enhanced by the ability to sit up and walk immediately after the procedure.

**Patient Selection and Use of the Allen’s Test**

The Allen’s test is used to demonstrate patency of both the ulnar and radial circulation through an intact palmar arch. Most operators require a normal or near-normal test before proceeding. The Allen’s test is performed as follows: After the patient makes a fist, both the radial and ulnar arteries are occluded simultaneously. When the hand is opened, it appears blanched. Release of the ulnar artery should result in return of pink hand color within 8 to 10 seconds. Satisfactory ulnar flow can also be documented by using the pulse oximeter. The pulse wave is displayed with both arteries open. The radial artery is then compressed and the pulse wave of ulnar flow observed. The results of the oximetric Allen’s test are divided into 3 grades of wave forms during radial artery occlusion: type A, no change in pulse wave; type B, a damped but distinct pulse wave; type C, loss of phasic pulse waveform. Radial artery cannulation can proceed with either type A or B and is not recommended for
type C or D (Fig. 21-1).

**FIGURE 21-1** Top, pulse oximeter displays radial pulse as transmitted to the thumb. Compression of the radial artery may result in 1 of the 4 patterns shown at right. Modified Allen’s test to assess patency of the palmar arterial arches. Barbeau Classification. The presence of an arterial waveform (even if delayed or with reduced amplitude) and a hemoglobin oxygen saturation >90% (Barbeau grades A, B, and C) confirms the adequacy of a collateral vascular supply to the hand. An arm with an abnormal modified Allen’s test result (Barbeau grade D) should be avoided.

In addition to type C Allen’s test, we also avoid patients who have forearm dialysis A-V fistulae or in whom the radial artery may be used for coronary artery bypass graft (CABG) surgery. In patients with CABG including a left internal mammary artery (LIMA) graft, the left radial approach is usually successful.
Use of the left radial artery approach provides easier manipulation of the Judkins shapes with minimal effort. The left arm should be brought over the abdomen so that the operator can work from his or her usual position on the right of the patient. In patients of small stature (under 5’5” in height) or those with CABG with LIMA, the left radial approach is preferred.

**Technique of Radial Artery Access and Catheter Selection**

The patient should be well sedated and comfortably positioned with a movable arm board allowing the arm to be positioned at the patient’s hip after radial sheath placement. The radial pulse is palpated, and lidocaine is given. Using a 0.018-in micropuncture needle, the artery is entered at 30° to 45° angulation.

Both arterial and venous access for either the femoral or radial approaches may be facilitated with ultrasonic direct visualization transducers (Fig. 21-2). Ultrasound access may be particularly valuable in patients who have altered anatomy, obesity, or scarring caused by prior surgical procedures (eg, peripheral vascular surgery, multiple prior catheterizations, or prior intraaortic balloon pumps [IABP] or support cannulas), where standard access technique may be unsuccessful.

![Figure 21-2](image-url)

**FIGURE 21-2** Technique of Ultrasound-Guided Radial Access. A. Axial position of draped ultrasound probe over the right radial artery. The needle is inserted just below the center of the probe when the artery is in the center of the image plane. B. Visualization of radial artery and veins. C. Compression causes closure of radial veins and reveals pulsatility of artery. D. Visualization of the needle tip (arrow) compressing and puncturing the artery. E. Confirmation of wire position (arrow) in

After introducing the guide wire and sheath, a vasodilator cocktail of verapamil or other calcium channel blockers can be given, followed by heparin or bivalirudin intravenously. The arm can now be moved to patient’s side for catheter introduction.

The most common catheters selected for the radial approach are the numerous specialized ‘universal’ shapes like the Jacky, TIG or multipurpose catheter (Fig. 21-3). A decrease in catheter exchanges has been shown to decrease the incidence of upper extremity vasospasm. The standard preformed diagnostic Judkins or Amplatzer catheter shapes may also be used, but require more manipulation. For selective engagement of the left coronary ostium, a Judkins left 3.5 catheter instead of the 4.0 size is typically used.
Femoral Artery Access and Catheter Selection

The femoral artery is palpated at the inguinal (groin) ligament which is often, but not always, denoted by the skin crease. Because of the uncertainty of external landmarks, a metal clamp can be laid over the proposed entry site visualizing the tip of the clamp over the medial edge of the middle of the head of the femur. The common femoral artery, between the lower edge of the inferior epigastric artery and above the bifurcation of the superficial and profunda branches, is the optimal location for introduction of the interventional sheaths and support devices (Fig. 21-4).

The importance of correct femoral puncture to avoid bleeding complications after interventional procedures in patients who are often intensely anticoagulated cannot be underestimated. The correct puncture site above the femoral bifurcation is a requirement for utilization of various arterial closure devices. A puncture site that is above the common femoral artery engenders the high risk of retroperitoneal bleeding and, in some elective procedures, may necessitate postponement of the interventional
portion of the procedure to another time when better access can be achieved. The steps to introduce a femoral artery sheath are similar to those for the radial artery sheath, and are described in detail elsewhere.\(^5\)

For the femoral procedure, the Judkins left (JL) catheter 4.0 size is the most commonly used for diagnostic studies (Fig. 21-5). In small aortic roots, a JL 3.5 catheter may be preferred, and, in very large aortic roots, it may be necessary to move to a JL 5.0 catheter. Right coronary artery cannulation is usually accomplished with the right Judkins catheter, but in cases of high origin or anomalous takeoff from the aorta, the Amplatz right catheter may be helpful. The Amplatz curve catheters are sometimes required for entry into an ectopically placed left coronary ostium and some very large aortic roots. The Amplatz left coronary catheter is helpful in intubating high and anteriorly placed right coronary ostia. Other catheters, such as the hockey stick curve, the multipurpose catheter and the Amplatz right catheter, as well as the internal mammary catheter, can sometimes be helpful in intubating right coronary arteries. Of particular help in the anteriorly placed ostium of the right coronary artery is the out-of-plane right coronary catheter (Williams catheter).

**FIGURE 21-5 Judkins catheters and pigtail ventriculography catheter.**

Operators should familiarize themselves with several of the unique catheters available for cases of difficult coronary arteriography. For example, there is a specially designed internal mammary artery catheter, left and right coronary bypass graft catheters, and the unique Amplatz curved catheters. The Amplatz left (AL) 2 catheter is used predominantly for the left coronary
artery and the AL 1 catheter most commonly for difficult right coronary intubation.

It is uncommon to perform coronary interventions with catheter sizes smaller than 6-French (Fr). For diagnostic studies, the most commonly used catheter sizes are 6-Fr, with some operators utilizing 5-Fr and, rarely, 4-Fr catheters. The advantage of 6-Fr diagnostic catheters over the 5-Fr and 4-Fr catheters is that their shape retention and torque control is optimal. While use of smaller size catheters may reduce femoral complications, most interventions require size 6-Fr to accommodate multiple stents or non-stent devices. While it is true that femoral vascular closure devices have reduced bleeding following the interventional procedures, their particular failure mode presents a source of continued concern in some patients.

**ANGIOGRAPHIC IMAGING ANGULATIONS FOR CORONARY INTERVENTIONS**

Before PCI, the angiographer should use experience and multiple angiographic projections to do the following:

1. Establish the relationship of the coronary ostium to the aorta for guide catheter selection.
2. Verify target vessel, pathway, and angle of entry.
3. Separate associated side branches and degree of ostial atherosclerosis.
4. Visualize distribution of collateral supply.
5. Determine the true (maximally vasodilated) diameter of the coronary artery at the target site. Angiography for coronary interventions requires establishing the lesion morphology, lesion length, degree of calcification, presence of thrombus and the associated involvement of side branches, and the extent of coronary artery disease which may lead to branch closure.

The routine coronary angiographic views used for diagnostic studies are normally incorporated into the interventionalist’s training and form the basic image set used for most interventions (Table 21-2). Individualized angiography projections may be needed to visualize the origin and course of
both the major and branch vessels in at least two different projections to eliminate branch overlap. Because of the wide variation in coronary anatomy, one should expect to use several modified views. The optimal projections for viewing various segments of the coronary tree are illustrated in Figures 21-6 through 21-9.

Abbreviations: AP, anteroposterior; LAD, left anterior descending artery; LAO, left anterior oblique; PDA, posterior descending artery (from RCA); RAO, right anterior oblique; RCA, right coronary artery.

*Horizontal hearts.
FIGURE 21-6 Commonly used angulations for coronary angiography. Top from left to right: right anterior oblique (RAO), anterior posterior (AP), left anterior oblique (LAO). Middle: AP projection; Bottom left: cranial angulation, caudal angulation.

FIGURE 21-7  A. Left panel: Diagrammatic representation of the left anterior oblique (LAO) left coronary arteriogram. The image intensifier is above the patient in the LAO position, and the x-ray beam travels in a posterior-to-anterior direction. The value of this view depends in large part on the orientation of the long axis of the heart. When the heart is relatively horizontal, the left anterior descending (LAD) coronary artery and diagonal branches are seen end-on throughout much of their course. In this illustration, the heart is in an intermediate position, and there is moderate foreshortening of the LAD and diagonal branches in their proximal portions. The left anterior oblique (LAO) projection is frequently inadequate to visualize the proximal LAD and its branches; the left main branch, which is directed toward the image tube and therefore foreshortened; and the proximal circumflex coronary artery, which may be obscured by overlapping vessels as in this illustration. The LAO projection is frequently used to visualize the proximal circumflex artery when there is not overlap, the distal LAD and its branches, the mid circumflex coronary artery in the atrioventricular groove, and the distal right coronary artery when it is filling via collaterals from the left coronary artery. (D1, D2, D3 = first, second, third diagonal; OM = obtuse marginal; SP = septal perforator.) (Reproduced from King SB III, Douglas JS Jr, Morris DC. New angiographic views for coronary arteriography. In: Hurst JW, ed. Update IV: The Heart. New York, NY: McGraw-Hill; 1981.)  

Right panel: Diagrammatic illustration of the left coronary arteriogram in the 45° left anterior oblique (LAO) view with 30° cranial angulation. The image intensifier is on the patient’s left and the direction of the x-ray beam is posterior to anterior. This is the most valuable view of the left coronary artery in most patients. Foreshortening of the left main and proximal LAD arteries and diagonal branches, which occurs in the LAO view, is usually overcome by cranial angulation of the intensifier. The proximal...
left coronary artery segments are usually visualized at an angle almost perpendicular to their long axis. The ostium of the left main coronary artery, the proximal portion of the LAD, and the origin of the diagonal branches are usually well visualized without overlap. Some overlap may occur with branches of the proximal circumflex coronary artery, and this may be overcome by using a 60° LAO with 30° cranial angulation. The value of the LAO cranial view is considerably less when the proximal left coronary artery has a cephalad direction, in which case caudal angulation of the image intensifier is frequently helpful. (D1, D2, D3 = first, second, third diagonal; OM = obtuse marginal; SP = septal perforator.) (Reproduced from King SB III, Douglas JS Jr, Morris DC. New angiographic views for coronary arteriography. In: Hurst JW, ed. Update IV: The Heart. New York, NY: McGraw-Hill; 1981.) B. Cineangiographic frames of left coronary artery in the LAO. Left: Cranial projection. Right: Caudal projection.
FIGURE 21-8  A. Left: Diagrammatic illustration of the left coronary arteriogram in
the 15° right anterior oblique (RAO) view with 30° cranial angulation. This view is particularly helpful in analyzing the mid–left anterior descending (LAD) coronary artery and the origin of diagonal arteries and septal perforating arteries. Overlap with diagonal branches is usually avoided. The origin of the circumflex artery may be well seen, as in this illustration. (D1, D2, D3 = first, second, third diagonal; OM = obtuse marginal; SP = septal perforator.) (Reproduced from King SB III, Douglas JS Jr, Morris DC. New angiographic views for coronary arteriography. In: Hurst JW, ed. Update IV: The Heart. New York, NY: McGraw-Hill; 1981.) Right: Diagrammatic illustration of the left coronary arteriogram in the 30° right anterior oblique (RAO) view with 15°caudal angulation of the image intensifier. The image intensifier is positioned over the patient’s liver and the direction of the x-ray beam is posterior to anterior. This view is helpful to unravel overlapping diagonal branches to better visualize the proximal portion of the circumflex coronary artery, whose long axis was parallel to the x-ray beam in the routine RAO view, and to better visualize the mid–lateral anterior descending (LAD) artery, which overlaps diagonal branches in the standard RAO views. In this illustration, the mid-LAD is well visualized, as is a portion of the first diagonal not well visualized in the RAO view. There is slight unfolding of the proximal circumflex artery as well. (D1, D2, D3 = first, second, third diagonal; OM = obtuse marginal; SP = septal perforator.) (Reproduced from King SB III, Douglas JS Jr, Morris DC. New angiographic views for coronary arteriography. In: Hurst JW, ed. Update IV: The Heart. New York, NY: McGraw-Hill; 1981.) B. Cineangiographic frames of left coronary artery in the RAO. Left: Cranial projection. Right: Caudal projection.
**FIGURE 21-9** A. Diagrammatic illustration of the right coronary artery in the 45° left anterior oblique (LAO) projection. The image intensifier is positioned on the patient’s left and the x-ray beam travels in a posterior-to-anterior direction. This view is excellent for visualizing the proximal, mid, and distal right coronary artery in the
atrioventricular groove, because the direction of the x-ray beam is perpendicular to these arterial segments. Ostial lesions of the right coronary artery are not well visualized if the proximal right coronary artery takes an anterior direction from the aorta and therefore travels in a direction parallel to the x-ray beam. This can usually be overcome by turning to a steeper LAO projection. The posterior descending (PD) and left ventricular (LV) branches of the right coronary artery, which pass down the posterior aspect of the heart toward the apex, may be severely foreshortened, because the long axis of these vessels is in the same direction as the x-ray beam. The proximal portion of the posterior descending branches can be visualized by cranial angulation of the overhead intensifier or using a right anterior oblique view with cranial angulation. (Reproduced from King SB III, Douglas JS Jr, Morris DC. New angiographic views for coronary arteriography. In: Hurst JW, ed. Update IV: The Heart. New York, NY: McGraw-Hill; 1981.) B. Cineangiographic frames of right coronary artery in the LAO. Left: Cranial projection. Right: RAO projection.

OVERCOMING PITFALLS IN THE INTERPRETATION OF CORONARY ANGIOGRAMS

Foreshortening

To estimate the length of target lesions, the coronary artery segment containing the lesion should be viewed en face. The x-ray beam should be perpendicular to the artery segment in question to demonstrate that the segment achieves its maximum length.

Vessel Size

Estimation of vessel size usually is performed by comparison with the angiographic catheter shaft. Larger angiographic catheters, such as 6-Fr and 7-Fr, provide easier calibration than smaller catheters. For best vessel size estimation, the operator must obtain views in which the catheter tip and the segment in question are at the same level relative to the x-ray tube and the image intensifier. Out-of-plane magnification errors will result if the catheter tip and arterial segment are different distances from the image intensifier. An example of such an error would be judging the size of the mid–anter
descending artery in the left anterior oblique cranial view. In this view, the anterior descending artery is foreshortened and closer to the image intensifier than the catheter tip seated in the aorto-ostium further away. This perspective would cause the image of the catheter to be magnified while decreasing magnification of the anterior descending artery, making it appear smaller than its actual size.

**Lesion Length**

Measurement of the length of the lesion should be accomplished using views in which foreshortening has been minimized. The most accurate measures of the lesion length are accomplished with guidewires having calibration marks or with balloon catheters utilizing the known distance between markers. Estimates of lesion length can be made from the diagnostic angiogram, however, by calibrating the guide catheter and then performing quantitative angiographic assessment of the lesion length. Although experienced interventionalists can often estimate lesion length from diagnostic angiograms within a reasonable margin of error, final assessment of lesion length should be obtained at the time of the interventional procedure. The assessments of edges of the lesion are often subjective due to the limited resolution of the angiogram. For the most precise determination of lesion length, intravascular ultrasound may be required.

**Bifurcations**

Bifurcations are best visualized from a perspective without branch overlap. Accurate visualization of a bifurcation lesion is critical in planning for the best interventional approach to assess the lesion severity, and to avoid plaque shifting and loss of side branches. Common views for left anterior descending diagonal bifurcations are left anterior oblique cranial views and occasionally anteroposterior cranial views; for the circumflex marginal branches, the right anterior oblique caudal views; and for the right coronary artery posterior descending bifurcation, the shallow left anterior oblique cranial view.

**Poor Contrast Opacification**
Contrast streaming or poor filling of the vessel may lead to a false impression of lesion severity or presence of a thrombus. Inadequate contrast opacification may appear as a luminal irregularity. Enhanced contrast delivery can be achieved by obtaining better coaxial engagement of the guiding catheter, using a larger bore catheter, injecting during phase 3 of the Valsalva maneuver, or using a power injector.

**Catheter-Induced Spasm**

Catheter-induced spasm may appear as a fixed atherosclerotic stenotic lesion. Catheter spasm usually occurs near the tip of the catheter and has been observed in both right and left (and left main) coronary arteries. Vasospastic areas may be single and proximal or may be multiple and located some distance from the coronary ostium. Nitroglycerin should be administered in every case of an ostial lesion not previously evaluated prior to initiating intervention. Repositioning of the catheter and administration of nitroglycerin (100-200 mcg through the catheter) may resolve the dilemma.

**Left Main Artery Angiography**

The left main aorto-ostial and mid-body lesions can be easily demonstrated in standard orthogonal views, but the distal left main coronary artery (LM) with left anterior descending/circumflex (LAD/CFX) ostial narrowings may be more difficult to delineate (Fig. 21-10). As in cases of any bifurcation angiography, branch overlap must be minimized. Optimal views to identify the LM remain the same as for those during diagnostic studies, with a shallow right anterior oblique (RAO) with cranial or caudal angulation often providing an excellent view. In addition, complementary LAO caudal view (spider view) will display the LM in an orthogonal projection. An additional problem is the appreciation of the hemodynamic significance of the left main stenoses especially when the angiographic narrowing is of questionable severity. For this situation, fractional flow reserve measurement (FFR) can provide the hemodynamic lesion severity. LM FFR (>0.80) has a low 5-year major adverse cardiac event rate comparable to that of CABG for FFR (<0.80).
Anomalous Coronary Artery Angiography

The most common coronary anomaly is origin of the circumflex artery arising from the right coronary cusp (Fig. 21-11). The vessel may come from the right coronary artery itself or separately just anterior to the right coronary ostium. Commonly, it arises in a caudal direction, and the multipurpose catheter is frequently helpful in selective cannulation of this vessel.
When the right coronary artery arises from the left coronary cusp, it is anterior to the left coronary ostium and sometimes can be cannulated with a left Judkins catheter or a long-tipped multipurpose catheter. The Amplatz L2 catheter is usually successful in engaging the ectopic origin of the right coronary artery from the left cusp. A discussion of the angiography of anomalous coronary arteries is provided in more detail elsewhere. PCI for these arteries is performed in a routine fashion once stable guide catheter position is achieved.

**Angiographic Lesion Severity**

The severity of a coronary stenosis is usually expressed as percent diameter and cross-sectional area reduction relative to the adjacent normal distal angiographic segment. Intravascular ultrasound imaging studies have shown that angiographic ‘normal’ segments are frequently not normal and therefore the reference vessel size may be underestimated. Adaptive (either positive or negative) arterial remodeling in response to atherosclerotic plaque...
accumulation further complicates assessment of lesion severity. Regardless of
the limitations, the minimal lumen diameter, percent diameter, or area
reduction, compared with the ‘normal’ reference segment, remain the
standards. Figure 21-12 shows the classic relationship of lesion severity to
flow reduction as identified in the experiments of Gould. In defining
angiographic lesion severity, experimental animal studies showed that
increasing coronary stenosis severity was associated with a predictable
decine in coronary flow reserve (CFR). CFR begins to decline at about a
60% artery diameter narrowing and, hence, it was thought that such
narrowings carried physiologic importance. This is a truth in the animal but
not the human experiment models, because CFR in humans is the sum of the
epicardial flow and the microvasculature. Thus, an abnormal CFR may
accompany a vessel with only a minimal degree of narrowing and, hence, the
correlation between angiographic lesion severity and CFR is poor. At
diameter stenoses >80% to 90%, all available coronary reserve has been
exhausted and resting flow begins to decline. Although on-line quantitative
assessment is available in many laboratories, it is seldom used in the
decision-making process. Although some form of quantitative angiography is
helpful for reproducibility, the functional significance of any lesion,
especially those in the intermediate range, should be determined by direct
measurements such as FFR. The degree of an angiographic narrowing
(stenosis) is reported as the estimated percentage lumen reduction of the most
severely narrowed segment compared to the adjacent angiographically
normal vessel segment, seen in the worst x-ray projection (Fig. 21-13).
Because the operator uses visual estimations, an exact evaluation is
impossible with a ± 20% variation even among experienced angiographers.
Stenosis severity alone should not always be assumed to be associated with
abnormal physiology (flow) and ischemia. Moreover, coronary artery disease
is a diffuse process and thus minimal luminal irregularities over a long
segment of the artery may produce abnormal flow despite appearing as non-
obstructive CAD. Area stenosis is always greater than diameter stenosis and
assumes the lumen is circular, whereas the lumen is usually eccentric. In
general, 4 categories of lesion diameter severity can be assigned:
FIGURE 21-12 The relation of resting mean blood flow (dotted line) and hyperemic flows (solid line) to percentage of arterial diameter reduction. Flows are expressed as ratios to control resting mean values at the beginning of the experiment. The shaded area represents the range of values measured in individual dogs: $r$ = correlation coefficient; $\text{SQ DEV} =$ mean square of deviations. (Reprinted from Gould KL, Lipscomb K, Hamilton GW. Physiologic basis for assessing critical coronary stenosis. *Am J Cardiol*. 1974;33(1):87-94, Copyright © 1974, with permission from American College of Cardiology Foundation.)
1. Minimal or mild CAD, with narrowings <50%
2. Moderate CAD, with stenosis between 50% and 75%
3. Severe CAD, with stenosis between 75% and 95%
4. Total occlusion

**Ischemia and Angiographic Lesion Severity**

Stenosis severity is an anatomic variable and may not always represent abnormal physiology (or ischemia), especially for lesions 40% to 70% narrowed. Anatomic factors producing resistance to coronary flow include morphologic lesion characteristics such as entrance angle, length of disease, length of stenosis, minimal lumen diameter, minimal lumen area, eccentricity of lumen, area of reference vessel segment, and viscosity (Fig. 21-14). To determine hemodynamic lesion severity and propensity to be associated with ischemia, translesion pressure ratios at maximal coronary flow, called the fraction flow reserve (FFR), is an in-lab standard prior to proceeding to intervention in the absence of other objective evidence of ischemia.\(^8\)\(^9\)

**Coronary Stenosis Morphology**

The morphology of the lesion can help guide the interventional approach.
The presence of angiographic calcifications may require the use of intravascular ultrasound to determine whether rotary ablation should be employed before stenting. The presence of angiographic lumen filling defects may prompt use of mechanical thrombectomy. Ulcerations and irregularities within lesions may identify them as culprit lesions in the acute coronary syndrome patient.

There are a number of general descriptive characteristics of the stenoses which aid the interventionalist in assessing the risk and outcome of the procedure. These characteristics include: tortuosity; arterial calcification; sequential or tandem lesions; length; eccentricity; ostial location (either aorto-ostial or branch ostium); bifurcation or side branch involvement; smooth, irregular, or ulcerated lumen contour; or thrombus. Intravascular ultrasound or optical coherence tomography (OCT) imaging of stenosis defines lumen and plaque characteristics better than angiography (Fig. 21-15).
FIGURE 21-15 Top panel shows ultrasound cross-sectional images of atherosclerotic vessel narrowing. Plaque characteristics, lumen and reference vessel area are more accurately quantitated with intravascular ultrasound than with angiography. Lower panels show optical coherence tomographic images of coronary plaque erosion (A), rupture (B), and thrombus (C).

Determination of Coronary Flow by Angiography

In the setting of acute myocardial infarction interventions, angiographic coronary flow rates predict short- and long-term outcomes. The relative flow in coronary arteries has been classified according to the TIMI (thrombolysis in myocardial infarction) flow scale, as follows:

- TIMI 0 (no flow).
- TIMI 1 (opacification of the distal vessel without runoff).
- TIMI 2 (reduced flow compared with non-obstructed arteries).
- TIMI 3 flow (flow in the affected artery that is equal to other unobstructed arteries).

To quantitate TIMI flow rates, the number of angiographic frames required for contrast media to traverse the coronary artery is reported.\(^\text{10}\) The number of frames from the initial appearance of the dye in the coronary artery to a distal predetermined landmark is calculated. Gibson has proposed a correction of this frame count called the corrected TIMI frame count, which uses the frame count from the ostial opacification to pre-specified distal targets in the left anterior descending artery such as the apical LAD bifurcation; the distal target in the circumflex artery is the distal bifurcation of the terminal segments, and for the right coronary artery as the first branch of the posterolateral artery.\(^\text{10}\) Because the anterior descending artery is longer than the other vessels, the normal TIMI frame count for the left anterior descending artery is 36; for the circumflex artery, 21; and for the right coronary artery, 22. The corrected TIMI frame count divides the anterior descending count by 1.7 to equate the three vessels. TIMI frame counts have been found to be of value in judging clinical response after reperfusion therapy in the setting of acute syndromes.

**CHRONIC TOTAL OCCLUSIONS**

Percutaneous coronary intervention (PCI) of a chronic total occlusion (CTO), defined as a total occlusion (with TIMI grade 0 flow) of >3 months’ duration, is one of the most technically challenging lesions with significantly lower success rates of crossing the lesions with the usual guide wires. PCI success rates for CTOs are reported in the 50% to 80% range (compared to >80%-90% for occlusions <3 months old). Recent developments and dedicated operators using both antegrade and retrograde approaches to CTO are increasing the success rates of recanalization. Newer techniques with specialized guide wires, retrograde access, and subintimal reentry methods increase the success rate to nearly 90%.\(^\text{11,12}\)

Numerous features have been identified that predict the ability to cross chronic total occlusions, including whether there is a tapering into the
occlusion or “a beak.” This angiographic appearance sometimes signals the presence of small recanalized channels within a total occlusion and correlates with an increased success rate from interventions. Conversely, there is a lower chance of success in patients with total occlusions that are abruptly occluded.

The least favorable appearance is the total occlusion that terminates in a side branch at the exit of the total occlusion; this scenario can cause wires to migrate into that side branch, minimizing the ability to cross the total occlusion. Other characteristics that influence success include the curvature of the artery at the site of the total occlusion and beyond it, and, especially, the length of the total occlusion. CTO PCI mortality rate is reported to be 0% to 2% and emergency coronary artery bypass surgery <1% to 2%. Abrupt vessel closure following CTO PCI may occur in up to 5% to 10% of patients, but is often clinically silent, depending on the collateral supply.

**Collateral Vessel Angiography**

Visualization of collateral circulation from contralateral or ipsilateral injections can identify the length of the total occlusion and thereby influence the chance for success from interventional procedures. Such an assessment of total occlusions is very important in selecting patients for attempted intervention versus continued medical therapy or bypass surgery.

The observation of collateral flow is used to estimate whether ischemia will be improved by revascularization. It is unusual to have no collateral filling into segments of viable myocardium in the chronic phase of CAD. Collateral flow is a sign that viable myocardium potentially exists in those zones. Examination of the left ventriculogram in combination with the collateral filling to discrete myocardial zones can help predict which patients will benefit symptomatically from reperfusion therapy.

The opacification of a vessel beyond a totally occluded segment from antegrade or retrograde contrast is defined as collateral filling. The collateral circulation is graded angiographically as follows:

**Grade Collateral Appearance**

0  No collateral circulation
1  Very weak (ghostlike) opacification
2. Opacified segment, less dense than the feeding vessel and filling slowly
3. Opacified segment as dense as the feeding vessel and filling rapidly

Important features for making decisions about which vessels might be protected or lost during the intervention include whether the collateral supply is ipsilateral (eg, same-side filling, proximal RCA to distal RCA collateral supply) or contralateral (eg, opposite-side filling, LAD artery to distal RCA collateral supply) or whether collateral filling forward (anterograde) or backward (retrograde).

**Left Ventriculography**

The left ventriculogram provides information about overall and regional myocardial function. Abnormal wall motion indicates the presence of coronary ischemia, infarction, aneurysm, or hypertrophy. Left ventriculography also provides quantitative information, such as the ventricular volumes, the ejection fraction, presence of hyperdynamic contraction, and valvular regurgitation. Left ventricular ejection fraction predicts the long-term outcome of patients with CAD.

Ventriculography may be performed before or after coronary angiography. Because ventricular function can be obtained through noninvasive methods, most accurately with echocardiography, ventriculography can be deferred in some patients with renal insufficiency, severe left main coronary stenosis, or aortic stenosis. Low-volume, nonionic, low-osmolar contrast ventriculograms can be performed with little or no complications related to myocardial depression, hypotension, or arrhythmias. The indications, contraindications, and complications for ventriculography are shown in Table 21-3.

**Table 21-3 Indications and Complications of Left Ventriculography**

<table>

</tr>
<tr>
<td>3. Quantitation of the degree of mitral regurgitation</td>
</tr>
<tr>
<td>4. Quantitation of the mass of myocardium for regression of hypertrophy or other similar research studies</td>
</tr>
</tbody>
</table>
Indications for right ventriculography are as follows:

1. Documentation of tricuspid regurgitation
2. Assessment of RV dysplasia for arrhythmias
3. Assessment of pulmonary stenosis
4. Assessment of abnormalities of pulmonary outflow tract
5. Assessment of right-to-left ventricular shunts

Complications:

1. Cardiac arrhythmias, especially non-sustained, brief VT, do not require treatment. Sustained VT and ventricular fibrillation require immediate cardioversion. *Note:* Arrhythmias and staining (see below) are more common with the use of end-hole catheters than with pigtail catheters
2. Intramyocardial contrast media staining during power injection (generally transient and of no clinical importance unless it is deep or perforating producing tamponade)
3. Embolism (thrombi or air)
4. Contrast-media related complications
5. Transient hypotension (<15-30 seconds) is common with ionic high osmolar contrast media

There are 3 specialized catheters—the pigtail, Halo, and multipurpose (MP)—used for ventriculography. The pigtail catheter is the safest and most commonly used. The preshaped circular tip has an end hole and 6 to 12 side holes on the catheter shaft above the curve. The method of catheter passage into the LV is described elsewhere. Once inside the ventricle, the catheter can be placed in front of the mitral valve with the loop directed toward the apex, away from the valve (in the RAO position). An angled (145°) pigtail catheter may be helpful for this purpose, especially for horizontally oriented hearts.

Abbreviations: LV, left ventricular; RV, right ventricular; VT, ventricular tachycardia.

A Halo catheter is a novel 5-Fr catheter with a perpendicular helical tip with inward-and-upwardly directed tip. The side holes are located on the helix (not the shaft) and produce ventriculograms without ectopy since the contrast jets are directly inwardly and not to the myocardium. Because there are no side holes on the shaft, it is ideal to measure distal left ventricular chamber pressure in patients with presumed hypertrophic obstructive
cardiomyopathy.

The multipurpose (MP) and other end-hole type catheters should not be used for ventriculography because of the increased risk of ventricular tachycardia, contrast injection in the myocardial tissue (contrast staining), or ventricular perforation.

In patients with CAD, left ventriculography may show asynchronous myocardial contractility relating to long term prognosis. Each of 5 myocardial segments may be graded as being either normal in contraction, hypokinetic, akinetic (no motion), or dyskinetic with paradoxical systolic expansion (Fig. 21-16 and Fig. 21-17). In the poorly contracting ventricle, myocardial viability is suggested by the thickness and movement of the impaired LV segment. Whereas akinetic and dyskinetic segments are often judged to have a low chance of recovery, more recent magnetic resonance assessments of viability have shown that even quite thin arterial segments can undergo significant recovery after revascularization.

Complications of Coronary and Ventricular Angiography

For diagnostic catheterization, analysis of the complications in more than 200,000 patients indicated the incidence of risks as follows: death, less than 0.2%; myocardial infarction, less than 0.05%; stroke, less than 0.07%; serious ventricular arrhythmia, less than 0.5%; and major vascular complications (thrombosis, bleeding requiring transfusion, or pseudoaneurysm), less than 1% (Table 21-4). Vascular complications occurred more frequently when the brachial approach was used and least when the radial approach was used. Risks are increased in well-described subgroups (Table 21-5).

**Other Complications**

Aortic or coronary dissection
Cardiac perforation, tamponade
Congestive heart failure
Contrast reaction, anaphylaxis, nephrotoxicity
Heart block, asystole
Hemorrhage (local, retroperitoneal, pelvic)
Infection
Protamine reaction
Supraventricular tachyarrhythmia, atrial fibrillation
Thrombosis, embolus, air embolus
Vascular injury, pseudoaneurysm
Vasovagal reaction

**Table 21-5 Conditions of Patients at Higher Risk for Complications of Catheterization**

Acute myocardial infarction
Advanced age (>75 years)
Aortic aneurysm
Aortic stenosis
Congestive heart failure
Diabetes
Extensive three-vessel coronary artery disease
Left ventricular dysfunction (left ventricular ejection fraction <35%)
Obesity
Prior cerebrovascular accident
Renal insufficiency
Suspected or known left main coronary stenosis
Uncontrolled hypertension
Unstable angina

The most potentially lethal condition leading to complications of diagnostic coronary arteriography is the presence of severe left main coronary artery stenosis, particularly ostial involvement. Placement of the diagnostic catheter into the coronary ostium, especially if it causes disruption of plaque, may lead to immediate hemodynamic instability and a downward spiral. All physicians performing angiography should be prepared to administer vasopressor agents immediately should blood pressure fall in the setting of left main artery stenosis. Increasing the filling pressure as quickly as possible is critical if one is to avoid the spiral of decreased coronary flow leading to decreased contractility and further decreases in arterial pressure. In centers equipped with interventional cardiology equipment, an early decision for urgent angioplasty and stenting as a bail-out technique for left main artery occlusion should always be added to the armamentarium. Lesser degrees of emergency can be dealt with using vasopressor agents, followed by catheter-based LV hemodynamic support (eg, IAPB or Impella) to stabilize the situation, and then definitive surgery; however, it is sometimes impossible to stabilize the patient quickly enough using these measures, and the emergency placement of left main artery stents has, in some cases, been lifesaving.

**Contrast-Induced Nephropathy (CIN)**

The most common contrast media for PCI is nonionic or low-osmolar contrast agents because of safety, patient tolerance, and cost.\(^{15,16}\) Any iodine-based intravascular contrast media may cause acute renal failure following PCI, called contrast-induced nephropathy (CIN). CIN is typically defined as a relative increase in serum creatinine of >25% or an absolute increase >0.5 mg/dL. While it is not uncommon to develop transient increases in serum
creatinine, it is rare to need temporary dialysis and even rarer to need permanent dialysis following CIN. The time course of CIN demonstrates an increase in creatinine starting in 12 to 24 hours for most patients, but it may take as long as 48 to 96 hours to peak. Mehran, et al developed a validated risk scoring system in order to predict the likelihood of developing CIN.\(^\text{17}\)

In high risk patients, CIN prevention consists of preprocedure hydration and limitation of the contrast volume administered. No specific pharmacologic regimen has been demonstrated to reduce CIN. Limiting the volume of contrast media is an important goal for both the diagnostic and interventional aspects of the procedure, since many procedures are combined. If prior coronary arteriograms have been obtained, it may be possible to avoid repeating unnecessary views and, if there has been no clinical change, it may also be possible to avoid ventriculography.

In patients at high risk for CIN, left ventriculography may be deferred in favor of echocardiography. Optimal views should be obtained, preferably in biplane imaging if available (Figure 21-18). Unnecessary additional views should be avoided. Rotational angiography (ie, rotating the x-ray tube or image tube gantry throughout an arc during coronary injection, thereby obtaining multiple views of the arteries with a single coronary injection) may be another method to reduce contrast volume in CIN-prone patients.
FIGURE 21-18 The cardiac cath lab with biplane cineangiographic imaging C-arms in place.

SUMMARY

Percutaneous coronary interventions must be based on accurate information supplied by the coronary arteriogram and left ventricular functional measurements. Inaccurate or poorly performed coronary angiography can lead to an erroneous decision for both the selection of appropriate candidates and for the performance of the interventional procedure.

As interventional procedures continue to evolve into more intricate and novel device applications including new bioabsorbable and second generation drug-eluting stents, debulking techniques and physiologic lesion assessment (eg, FFR), intravascular ultrasound and optical coherence imaging, the interventionalist must not forget the more “mundane” activity of coronary arteriography. The successful procedure must start with the proper clinical assessment and accurate diagnostic testing, including basic coronary angiography and ventriculography, to deliver the highest quality outcomes of coronary interventions.

MULTIPLE CHOICE QUESTIONS

1. A 59-year-old man is admitted to the emergency department with chest pain that has mostly resolved. The ECG shows nonspecific ST-T changes. Of the following, what is an indication for urgent coronary angiography?
   A. Frequent PVCs
   B. Elevated troponin
   C. Decreased ejection fraction on echocardiography
   D. Hypotension corrected by IV fluids

2. During coronary angiography, the operator notes a very long ‘left main’ segment. Which is the most common coronary anomaly associated with this finding?
   A. Right coronary artery (RCA) originating from the Left coronary sinus
   B. Left main originating from the right coronary sinus
   C. High take-off of the RCA
   D. Circumflex artery originating from the right coronary artery
   E. Single coronary originating the non-coronary cusp

3. The operator has finished the diagnostic portion of the angiography and is
preparing to perform percutaneous coronary intervention (PCI) when a cardiology fellow suggests that the 60% narrowing of the left anterior descending (LAD) artery is occurring in an area opposite that identified on the stress test. What is the best way to determine if this lesion is appropriate for revascularization?
A. Quantitative analysis of the angiogram
B. Intravascular ultrasound imaging
C. Optical coherence tomography
D. Defer the PCI and repeat the stress test
E. Fractional flow reserve measurement (FFR)

4. A 72-year-old man undergoes a stress exercise test and develops chest pain and new ST-segment elevation in anterior leads and AVR. All ST changes resolve on recovery, but there is persistent ST elevation in AVR. The patient is pain free and after an overnight stay in the critical care unit (CCU), undergoes cardiac catheterization and angiography. Which of the following most likely explains the clinical scenario?
A. Exercise-induced vasospasm
B. Congestive heart failure with sudden decompensation
C. Left main stenosis
D. Takasubo cardiomyopathy
E. Proximal left anterior descending (LAD) artery stenosis

5. An 81-year-old woman with diabetes mellitus, hypertension, peripheral vascular disease, and creatinine of 1.5 mg/dL is scheduled to undergo cardiac catheterization and angiography. Which of the following is the best prevention to reduce the chances of contrast-induced nephropathy (CIN)?
A. Lasix (furosemide) before the procedure
B. 500 to 1000 mL of normal saline before the procedure
C. Nifedipine 10 mg orally, 3 days before the procedure
D. Mannitol, intravenously, on the day of the procedure
E. N-Acetylcysteine (Mucomyst), orally, 3 days before the procedure

ANSWERS
1. B

This patient has a non-ST segment elevation myocardial infarction (NSTEMI) and the timing of catheterization will be related to his event risks. Other indications for catheterization as noted in the 2014 ACC/AHA/AATS/PCNA/SCAI/STS Focused Update of the Guideline for the Diagnosis and Management of Patients with Stable Ischemic Heart Disease: A Report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines for coronary arteriography are summarized below:

1. Patients with stable angina or asymptomatic individuals with high-risk criteria on noninvasive testing.
2. Patients resuscitated from sudden cardiac death or having threatening ventricular arrhythmias.
3. Patients with unstable coronary syndromes of all varieties, including acute myocardial infarction as a preamble to primary angioplasty and those who developed complications of acute infarction.
4. Patients with ischemia at low levels of exercise in the recovery phase of myocardial infarction.
5. Patients with suspected or known coronary artery disease undergoing preoperative evaluation.

2. D

The most common coronary anomaly is origin of the circumflex artery arising from the right coronary cusp (See Fig. 21-11). The vessel may come from the right coronary artery itself or separately just anterior to the right coronary ostium. Commonly, it arises in a caudal direction, and the multipurpose catheter is frequently helpful in selective cannulation of this vessel.

When the right coronary artery arises from the left coronary cusp, it is anterior to the left coronary ostium and sometimes can be cannulated with a left Judkins catheter or a long-tipped multipurpose catheter. The Amplatz L2 catheter is usually successful in engaging the ectopic origin of the right coronary artery from the left cusp. Percutaneous coronary intervention (PCI) for these arteries is performed in a routine fashion once stable guide catheter position is achieved.
Stenosis severity is an anatomic variable and may not always represent abnormal physiology (or ischemia), especially for lesions 40% to 70% narrowed. Anatomic factors producing resistance to coronary flow include morphologic lesion characteristics such as entrance angle, length of disease, length of stenosis, minimal lumen diameter, minimal lumen area, eccentricity of lumen, area of reference vessel segment and viscosity (See Fig. 21-14). To determine hemodynamic lesion severity and propensity to be associated with ischemia, translesion pressure ratios at maximal coronary flow, called the fraction flow reserve (FFR) is an in-lab standard prior to proceeding to intervention in the absence of other objective evidence of ischemia.

**FIGURE 21-14** Morphologic characteristics of a stenotic lesion. 1. entrance angle; 2. lesion length; 3. minimal lumen diameter length; 4,5,6 lumen area, eccentricity, diameter; 7. normal reference vessel area.

ST elevation during an exercise tolerance test is often associated with left main coronary artery (LM) stenosis or 3V coronary artery disease. High-risk features of stress testing may also be demonstrated including persistent chest pain, drop in blood pressure with exercise, marked ST segment depression or new elevation, or short duration of exercise with onset of symptoms.
It should be noted that the most potentially lethal condition leading to complications of diagnostic coronary arteriography is the presence of severe LM stenosis, particularly ostial involvement. Placement of the diagnostic catheter into the coronary ostium, especially if it causes disruption of plaque, may lead to immediate hemodynamic instability and a downward spiral. All physicians performing angiography should be prepared to administer vasopressor agents immediately should blood pressure fall in the setting of left main artery stenosis. In centers equipped with interventional cardiology equipment, an early decision for urgent angioplasty and stenting as a bail-out technique for left main artery occlusion should always be added to the armamentarium. Lesser degrees of emergency can be dealt with using vasopressor agents, followed by catheter-based left ventricle (LV) hemodynamic support [eg, intraaortic balloon pump (IABP) or Impella] to stabilize the situation, and then definitive surgery; however, it is sometimes impossible to stabilize the patient quickly enough using these measures, and the emergency placement of left main artery stents has, in some cases, been lifesaving.

5. B
Contrast-induced nephropathy (CIN) is typically defined as a relative increase in serum creatinine of >25% or an absolute increase >0.5 mg/dL. No single factor or agent has been shown to reduce the risk of CIN better than hydration with normal saline in even the most high-risk patient.

The most common contrast media for angiography are nonionic or low-osmolar contrast agents because of safety, patient tolerance, and cost. Any iodine-based intravascular contrast media may cause acute renal failure following percutaneous coronary intervention (PCI). While it is not uncommon to develop transient increases in serum creatinine, it is rare to need temporary dialysis and even rarer to need permanent dialysis following CIN. The time course of CIN demonstrates an increase in creatinine starting in 12 to 24 hours for most patients, but it may take as long as 48 to 96 hours to peak. Mehran et al developed a validated risk scoring system in order to predict the likelihood of developing CIN.

In high risk patients, CIN prevention consists of pre-procedure hydration and limitation of the contrast volume administered. No specific pharmacologic regimen has been demonstrated to reduce CIN. Limiting the volume of contrast media is an important goal for both the diagnostic and
interventional aspects of the procedure since many procedures are combined. If prior coronary arteriograms have been obtained, it may be possible to avoid repeating unnecessary views and if there has been no clinical change, it may also be possible to avoid ventriculography.
Radial Approach to Coronary Angiography

Jennifer A. Tremmel

**HISTORY**

The first known attempt at radial artery access for angiography was made in March 1947 by Dr. Stig Radner in Lund, Sweden. He reported on his new technique a year later, describing a radial artery cutdown in the upper third of the forearm, after which a 7-Fr to 9-Fr catheter was advanced in a retrograde fashion to perform a thoracic aortogram.\(^1\) It was not until over 4 decades later that the radial artery started to be accessed percutaneously, rather than through a cutdown, and for the purpose of cannulating the coronary arteries. In 1989, emboldened by the safety of the radial arterial line for critically ill patients, Dr. Lucien Campeau from Montreal Heart Institute described his experience of accessing the left radial artery for coronary angiography in 100 patients (90 men and 10 women).\(^2\) Primarily using a 5-Fr system, he was successful in cannulating the radial artery in 90% of patients, and reported only 2 complications, including a brachial artery dissection and a radial artery occlusion, neither of which were symptomatic. Three years later, in 1992, the first coronary stents were placed in 3 men via the right radial artery by Dr. Ferdinand Kiemeneij in Amsterdam.\(^3\) He attributed his ability to do this to “miniaturization” of coronary guiding catheters to 6-Fr and adequate crimping of a Palmaz-Schatz stent on a balloon to allow it to pass without becoming dislodged within the small guide.
Following these successes, the use of radial access spread worldwide. However, the enthusiasm was short-lived in some countries, including the United States, where there was a rise and fall of radial procedures during the 1990s. United States operators quickly grew frustrated by the difficulty in performing a radial procedure compared to the ease of a femoral procedure, in which there were not issues of spasm, tortuous anatomy, or limitations in guide size. By the late 2000s, 50% of percutaneous coronary interventions (PCI) were performed radially in Europe and Canada, and 60% in Japan, but only 1.7% in the United States, putting it on par with the Middle East and Africa.\textsuperscript{4,5} Around the same time, though, concerns regarding the morbidity and mortality associated with bleeding and vascular complications, the emergence of new radial-specific equipment, and the enthusiasm of young operators who had no memory of the struggles of their predecessors, began to take hold. Within a 6-year period, radial PCI in the United States grew to over 30%, and has not shown signs of stopping (Fig. 22-1). Few interventional fellows in the country now graduate without being proficient in both radial and femoral procedures, and a new paradigm is seen within cardiac catheterization laboratories across the country where patients can ambulate right after their procedure and go home that same day.

**BENEFITS OF THE RADIAL APPROACH**

*Reduction in Bleeding and Vascular Complications*

Bleeding is the most common complication after PCI. It is independently associated with a 3-fold increase in mortality and major adverse cardiovascular events (MACE)\(^6\) and contributes to 12.1% of all in-hospital mortalities after PCI.\(^7\) In addition, 2.3% of patients receive a blood transfusion post-PCI, which has also been independently associated with an increased risk of mortality and MACE.\(^8\) Although non-access site bleeding has been associated with a worse prognosis than access site bleeding, access site bleeding still carries a 1.7-fold increased risk of mortality compared with no bleeding.\(^9\) While femoral access site bleeding and vascular complications have decreased over the past decade, they still occur in ~2% of all PCIs, and women have a >2-fold increased risk compared to men.\(^10,11\) Moreover, patients with a particularly high bleeding risk, such as those presenting with ST-segment elevation myocardial infarction (STEMI), have femoral bleeding rates of 5% or more.\(^12,13\)

Observational studies and randomized controlled trials (RCTs) have consistently demonstrated a reduction in bleeding and vascular complications with radial versus femoral access.\(^5,14-17\) In addition, this reduction increases as a patient’s bleeding risk increases, and those with the highest baseline bleeding risk benefit most from a radial approach.\(^18\) Similarly, as the baseline bleeding risk increases, there is an increased risk of mortality, and the impact of strategies that reduce bleeding, such as the radial approach, begin to reduce mortality. It has been demonstrated in larger RCTs of STEMI patients that those who have a higher risk of baseline bleeding and mortality do benefit from radial versus femoral access, whereas this has not necessarily been the case in lower-risk cohorts.\(^13,15,16,19\)

*Decreased Cost*
In 2013, there were several studies published evaluating the cost benefit of radial procedures, and all showed very similar results.\textsuperscript{20-22} They all examined both the periprocedural and postprocedural costs associated with radial versus femoral access. There was no periprocedural cost benefit with radial PCI versus femoral PCI, and, in fact, in the case of a diagnostic catheterization, the cost of radial PCI was slightly higher (likely due to the radial-specific equipment) compared to femoral PCI, when vascular closure devices were rarely used (~10%).\textsuperscript{21} On the other hand, radial PCI produced a cost savings postprocedurally of $571 to $705 per case. This savings was primarily due to a decreased length of stay rather than bleeding, which accounted for <20% of the savings. The shortened stay was not due to same-day discharge, which was occurring in <5% of the cases. Instead, presumably from early ambulation and recovery, radial patients were able to leave the hospital approximately one third of a day sooner than femoral patients, saving money on bed space and nursing staff. While the amount of money saved per patient seems small, the effect on the health care system is quite large when translated across the country, totaling $50 million or more.\textsuperscript{20} It is also noteworthy that the largest cost savings from radial PCI comes when employed in patients who were at the highest risk of bleeding ($642 in low risk patients and $1621 in high risk patients). This mirrors the data seen with bleeding and mortality—the higher-risk the patient, the more benefit is gained from a radial procedure.

**Higher Patient Satisfaction**

The data regarding patient satisfaction with radial procedures is limited, but for anyone who does radial procedures, the testimonials given by patients are convincing enough. Still, in an old, but often-cited article, Cooper et al. reported that 80% of patients who had undergone both techniques strongly preferred the radial approach, whereas only 2% preferred the femoral approach.\textsuperscript{23} Likewise, patients in both RIVAL (Radial Versus Femoral Access for Coronary Intervention) and SAFE-PCI (Study of Access Site for Enhancement of PCI for Women) significantly preferred radial access over femoral access if they were to need to have their procedure again.\textsuperscript{15,24}

**DOWNSIDES OF THE RADIAL APPROACH**

*The Learning Curve*

One of the biggest challenges of doing radial procedures is getting through the learning curve. It must be remembered that the wrist is not a small groin, and that there are new skills to learn, even for the most adept femoral operator. Becoming proficient at radial procedures is about case volume, not operator status. Therefore, when learning radial approaches, everyone is starting at ground zero, which can be frustrating, particularly for long-standing femoral operators, as well as their staff. Investigations into the initial learning curve have suggested that it takes approximately 50 cases to master the basics. However, as with learning any skill, technical proficiency continues to improve well beyond the initial learning curve, so the more cases one does, the better one gets.  

In a study evaluating the learning curve for diagnostic cases, radial experts (defined as experienced femoral angiographers who had received formal training in radial techniques with >100 previous radial procedures) were compared with radial non-experts (defined as experienced femoral angiographers with basic or no radial experience) at baseline, and then over the course of 12 months as both groups performed radial procedures. At baseline, the radial experts had significantly shorter procedural and fluoroscopic times compared with the radial non-experts. By ~36 cases, there was no significant difference in procedural times between the experts and non-experts, but still a difference in fluoroscopic times. By ~63 cases, the procedural and fluoroscopic times between the radial expert and non-expert were no longer appreciably different. Similarly, in operators newly performing radial PCI, the odds of failure decline substantially up to 50 cases, while further decline in failures after 100 cases is small. A large analysis tracking new radial operators in the United States also concluded that the threshold to overcome the learning curve is approximately 30 to 50 PCIs. In addition, median fluoroscopy times and contrast use decreased significantly with increasing radial volume, and despite operators doing more complex radial procedures, as their experience grew, procedure success
remained consistently high.

There are several ways to approach one’s learning curve. To begin with, operators can start on their own, or the entire cardiac catheterization laboratory can change together. The latter may be more logistically difficult in the beginning, but likely results in more efficiency in the end. Operators can also choose to start with easy cases, gradually increasing to more complex cases as their comfort and skill level grows, or they can take a “radial-first” approach from the start. A rapid transition to a radial-first approach is likely best. Many operators get stuck in their learning curve, tending to favor the radial approach in stable male patients, whereas the patients most likely to benefit, due to higher risk of bleeding and vascular complications, are older, female, and unstable patients, particularly those with STEMI. This avoidance of the radial approach in potentially more challenging cases has created a risk–treatment paradox in the United States, whereby the patients who are most expected to benefit from a radial procedure are the least likely to receive it. Consequently, it is encouraged that operators complete their learning curve, pushing themselves to do more radial procedures and to get comfortable with all types of patients. It has been shown that as radial PCI volume increases, more females, more patients with New York Heart Association class IV heart failure, and more patients with higher bleeding risk are selected to undergo radial PCI. Operators also perform more multi-vessel PCIs and technically complex PCIs as they gain experience with radial interventions. The last frontier of the learning curve is generally the STEMI patient, who will be discussed in more detail later in this chapter.

**Excess Radiation Exposure**

Data regarding radiation exposure with radial versus femoral procedures have been mixed. Overall, it appears that operators and patients get higher radiation exposure with radial procedures compared with femoral procedures, but this improves as operators advance through their learning curve. In fact, one of the biggest factors of radiation exposure for either a radial or femoral operator is procedural volume. In a radiation substudy of the RIVAL trial, there was a nominal overall increase in radiation dose with radial versus femoral access, but this difference was observed only in lower-volume centers and operators. Medium- and high-volume centers showed no
significant difference, and high-volume centers had the lowest radiation dose irrespective of which access site they used.

All operators should do what they can to minimize radiation exposure. In addition to the usual steps such as using standard shielding, maintaining distance, and lowering the frame rate, certain radial-specific devices, including a radial radiation protection board, a radiation shield over the radial sheath insertion site, and draping the patient’s pelvis with a lead shield, should be strongly considered.

**Radial-Specific Vascular Complications**

While bleeding and vascular complications with the radial approach are rare, they can occur. Hematoma of the forearm is generally easily controlled with a brief course of manual compression. Wrapping the forearm with an Ace bandage or a self-adherent elastic wrap for 15 to 30 minutes following manual compression can prevent recurrence, but close attention needs to be paid to make sure that the hematoma is not expanding, in which case manual compression needs to be resumed. A blood pressure cuff may also be utilized, inflated to systolic pressure and then gradually released over time. In all cases where there is circumferential pressure around the arm, venous stasis can occur. A brief hiatus to allow perfusion before continued compression may be necessary. Compartment syndrome is a poorly managed hematoma that leads to hand ischemia. If radial patients are being closely tended to in recovery, compartment syndrome should never occur.

Both pseudoaneurysms and arteriovenous fistulas can occur in the radial artery, but are rare. A pseudoaneurysm is usually easily treated by having patients wear a hemostatic device over the radial artery for up to an hour. If unsuccessful, a longer duration may be necessary or a thrombin injection could be considered. Other complications, including spasm, vessel dissection or perforation, and radial artery occlusion will be specifically addressed below.

**THE RADIAL TECHNIQUE**

**Patient Preparation and Setup**
The entire cardiac catheterization laboratory needs to be educated about the radial approach so that procedures run smoothly and safely from the time of the patient’s arrival to his or her departure. In the pre-procedural area, intravenous (IV) tubes should not be placed near the wrist, and an antecubital IV should be placed if a right heart catheterization (RHC) is anticipated (see below). Groins will often be prepped, particularly earlier in the learning curve.

Most patients are suitable candidates for radial access. Some relative contraindications to consider are the presence of severe Raynaud’s phenomenon, presence of a dialysis arteriovenous fistula, and history of a left internal mammary artery (LIMA) bypass graft where the left radial artery has also been used as a bypass conduit. In this situation, the LIMA will have to be accessed from the right radial artery, which is challenging, though not impossible. Whether to also forgo the radial approach on patients who have an abnormal modified Allen’s or Barbeau test is controversial. There are no data demonstrating that performing a modified Allen’s or Barbeau test to evaluate the patency of the ulnopalmar arch predicts hand ischemia, but many operators, particularly in the United States, still prefer to do it. Compared to the modified Allen’s test, the Barbeau test has been found to be more sensitive and is also typically used in a reverse fashion when assessing for patent hemostasis (see below).

Once in the procedural room, either the right or left arm will be prepared for access. The right arm is generally more convenient, but there are advantages to the left arm. The left subclavian artery is often less tortuous than the right subclavian/innominate, particularly in patients who are older than 75 years of age and shorter than 165 cm. In addition, the curves taken by the catheter more closely mimic those seen when coming from the groin. As a consequence, operators may find the procedures easier and the learning curve shorter when using the left arm. There are also data to suggest that radiation exposure is less from the left arm. Regardless of the preferred side, becoming facile at left arm setup is a must for any lab. The left arm will be needed for coronary artery bypass grafting (CABG) cases and crossover if access or engagement from the right radial artery fails.

For left arm procedures, the left radial artery is typically accessed from the left side of the patient. Then the operator returns to the right side of the patient, where she or he is accustomed to standing and driving the table. The
left arm is brought up on the patient’s body and secured in place. Various methods have been employed for securing the arm, but a high arm board and some blankets usually suffice. The wrist then sits at about the level of the left groin.

For radial access preparation, the arm is placed on a board that will allow the arm to be brought to the patient’s side during the procedure, or up on the body in case of left wrist access. The wrist is slightly hyperextended, either with a rolled towel or specialized wrist splint (Fig. 22-2). For new radial operators, the groin should be prepped and ready for access, so that crossover does not add to the burden of learning a new skill. However, as proficiency grows and crossover decreases, consideration should be given to discontinuation of groin prep, which is rarely needed and only adds to staff preparation time. For right arm procedures, there should be a board distal to the arm that extends from the table and provides a working surface, as it is often not feasible to work on the patient’s body, as is usually done from the femoral approach. Finally, the patient can be draped with a specialized radial drape, or a neck drape can be used to cover the arm in addition to the usual femoral drape (Fig. 22-3).

**FIGURE 22-2** The wrist is slightly hyperextended.
FIGURE 22-3 Patient prepped for radial access.

Access

Prior to starting the case, take a moment to make sure that the patient is
comfortable and reasonably sedated. Anxious patients are more prone to spasm, and the key to avoiding spasm is prevention. The optimal site for radial access is approximately 2 cm proximal to the radial styloid process (Fig. 22-4). There is a tendency for new operators to creep distally, but while the radial pulse may be stronger at the level of the styloid process, the radial artery is more likely to turn or give off branches in this area, making access more difficult. Once the proper location is identified, a small amount of lidocaine should be administered. Only about 1-2 mL is needed (Fig. 22-5), and too much may obscure the pulse.

FIGURE 22-4 The optimal site for radial access is approximately 2 cm proximal to the styloid process.
There are 2 techniques for accessing the radial artery. The first is the modified Seldinger technique, which uses a short micropuncture needle, and the second is the Seldinger technique, which uses an angiocath needle. The modified Seldinger technique involves making an anterior wall stick and, once in the vessel, slightly adjusting the needle’s position for the best blood return possible prior to advancing the wire. The Seldinger technique involves puncturing the anterior wall, which results in blood return, and then continuing the puncture through the posterior wall until the blood return stops (Fig. 22-6). This ensures that the needle catheter is deep enough when the needle is removed. After removal of the needle, the catheter is pulled back at a superficial angle until there is blood return, at which point the wire is advanced (Fig. 22-7). With this latter technique, there are no other adjustments of the needle catheter—once it is in, it is in. While either technique is safe and effective, the Seldinger technique may be easier, particularly for new operators.45

FIGURE 22-6 The Seldinger technique involves puncturing through the anterior and posterior walls.
For access, the needle is held at a 30° angle, and once the pulse is identified, the needle should be advanced gently, but definitively. If the artery is missed, prior to pulling back on the needle, determine if the pulse is more medial or lateral. Then, withdraw the needle just to the surface of the skin and redirect, preferably without making a new puncture in the skin. Rather than manual palpation, another option is ultrasound. Some operators like to use it when they are having difficulty hitting the artery or the pulse is weak, whereas others use it routinely. When used routinely, ultrasound has been shown to decrease the number of attempts and time to access. Another trick to use if the pulse is weak is to have someone occlude the ulnar artery or the radial artery distal to the access site to increase the force of the pulse.

The hydrophilic sheath is one of the advances in radial artery equipment that has improved the procedure since the 1990s. Hydrophilic sheaths have been shown to reduce spasm, but the length of them has not. Since the sheath has the largest outer diameter of anything being put in the artery, minimizing its length whenever possible seems prudent. Because of its hydrophilicity, a skin nick is rarely needed. Instead, the sheath is advanced directly through the skin while being rotated side to side (Fig. 22-8). If the skin is tough, a small nick can be made. However, the sheath can slide easily in and out of the skin, so the nick should be kept to a minimum. Once the sheath is in place, some operators like to secure it with a Tegaderm dressing to keep it from slipping out. There should not be any significant pain or resistance.
when advancing the sheath. If there is, investigate before advancing further. Perhaps the artery is too small for the sheath, or there is spasm or heavy calcification.

![Image](image_url)

**FIGURE 22-8** The hydrophilic sheath is advanced directly through the skin—no nick is generally required.

Sheath size should be kept to a minimum. Larger sheaths, particularly in relation to the size of the radial artery, have been implemented as one of the causes of radial artery occlusion.\(^ {47}\) For diagnostic cases, a 5-Fr system is generally sufficient and some operators use 4-Fr. Newer thin-walled sheaths allow for passage of 6-Fr equipment while maintaining a 5-Fr outer diameter, or 5-Fr equipment while maintaining a 4-Fr outer diameter. Another advantage to the thin-walled sheath is that it can minimize sheath exchanges. Prior to their advent, an operator would start with a 4-Fr or 5-Fr sheath for the diagnostic angiogram, but if the case needed to go to PCI, the operator either had to do a 5-Fr PCI, which had equipment limitations, or upsize to a 6-Fr sheath. Now, a 6-Fr thin-walled sheath can be used for the entire case. Most PCIs can be done with a 6-Fr system. In rare circumstances, an operator might want to upsize to a 7-Fr or 8-Fr. Few patients, especially women, can safely accommodate that size sheath in their radial artery. As an alternative, there is a now a 7-Fr thin-walled sheath (with a 6-Fr outer diameter) or there are sheathless systems. Sheathless systems eliminate the sheath and drop the French size down to the outer diameter of the guide, which is ∼2-Fr smaller than the outer diameter of the traditional sheath. The sheathless system,
however, requires a smooth transition at the tip of the guide so that it can be advanced from the skin into the artery with minimal trauma. There are limited dedicated sheathless guides or one can be made by putting a smaller introducer within the guiding catheter.\textsuperscript{48}

Once the sheath is in place, a radial artery cocktail is given to reduce spasm. This can be varied based on operator preference, but a good rule of thumb is 2.5 mg of verapamil and 100 to 200 μg of nitroglycerin. These drugs are generally well tolerated except by patients who have severe aortic stenosis, in which case they should be avoided or given with caution. The cocktail may also contain heparin, which is important for reducing radial artery occlusion. If given via the radial artery, it is often diluted with blood because it tends to burn. It is also fine to give the heparin via a peripheral IV. Some operators like to wait to give heparin until after they have successfully navigated up the arm in case they have to cross over to the groin. The recommended dose is 50 units/kg. Bivalirudin has also been shown to be effective in reducing radial artery occlusion, and is an acceptable alternative. However, warfarin (Coumadin) is not. Patients with a therapeutic International Normalized Ratio (INR) from warfarin still need to be given the usual dose of heparin.

**Navigating Up the Arm**

In the majority of cases, a J-tipped guidewire (either 3 mm or 1.5 mm) will slide up the arm without difficulties. Using such a wire provides safety and minimizes the need for fluoroscopy. If any resistance is met with the J-tipped wire, fluoroscopy can be used to see where the wire is impeded. At that point, switching to a straight hydrophilic wire and maneuvering it under fluoroscopy is generally enough to successfully navigate the arm. However, if there are still issues, an angiogram of the arm should then be performed to ascertain the necessary path. A notable obstacle that may be seen is the radial loop (Fig. 22-9). The radial loop varies in terms of complexity and can often be navigated without much difficulty. In such cases, the hydrophilic wire may easily go through and straighten the loop itself, or the guide can be manipulated around the loop and then gently pulled back and torqued to straighten the loop. Other times, a coronary wire and smaller catheters are needed, and the patient may find it painful. In such situations, operators have to decide if they want to continue their efforts or switch to the contralateral
wrist. A radial loop on one side does not necessarily predict a radial loop on the other side.

Another, more common, encounter when going up the arm is a high-takeoff of the radial artery, where the origin of the radial artery is proximal in the brachial artery or even in the subclavian artery. If the radial artery is reasonably sized, this anomaly generally goes unnoticed. However, it is often detected when the wire passes smoothly, but the catheter meets resistance. A similar situation can occur if one has gone into an accessory radial artery. Caution needs to be taken in these smaller radial vessels, which are more
prone to spasm and dissection or perforation. An angiogram of the arm should indicate if there is an alternate path into the brachial artery that was missed, in which case the wire should be redirected, or if one has only the small radial to use. If the latter is the case, the operator needs to decide if she or he can safely advance the catheter, or if she or he needs to use an alternate access site. Downsizing the catheter may be helpful. Another useful technique for navigating small or tortuous vessels is balloon-assisted tracking. This involves inflating a coronary balloon at the end of the catheter to make an atraumatic tip, which is then advanced over a coronary wire.

If a dissection, a perforation, or both occur in the arm, a new operator’s instinct is often to abort the procedure. However, this is the wrong inclination. On the contrary, trying to safely advance a wire and catheter through the traumatized area is the key to treating it. This may require a coronary wire, a smaller catheter, and balloon-assisted tracking. Still, once the catheter is across the dissection/perforation, the vessel will tamponade and seal itself. This can be confirmed with an angiogram at the end of the case (Fig. 22-10).

Once up the arm, the catheter has to be advanced into the ascending aorta.
The subclavian/innominate arteries can be tortuous, but with practice, these curves become less cumbersome. Having the patient take a deep breath will often straighten out the path. In addition, pointing the catheter in the direction one needs to go will aid wire passage. The use of a hydrophilic wire can also be helpful. The most challenging type of curve in the aortic arch is due to arteria lusoria. Arteria Lusoria is the most common aortic arch anomaly, in which the right subclavian artery arises as the most distal branch off the aortic arch, and then travels between the esophagus and trachea to supply the right arm. This can be negotiated, but sometimes requires great effort and may be an instance in which to consider crossing over to another access site.

Tortuosity in the subclavian/innominate and aortic arch also leads to difficulties in engaging catheters even once one makes it into the ascending aorta. Again, having the patient hold a deep breath while torquing can be helpful, as can leaving the guidewire in the catheter/guide while torquing. These 2 maneuvers become increasingly necessary as the amount of torque increases. A novel complication with radial procedures is the catheter loop and kink, which is the result of excessive torque. Not only is there a kink in the catheter, which is seen with excessive torquing from the femoral artery, but there is also a loop, which simply spins around and cannot be undone without traction on the distal catheter (Fig. 22-11). The best approach is to have a high index of suspicion for this complication when aggressively torquing a catheter and to stop immediately if pressure dampening is noted or the distal end of the catheter does not seem to be responding to proximal movements. If the kink has not gotten too bad, it can often be undone with a counter-torque while advancing the guidewire. On the other hand, if a loop and kink occur, and no wire can be advanced, distal traction needs to be placed on the catheter, either externally or internally. External traction can include manually trying to compress the catheter through the arm or application of a blood pressure cuff. Internal traction is generally done with a snare. Once the distal catheter is fixed, the proximal end can be counter-torqued to get rid of the loop and kink. Another option is to try advancing a longer sheath or a larger catheter over the existing catheter. This involves cutting the end of the existing catheter, removing the sheath, and then sliding the longer sheath or larger catheter over the existing catheter up to the location of the loop/kink. Then, the existing catheter is counter-torqued and pulled into the larger lumen.
A final problem encountered in the arm is spasm. As previously mentioned, the key to avoiding spasm is prevention. In addition, as radial operators become more experienced, their rates of spasm decrease. The use of adequate sedation, a hydrophilic sheath, and a spasmolytic cocktail have already been discussed. In addition, minimizing catheter manipulations and exchanges is important. There are early signs of impending spasm including more friction on the catheter and complaints of pain by the patient. These warnings should result in immediate cessation of catheter manipulation, at which time the patient should be given more sedation. Consideration should also be given to downsizing the catheter. If the catheter is exchanged for a smaller size, an additional spasmolytic cocktail can be administered. A warm blanket can also be placed on the arm. If early warning signs are ignored and frank spasm occurs, additional sedation should be given and the catheter should be left alone. Continuing to pull on it only exacerbates the spasm and an overly forceful pull could result in radial artery evulsion. Another trick is to inflate a blood pressure cuff for 5 minutes on the arm and then release it.
The resultant flow-mediated dilation may allow release of the catheter. If after 10 to 20 minutes of rest, adequate sedation, and readministration of vasodilators, the catheter is still stuck, an anesthesiologist needs to be called. She or he can administer propofol, which is generally successful in getting the radial artery to relax. If not, general anesthesia may be required.

**Catheters/Guides**

Each operator must find his or her own workhorse catheters and guides. For diagnostic cases, some operators like a universal catheter (used for both the left and right coronary arteries), while others prefer to stick with a Judkins left 4 and Judkins right 4. The advantage to a universal catheter is that it minimizes catheter exchanges. The disadvantage is that it is a new catheter for most operators and takes some getting used to. Still, with practice, the universal catheters can be mastered fairly easily. Similarly, for interventional cases, there are radial-specific guides, some universal, as well as all of the standard femoral guides that operators are familiar with. For most PCIs, standard femoral guides work very well. Because support is more commonly an issue from the wrist than the groin, one may want to start with a more supportive guide, such as an extra back-up guide for the left coronary artery and an Amplatz for the right coronary artery. For STEMI cases, starting with a universal guide can decrease time by eliminating catheter exchanges.

For diagnostic cases in a coronary artery bypass graft (CABG) patient, the left radial artery will generally be accessed, and any of the diagnostic catheters used for the femoral approach can also be used from the radial approach. If the angle into the LIMA is less than 90°, a no-torque right catheter may be able to better make the hook than the internal mammary artery catheter. For PCI of a saphenous vein graft (SVG), an Amplatz guide is usually needed. An exception is the vertically oriented SVG to the right coronary artery, in which case a multipurpose guide can be deep-seated and will offer the best support.

All catheter/guide exchanges need to be made over a wire. This keeps catheters and guides from catching on the great vessels and maintains positioning in the ascending aorta. This becomes especially important if it was hard to get into the ascending aorta to begin with. In addition, it is common when approaching from the right radial artery that catheters/guides will need to be downsized a half French size for the left coronary artery and
upsized a half French size for the right compared to what is usually used from the femoral approach.

Because having adequate support is more of an issue from the radial approach, in addition to using supportive guides, operators need to become adept at using tools and techniques that will provide them with increased support when necessary. A simple buddy wire will often suffice. More often, a guide extension catheter will be needed. If neither of those options is enough, use of an anchor balloon provides the most support. In this situation, a second coronary wire is advanced into a less important branch, generally a marginal on the right or a septal branch on the left. Next, a semi-compliant balloon sized to the branch is gently inflated in the branch. This anchors the guide in place and the equipment for the target lesion can now be advanced into the artery (Fig. 22-12).
branch to anchor the guide.

**Right Heart Catheterization**

The need for a right heart catheterization (RHC) should not be a reason to forgo the radial approach. Instead, the right brachial vein can be used. In fact, any superficial vein will go to the deep veins, so all that is needed is an IV placed in the antecubital fossa. This can be done preprocedurally by a nurse and then the area can be prepped and draped by the staff in the room. It is preferable if a more medial vein is chosen, which is more likely to drain in a relatively straight course into the basilic vein that then joins with the brachial vein to form the axillary vein and, ultimately, the subclavian vein. When advancing up by this approach, little to no fluoroscopic guidance may be required. More lateral veins, on the other hand, may drain into the cephalic vein, which enters the axillary vein at a “T-junction.” This intersection results in a right angle turn that can be more difficult to negotiate. If the nurses are unable to place an antecubital IV, the brachial vein can be accessed directly by the operator using ultrasound and a micropuncture kit.

In a sterile fashion, the existing IV is threaded with an 0.018-in wire. Once the IV is removed, a small amount of lidocaine is administered at the site. Next, a 5-Fr hydrophilic sheath is advanced over the wire and gently pushed right through the skin into the vein. No nick is needed. The wire can be left in place and used as a track to advance the 5-Fr balloon-tipped pulmonary artery (PA) catheter, or the PA catheter can be advanced without the wire. It must be recognized, however, that the PA catheter will sometimes get hung up on valves or have a hard time making a turn, in which case the wire may be needed after all. Force should never be applied as veins are more fragile than arteries and can tear or perforate if aggressively handled. If a wire or catheter is not progressing, a limited venogram can be helpful. For routine diagnostic right heart catheterization, the commercially available 5-Fr balloon-tipped catheters and thermodilution catheters are generally best, although larger systems can be used if needed.

**Hemostasis**

Once the case has ended, a hemostatic device is placed on the wrist. While some operators simply use a rolled piece of gauze and an Ace bandage, it is
strongly recommended that a device with a mechanism for fine-tuning the amount of pressure on the radial artery be used. This is because the goal is not to simply have hemostasis, but to have patent hemostasis, meaning that the artery is not only not bleeding, but is still perfusing. Patent hemostasis, along with adequate anticoagulation and minimizing the sheath size, are the 3 key components to minimizing radial artery occlusion.\textsuperscript{50,51} The reported incidence of radial artery occlusion is quite variable, but is probably somewhere around 10%. However, when these 3 particular evidence-based steps are taken to reduce radial artery occlusion, the incidence drops to <1%, so they should be routine goals in every cath lab.

To achieve patent hemostasis, a pulse oximeter with plethysmography is placed on the index finger, and the hemostatic device is applied with the least amount of air or pressure possible. Next, the operator occludes the ulnar artery and evaluates the plethysmograph to confirm patency of the radial artery (reverse Barbeau test). Simply feeling the radial pulse once the hemostatic device is in place is insufficient because the pulse may actually be arising from the ulnar artery and going around the palmar arch rather than coming from the radial artery. Ideally, one will achieve a reverse Barbeau A, B, or C waveform on the plethysmograph (Fig. 22-13). If the plethysmograph shows a flat line (reverse Barbeau D), an attempt should be made to decrease the amount of air/pressure in the device. If further air/pressure cannot be removed without bleeding, then the band is left as is with the expectation that it will be tended to in recovery. Upon arrival to recovery, it should be standard protocol that the reverse Barbeau test be repeated. If the patient still has a reverse Barbeau D, another attempt should be made to decrease the amount of air/pressure while maintaining hemostasis. Generally, patent hemostasis can be achieved upon arrival to recovery if it was not achieved in the cath lab. If patent hemostasis still has not been achieved upon arrival to recovery, attempts should be repeated every 15 minutes until they are successful. Once patent, it is also important to have periodic checks to confirm that the radial artery remains patent. In the very rare situation that the radial artery is not patent by discharge, the hemostatic device can be reversed, occluding the ulnar artery for up to 1 hour to get the radial artery open.\textsuperscript{52} Low-molecular-weight heparin can also be given for several days post discharge if the radial artery remains occluded, although there are limited data regarding this technique. Early occlusion (≤24 hours) is associated with late occlusion (≥30 days), whereas early patency nearly guarantees late
patency (99.1%), so every effort should be made to keep the artery open throughout recovery.

FIGURE 22-13 Reverse Barbeau oximetry waveform categories. (Adapted by James Bonnett from Barbeau, 2004 (40).)

The duration of use of the hemostatic band will vary depending on the type of procedure. Generally, for a simple diagnostic case, the band will stay on for 1-2 hours. Some operators will start gradually decreasing the air/pressure prior to removal, whereas others do not. For interventional cases, the band will generally stay on for 2-4 hours. Nursing protocols need to be adapted to each institution’s practice. Notably, for prevention of radial artery occlusion, the duration of the hemostatic device is less important than the maintenance of patent hemostasis. Since some patients will be cared for on an inpatient unit, unit nurses also have to be trained on how to use the hemostatic device and how to maintain patent hemostasis. While it may seem obvious, recovery staff should be reminded that radial patients (whether diagnostic or PCI) are to be ambulatory during recovery as soon as their hemodynamic stability has been confirmed. Keeping radial patients in cardiac chairs rather than on hospital beds and letting them get dressed can also facilitate their recovery and discharge.

INCORPORATING STEMI INTO A RADIAL PROGRAM
As mentioned, it is important to complete one’s learning curve, being able to tackle the most challenging cases radially, in order to provide the most benefit to patients from this approach. The pinnacle of the learning curve is primary PCI. Doing STEMI patients requires not only a certain level of mastery of the radial approach, but also a confidence in one’s ability. It requires that the cath lab staff be skilled and comfortable with the approach as well.

Once one has decided to start doing STEMIs radially, it is advisable to begin with some straightforward cases, such as good-sized men who are hemodynamically stable. As confidence grows, more and more challenging cases can be taken on until the radial approach is the default strategy for all STEMI cases. Even if one no longer preps the groin for elective radial cases, the groin should always be prepped for STEMI radial cases. The good possibility of the need for an intra-aortic balloon pump (IABP) and/or left ventricular assist device (LVAD) makes easy femoral access a necessity. In addition, operators new to radial STEMI naturally feel more comfortable knowing a bailout strategy is close by. Rough guidelines as to when a radial operator may want to cross over to the groin during a STEMI include when radial access is taking >3 minutes, when the time from sheath placement to engaging the infarct-related artery with the guide catheter is taking >10 minutes (including the time to inject the non-infarct artery), or when the total time from radial artery access to crossing the infarct lesion is taking >20 minutes.

Patients with cardiogenic shock can be the most challenging. The radial pulse can be hard to feel due to poor perfusion and the radial artery may be constricted from vasopressors. Moreover, giving a spasmolytic cocktail may be unsafe. An operator ultimately has to do what she or he thinks is in the best interest of the patient. Still, small studies have shown that a radial approach is safe and feasible in at least one half of cardiogenic shock patients. The use of ultrasound for access can facilitate radial artery cannulation when the pulse is weak. Likewise, up-front placement of an IABP, LVAD, and/or pacer may be helpful, as the patient’s hemodynamic status may improve. There is less chance of a bleeding or vascular complication with 1 stick to the groin rather than 2, so having accessed 1 femoral artery is not a good reason for accessing a second if the radial approach is an option.

One of the biggest concerns for operators in transitioning to a radial
STEMI program is that it will adversely affect their door-to-balloon (D2B) times. In fact, the impact is negligible. An interesting study modeling the mortality benefit of the radial approach against the mortality benefit of minutes to reperfusion found that a delay of 83 minutes in D2B time would be needed to fully offset the mortality benefit gained by the radial approach. When beginning a radial STEMI program, it is reasonable to track D2B times, and if any significant deviations are noted, it should be decided if they were secondary to the access site. If so, further radial training or stricter guidelines for crossover may be needed.

**SAME-DAY PCI**

One of the advantages to the radial approach is the ability to comfortably send patients home the same day. This adds to patient satisfaction and lower costs, and is the result of fewer bleeding and vascular complications. While most of the data regarding same-day PCI are based on femoral patients, most operators do not send their femoral cases home same-day because the concern for a femoral complication is simply too high. There are several studies demonstrating that same-day discharge for patients undergoing radial PCI is safe and effective. In fact, if any complications are going to occur after a radial procedure, they either occur in the first 6 hours or after 24 hours, with no unheralded complications occurring between 6 to 24 hours.

In the femoral era, most patients undergoing an uncomplicated PCI typically stayed in the medical facility overnight (considered an outpatient or 23-hour observation stay with same-day PCI, the patient returns home or to a nonmedical facility (ie, a hotel) the same day. Currently, the reimbursement for a same-day PCI is the same as for a 23-hour observation stay. That means that the hospital gets paid the same amount, but with same-day discharge there are fewer nursing costs, as well as an open bed that can be used for someone else.

Sending patients home with same-day discharge requires a protocol. Based on current data, patients should be kept 6 hours after their procedure, but less time before discharge may be possible. Regardless, doing PCIs earlier in the day to allow for same-day discharge is recommended. Certain patients will not be eligible for same-day procedures, such as those with an unstable residual dissection, loss of a major side-branch, or ongoing evidence of
ischemia. Likewise, certain social situations may preclude same-day discharge, such as having no driver or living too far from a medical facility. All patients should have a designated responsible adult who can be available for assistance if necessary. If a patient is already an inpatient, same-day discharge may also not make financial sense (since inpatients are reimbursed at a higher rate than outpatients) or may not be feasible because of the time needed for discharge planning. Some discharge planning is required even for patients who are simply being discharged from the recovery unit. By discharging patients the same day rather than the next morning, operators are eliminating morning rounds, which is where there is often an important discussion regarding the procedure, the need for dual antiplatelet therapy, and the plans for followup. This all has to be done prior to discharge on the same day. These details can be hard for patients to remember, especially after sedation, so having another adult present can be helpful. In addition, there must be a planned call the following morning by a nurse to review the above details and to see if the patient had any concerns overnight or has any questions. The attending physician should be contacted if there are any outstanding issues. If the patient cannot be reached, the responsible adult should be contacted.

SUMMARY

Within the past several years, the radial approach has gained traction and is changing the paradigm of interventional cardiology in the United States. Transitioning from a femoral to radial lab takes a patient and cooperative effort from all members of the cardiac catheterization team, but is routinely being done with great effect. The benefits are clear, with significant reductions in bleeding and vascular complication rates, improved patient satisfaction, and decreased cost. The more high-risk the patient, the more pronounced the benefits. Increasingly, PCI is being seen as a same-day procedure, and the radial approach is making that possible. All because of where we stick a patient, interventional cardiology will never look the same again.

**MULTIPLE CHOICE QUESTIONS**

1. Which patient would benefit most from a radial procedure?
   A. 67-year-old man with a body mass index (BMI) of 32 and unstable angina
   B. 83-year-old woman with a BMI of 19 and ST-segment elevation myocardial infarction (STEMI)
   C. 54-year-old man with a BMI of 28 and STEMI
   D. 64-year-old woman with BMI of 33 and unstable angina
   E. 85-year-old man with BMI of 23 and stable angina

2. What is the primary driver of decreased cost with radial procedures?
   A. Less expensive equipment
B. Fewer complications
C. Shorter lengths of stay
D. Higher reimbursement
E. Faster procedure times

3. What is the advantage of right radial access compared with left radial access?
   A. Convenience
   B. Less radiation exposure
   C. Shorter learning curve
   D. Easier in post-coronary artery bypass graft (CABG) patients
   E. Less tortuosity

4. Which of the following is most important in reducing radial artery occlusion?
   A. Minimizing sheath size
   B. Minimizing sheath duration
   C. Achieving patent hemostasis
   D. Giving intravenous or intra-arterial heparin
   E. Giving intra-radial nitroglycerin before pulling the sheath

5. Which of the following is true regarding ST-segment elevation myocardial infarction (STEMI) procedures from the radial artery compared with the femoral artery?
   A. Door-to-balloon times are significantly slower
   B. Mortality is significantly lower
   C. Cardiogenic shock is an absolute contraindication
   D. Stroke rates are significantly higher
   E. Most operators doing radial procedures do their STEMIs radially

ANSWERS

1. B

Bleeding risk is higher in those who are older, female, and presenting with a more severe coronary syndrome. In addition, bleeding risk is highest in those
with the lowest body mass index (BMI) (<22.5). Excess BMI does not start to increase bleeding risk until it reaches 40 (morbid obesity), and those with a BMI of 25 to 35 have the lowest risk. Therefore, “little old ladies” are at the highest risk of bleeding, especially when presenting with an ST-segment elevation myocardial infarction (STEMI), and will most benefit from a radial approach. However, these are the patients who are least likely to get a radial procedure. Operators tend to use radial access in younger, average-sized male patients with stable angina (risk–treatment paradox) because these patients are typically easier—larger vessels, less tortuosity, less urgency. In order to reap the bleeding and mortality benefits, operators need to master radial procedures in all patient subsets.

2. C

While fewer complications contribute to the decreased cost of radial procedures compared with femoral procedures, the primary economic benefit comes from shorter lengths of stay. For any observational patient post-percutaneous coronary intervention (PCI) (radial or femoral), regardless of how long they stay during that observational period, the reimbursement is the same. As a consequence, the sooner a patient goes home, the less money is used on resources, especially nursing, and the sooner that bed can be filled with another revenue-generating patient.

3. A

The main advantage of right radial access is convenience. Left radial procedures require that the operator either go around or reach across the table for access, and then the left arm has to be positioned and secured on the patient’s torso, so that the operator can work from the right side of the table, which they are most familiar with, without leaning over. While less convenient, being able to do procedures from the left radial is still a must. This is primarily for post-coronary artery bypass graft (CABG) patients who have a left internal mammary (LIMA) bypass graft, because engaging the LIMA from the right radial approach can be challenging. Left radial access may also be needed for patients who do not have an accessible right radial artery or whose procedure cannot be completed from the right because of technical difficulties. In addition, it has been shown that there is a shorter learning curve and less radiation exposure with the left radial approach.
compared to the right. The left radial approach may also be easier in those who are shorter and older, as these patients tend to have more right subclavian/innominate artery tortuosity.

4. C

All of the choices have been shown to reduce radial artery occlusion, but achieving patent hemostasis appears to be the most important. In comparing sheath size, sheath duration, and patent hemostasis, only patent hemostasis was a predictor of radial artery occlusion. More recent data also suggest that heparin use may not be as important if radial artery patency is actively maintained during hemostasis.

5. B

Radial access for STEMI has been shown to significantly reduce bleeding, major adverse cardiovascular events (MACE), and mortality compared with femoral access. The impact on door-to-balloon time is negligible, adding ~1 to 4 minutes. As operators improve, this time lessens, and some investigators have even reported faster door-to-balloon times with the radial approach compared with the femoral approach. There is no difference in stroke rate with the radial vs the femoral approach. Cardiogenic shock makes radial access more challenging because the pulse may be weak and spasmolytic agents may be unsafe. In addition, if vasopressors are used, radial lumen size can be reduced. Still, at least half of patients with STEMI and cardiogenic shock can be done via the radial artery. While STEMI patients have the most significant reductions in bleeding, as well as a mortality benefit with the radial approach, a minority of STEMI cases are performed radially, even by operators who frequently use the radial artery for their non-emergent cases. Completion of the learning curve by performing emergent cases radially will ultimately be necessary to maximize the positive impact of the radial approach on patient outcomes.
Peripheral Angiography

Jose A. Silva

INTRODUCTION

Atherosclerosis is a systemic vascular disease that often affects multiple vascular territories and leads to peripheral artery disease (PAD). The age-adjusted prevalence of peripheral atherosclerotic disease is approximately 12%. However, patients with established risk factors for this condition, such as diabetes mellitus, or patients with known coronary artery disease (CAD), have a much higher prevalence of peripheral athero-occlusive disease.

Peripheral atherosclerotic disease remains poorly recognized, as recently demonstrated by the PARTNERS (Peripheral Arterial Disease Awareness, Risk and Treatment: New Resources for Survival) Investigators, a US national survey of almost 7000 patients seen in 320 primary care clinics. The survey showed that only 45% of the patients with peripheral vascular disease had been diagnosed with this condition prior to the PARTNERS Program.

Consequently, clinicians must have a high grade of suspicion for detecting PAD in patients with known risk factors or with established CAD, and these patients must undergo a detailed history and physical examination as well as non-invasive tests such as ankle-brachial index and/or arterial duplex ultrasound to rule out the presence of peripheral vascular disease. In those with significant symptoms, assessment of the peripheral vascular anatomy is necessary if intervention is being considered.

Despite major advances in noninvasive imaging techniques such as duplex ultrasonography, angiographic computerized tomography (CTA) (Fig. 23-1),
and magnetic resonance angiography (MRA) (Fig. 23-2), contrast angiography remains the gold standard method for diagnosing peripheral arterial vascular disease, because it provides the anatomic details necessary to plan percutaneous or surgical revascularization. In the present chapter, we will address the basic anatomy and angiographic procedures for the vascular territories that more commonly undergo percutaneous or surgical intervention.

**FIGURE 23-1** Digital subtraction angiography of a severely diseased superficial artery (right) compared with angiographic computerized tomography (CTA) (left).
FIGURE 23-2 Magnetic resonance angiography (MRA) of the aortic bifurcation, iliac, femoral, popliteal and infrapopliteal arteries.

GENERAL CONSIDERATIONS

The operator must be familiar with the techniques and equipment for different arterial vascular access sites (ie, common femoral artery [CFA], brachial artery, and radial artery). To obtain high quality angiographic images, it is essential to have a radiographic gantry with angulation capability in both the axial and sagittal planes as well as a large-field (14-16-in or 36-41-cm) image intensifier capable of capturing the larger regions of interest, such as the entire aortic arch, entire pelvic vasculature, and both legs.\(^5\)

Digital angiography allows immediate monitor display of the acquired image, as well as electronic processing to enhance contrast, reduce noise, and subtract bony and soft-tissue density. Digital subtraction angiography (DSA) significantly enhances the angiographic anatomical detail and allows less contrast to be used, which shortens procedure time. A preliminary image
(mask) is recorded immediately prior to the contrast injection, so that any background densities—such as bone, calcification, radiopaque objects, soft tissue, and air densities—can be subtracted from subsequent images (Fig. 23-3). Quantitative online angiographic analysis is available and often helps to provide an objective method of measurement.\textsuperscript{5} We have presented the most common angiographic views for performing peripheral angiography in Table 23-1.

\end{figure}

\begin{table}[h]
\centering
\caption{Most Useful Angiographic Views for Different Vascular Territories}
\end{table}
The use of low or iso-osmolar contrast agents is preferred to the use of high osmolar agents. These new agents are better tolerated since they produce fewer undesirable side effects such as nausea, vomiting, lightheadedness, or pain. In addition, low/iso-osmolar agents carry a lower osmotic load. This results in less fluid retention, which is desirable in patients with impaired left ventricular and/or renal function.

Alternatives to iodinated contrast, including carbon dioxide (CO₂) and gadolinium (eg, gadopentetate dimeglumine), are available to patients with severely impaired renal function and/or a history of life-threatening contrast allergy; however, these agents can also cause complications in a small
percentage of patients, including distal embolization and stroke if used above the diaphragm (occurring with CO\textsubscript{2}), or nephrogenic systemic fibrosis (occurring with gadolinium).\textsuperscript{7-10}

A wide variety of diagnostic catheters and guidewires are available for vascular angiography. Standard guidewires vary in diameter from 0.012 to 0.052 inch, but the most commonly used sizes are 0.035 and 0.038 inch. The length of most standard guidewires is between 100 and 180 cm, and the longer exchange guidewires measure between 260 and 300 cm. Tip configurations include straight or angled tip and “J” shape. Shafts may have varying degrees of stiffness. Devices with stiff, rigid shafts allow advancement through tortuous vessels, and low-friction, hydrophilic-coated wires allow passage in tortuous or difficult-to-cross lesions.

**AORTIC ARCH AND THORACIC AORTA**

The aortic arch and thoracic aorta include the ascending, transverse, and descending aorta to the diaphragm. The ascending aorta begins just distal to the sinus of Valsalva and courses from anterior to posterior in the chest. The transverse portion begins as the aorta crosses the main pulmonary artery and the left mainstem bronchus, and stretches to the ligamentum arteriosum (the remnant of the fetal ductus arteriosum). The descending portion begins distal to the ligamentum arteriosum and continues to the diaphragm.\textsuperscript{11} The normal aortic diameter ranges from 2.2 to 3.8 cm.\textsuperscript{12}

The transverse portion of the thoracic aorta courses posteriorly and gives rise to the brachiocephalic trunk proximally, the left common carotid artery in the mid portion, and the left subclavian artery in its distal portion. In 10% to 20% of patients, the left common carotid artery may originate from a common ostium with the brachiocephalic trunk or from the brachiocephalic trunk itself, an anatomic variation also known as a “bovine arch” (Fig. 23-4).\textsuperscript{13} Other less common anatomic variations also occur, including origination of the left vertebral artery directly from the aortic arch between the left common carotid artery and the left subclavian artery, and the origination of the right subclavian artery from the aortic arch distal to the origin of the left subclavian artery.\textsuperscript{13} The descending aorta courses anterior to
the spine and gives origin to nine pairs of intercostal arteries (T3 to T11).

**FIGURE 23-4** Bovine aortic arch showing the left common carotid artery arising from the brachiocephalic trunk.

**Thoracic Aortography**

Thoracic aortography is usually performed for the diagnosis of vascular diseases such as aneurysms, aortic dissection, coarctation of the aorta, patent ductus arteriosus, or vascular rings, as well as for the evaluation of vascular injuries such as blunt or penetrating chest trauma and stenoses in the origin of the great vessels. It is also useful prior to planning cerebrovascular intervention, to determine whether a brachial or femoral access site would be most beneficial. However, most of this pathology may also be diagnosed with high accuracy using non-invasive tests such as CT scan, magnetic resonance imaging, ultrasonography, and transesophageal echocardiography.14
The common femoral arterial access is the most frequently used vascular access, although the brachial or radial approaches are also useful for performing thoracic aortography. A 4- to 6-French (Fr) pigtail catheter is advanced into the ascending aorta and positioned just above of the sinus of Valsalva. Using a power injector, a total of 40 to 60 mL of contrast material is injected at 20 to 30 mL/sec. For cine imaging, 15 to 30 frames/sec is commonly used. The left anterior oblique (LAO) projection (30°-60°) best separates the ascending from the descending aorta and allows visualization of the origin of the great vessels. The anteroposterior (AP) and right anterior oblique (RAO) views may be helpful to assess the cervical branching vessels (vertebral, subclavian, common carotid).

The anatomy of the aortic arch has recently been classified into three types based on the relationship between the origin of the great vessels and a transverse line drawn at the level of the apex of the aortic arch. The Type I aortic arch is characterized by origin of all three great vessels in the same horizontal plane as the outer curvature of the aortic arch. In the Type II aortic arch, the innominate artery originates between the horizontal planes of the outer and inner curvatures of the aortic arch. In the Type III aortic arch, the innominate artery originates below the horizontal plane of the inner curvature of the aortic arch. (Fig. 23-5).\(^{15}\) This classification has practical clinical applications since the degree of difficulty and complication rates for performing selective cervical and cerebrovascular angiography and intervention are related to the aortic arch type (III > II > I).
Cervical Vessels

Three arteries originate in the transverse portion of the thoracic aorta, the brachiocephalic trunk, the left common carotid, and the subclavian artery. The brachiocephalic trunk or “innominate artery” bifurcates into the right common carotid artery and the right subclavian artery. Although the left common carotid most commonly arises separately from the aortic arch, in 10 to 20% the left common carotid artery may originate from a common ostium or from the proximal portion of the innominate artery and is termed a “bovine arch.”

The common carotid arteries run lateral to the cervical vertebral bodies in the AP view and bifurcate into the external and the internal carotid arteries at the level of C4 vertebrae. The internal carotid artery does not give origin to branches in its extracranial portion. It then enters the skull through the petrous portion of the temporal bone, after which it becomes very tortuous in a portion known as the carotid siphon, which courses within the cavernous sinus and the supraclinoid segment. Thereafter, it terminates into the anterior cerebral artery (ACA) and middle cerebral artery (MCA).

The most important branches of the subclavian artery are the internal mammary and the vertebral arteries, which arise at the inferior and the
superior aspects of this vessel, respectively, opposite each other. The vertebral artery is the first, and usually the largest, branch of the subclavian artery, arising from the upper and posterior surface of the vessel. It angles backward to the transverse process of the C_6 vertebra and courses cephalad through the foramina of the transverse processes of the upper five cervical vertebrae, where it enters the skull. After penetrating the foramen of the atlas, it turns medially and posteriorly to enter the skull through the foramen magnum. It then gives origin to the posterior inferior cerebellar artery (PICA), and subsequently joins the contralateral vertebral artery to form the basilar artery.

The vertebral artery is divided into four segments, identified as V_1 to V_4 (Fig. 23-6). This division is of clinical importance because atherosclerotic disease is commonly located in the most proximal 2-cm segment, sometimes called V_0, and within the first 2 segments of the vertebral artery (V_1 and V_2). V_1 begins after the ostial (V_0) portion and continues to the vertebral artery’s entrance into the foramen of the 6th transverse process (in 88% of cases). V_2 courses cephalad through the foramina of the transverse processes until it reaches the transverse process of the axis. V_3 continues to its entrance into the spinal canal, and it courses laterally and posteriorly to pass through the transverse foramen of the atlas, approaching the midline and then cephalad to perforate the posterior atlanto-occipital membrane to enter the vertebral canal. V_4 perforates the dura mater and passes through the foramen magnum, then joins the contralateral vertebral artery to form the basilar artery.
FIGURE 23-6 Diagrammatic representation of the 4 segments of a vertebral artery.
Angiography of the Brachiocephalic and Cervical Arteries

Vascular access may be obtained at the common femoral artery, the brachial artery, or the radial artery. An aortic arch aortogram (30°-60° LAO) is performed prior to selective angiography. This nonselective angiogram allows the operator to identify ostial disease, significant tortuosity, or anatomic variations in any of the brachiocephalic vessels.

Carotid Angiography

Carotid angiography remains the gold standard diagnostic technique for estimation and quantitation of stenoses of the carotid arteries, despite major advances in non-invasive diagnostic modalities such as duplex ultrasonography, MRA, and CTA in recent years. Selective carotid angiography is performed after obtaining an aortic arch aortogram in the LAO (30°-60°) view, which allows the operator to visualize the level at which the brachiocephalic trunk and left common carotid artery originate from the aortic arch. Using the same LAO angle, the brachiocephalic trunk may be easily engaged from the femoral access with a variety of shaped catheters: 4- or 6-Fr angled catheters such as right Judkins-4, internal mammary, and Berenstein; or shepherd’s crook shapes, such as Vitek, Headhunter, and Simmons Types I, II, and III. From the arm access, selective angiography may be performed with the shepherd’s crook shapes, particularly the Simmons catheters.

For selective angiography, after the ostium of the primary branch vessel has been cannulated, a 0.035-in “J” tip or soft-tip guidewire (Wholey wire, Covidien/Medtronic, Dublin, Ireland) is steered into the proximal portion of the common carotid artery and the catheter advanced over the guidewire, positioning it at the origin of the common carotid artery. The catheter is then aspirated and cleared to minimize the risk of embolization. Injections of contrast by hand are preferred to power injections for selective angiography (Fig. 23-7 and Fig. 23-8). When using small catheters and DSA, iodinated contrast may be diluted with saline 1:1 or 1:2 to enable better filling of the vessels.
FIGURE 23-7 Digital subtraction angiography of a left internal carotid artery stenosis affecting the ostium of the internal carotid artery in an oblique view.
FIGURE 23-8 Intracranial angiography of the left internal carotid artery and its bifurcation into the left anterior and middle cerebral arteries. It can also be appreciated with the right anterior and middle cerebral arteries (arrow), filling through the anterior communicating artery in the AP view. This particular patient had a chronic total occlusion of the right internal carotid artery.

Subclavian and Vertebral Angiography
The right or left subclavian arteries can be selectively engaged using the same technique, catheters, and guidewires previously described for selective carotid angiography. The AP view with or without shallow oblique views usually will demonstrate the area (or areas) of stenosis. In patients with a tortuous proximal left subclavian artery (the left subclavian artery is affected with PAD 3-4 times more frequently than the right\textsuperscript{20}) a steep caudal or RAO view with steep caudal views are very useful for showing the proximal vessel, which may not be obvious in the AP view. When the stenosis is suspected in the ostium of the right subclavian artery, the AP view may not
show the stenosis due to overlapping of the origin of the right common carotid artery (Fig. 23-9). A steep RAO caudal (40°-60° RAO with 10°-20° caudal), or RAO cranial view may be necessary to separate the origin of the right subclavian artery from the right common carotid artery (Fig. 23-10).

**FIGURE 23-9** Angiography in the AP view of the innominate artery and its bifurcation into the right subclavian and common carotid artery. The AP view overlaps the origin of the right subclavian artery and the right common carotid artery and may obscure a significant stenosis in the proximal portion of the subclavian artery.
FIGURE 23-10 The same patient as Figure 23-9 shown in the RAO caudal view, which separates the view of these two vessels and allows visualization of a mild plaque in the proximal right subclavian.

Vertebral artery angiography is usually performed with a non-selective injection of contrast in the subclavian artery close to the origin of vertebral artery, since the ostium is the most commonly affected area of stenosis. The vertebral artery usually arises from the superior aspect of the subclavian artery; however, not infrequently, the vertebral artery may arise posteriorly. A shallow cranial oblique (RAO or LAO with cranial angulation 10°-30°) is often needed to demonstrate the ostial stenosis (Fig. 23-11).
FIGURE 23-11 Non-selective digital subtraction angiography of the right vertebral artery in the AP view. The ostium in the V₁ portion of the vessel may not be well appreciated in this view. An AP cranial view is often necessary for better visualization of these segments.

When necessary, selective engagement of the vertebral artery can be performed with angled tip catheters (4-6-Fr internal mammary catheter, Berenstein catheter, or right Judkins-4 diagnostic catheter).

ABDOMINAL AORTA

The abdominal aorta begins at the level of the diaphragm at the 12⁰ thoracic vertebra. At this level, the aorta is anterior and leftward of the spine before its bifurcation into the common iliac arteries at the fourth lumbar vertebra.¹¹ The normal diameter of the abdominal aorta ranges between 1.5 cm and 2.15 cm.²² There are 3 main branches originating from the anterior aspect of the abdominal aorta: The first is the celiac trunk or celiac artery which arises at
the level of T₁₂ to L₁. Next, the superior mesenteric artery (SMA) originates above the renal arteries, between L₁ and L₂. The final branch, the inferior mesenteric artery (IMA), takes off in a left anterolateral direction at the level of L₃ to L₄. The renal arteries originate from the lateral aspect of the abdominal aorta at the level of L₁ to L₂ taking a lateral and posterior direction. Below the main renal arteries, four pairs of lumbar arteries arise in a posterolateral direction.¹¹

**Abdominal Aortogram**

Vascular access may be obtained from the arm or leg. A 4-Fr to 6-Fr pigtail catheter is positioned in the abdominal aorta so that the side holes are directly adjacent to the ostia of renal arteries. With a breath hold and subtraction angiogram, a power injection of contrast at 15 to 20 mL/sec, for a total of 30 to 40 mL of contrast, is usually adequate for good quality angiograms. It is important that the upper, lower, and lateral margins of both kidneys are visualized. This usually requires an image intensifier of 12 inches or larger. Two views should be obtained: the AP view allows good visualization of the renal arteries, and the lateral view enables assessment of the origin of the celiac and mesenteric arteries (Fig. 23-12 and Fig. 23-13). It is important to obtain images through the venous phase to visualize any late-filling collaterals. Of particular importance are pelvic collaterals that may be filling the mesenteric vessels.
FIGURE 23-12 Abdominal aortogram in the AP view showing significant ectasia and stenosis of the abdominal aorta.
Renal Arteries

The renal arteries arise from the lateral aspect of the abdominal aorta, usually between L₁ and L₂. They course laterally and posteriorly, and may take a caudal, horizontal, or cranial orientation. In about one quarter of the normal population an accessory renal artery will be present, which may originate anywhere from the suprarenal aorta down to the iliac arteries. Identifying these accessory branches is a major reason to perform an abdominal aortogram first, rather than proceeding immediately to selective renal angiography.

Renal Angiography

After an abdominal aortogram has identified the origin of the renal arteries,
selective renal angiography may be indicated if the aortogram demonstrates a renal artery stenosis of questionable hemodynamic significance, detailed images are required, or there is a need for pressure gradient measurement. Selective renal angiography is indicated if intrarenal vascular disease is suspected, as in fibromuscular dysplasia (FMD), vasculitis, or aneurysmal disease.

The renal arteries can be selectively engaged with 4-Fr to 6-Fr angled diagnostic catheters, although shepherd’s crook shapes (Sos Omni or Simmons) may be helpful in some cases. Selective renal angiography is performed with hand injection of contrast in a shallow LAO angulation (5°-10°) for both renal arteries (Fig. 23-14). The shallow LAO view has been shown to be the best view for the assessment of the ostium and proximal portions of both the right and the left renal arteries. Occasionally, some caudal or cranial angulation (15°-20°) may be helpful for tortuous vessels.

![Non-selective subtracted abdominal aortograms in the AP view of normal renal arteries (left) and bilateral renal artery stenoses (right).](image)

**FIGURE 23-14** Non-selective subtracted abdominal aortograms in the AP view of normal renal arteries (left) and bilateral renal artery stenoses (right).

**Mesenteric Arteries**

The celiac artery, superior mesenteric artery (SMA), and the inferior
mesenteric artery (IMA) constitute the mesenteric or splanchnic circulation. The celiac artery arises at the level of T₁₂ to L₁ and supplies blood to the stomach and half of the duodenum (foregut). The SMA originates at the level of L₁ to L₂ and provides blood flow to the lower half of the duodenum, ileum, cecum-appendix, ascending colon, and proximal two-thirds of the transverse colon (midgut). The IMA takes off in a left anterolateral direction at the level of L₃ to L₄ and supplies blood to the distal third of the transverse colon, descending colon, sigmoid colon, rectum, and the upper part of the anal canal (hindgut).²⁴

**Mesenteric Angiography**

Angiography of the mesenteric arteries is the gold standard to assess the anatomy of this vascular system. As is the case for the renal arteries, before selective angiography is performed, an abdominal aortogram should be obtained in the AP and lateral projections (Fig. 23-15). After the origin of the mesenteric vessels has been identified, selective angiography, if indicated, may be performed in the lateral view using angled diagnostic catheters (Fig. 23-16). The IMA often arises in a very acute inferior angle on the anterior portion of the abdominal aorta, for which a Simmons-1 or Sos Omni catheter is very useful for engagement.
FIGURE 23-15 Subtracted abdominal aortogram in the lateral view to assess the ostium and proximal portion of the celiac trunk and the superior mesenteric arteries.
Selective engagement of the mesenteric arteries allows measurement of translesional pressure gradients, since, as is the case for the renal arteries, the majority of stenoses in these vessels are located in their ostium or their very proximal portion. Using hand injections, selective angiography is performed in the lateral and oblique views.

**Pelvic and Lower Extremity Arterial Circulation**

The abdominal aorta bifurcates into the common iliac arteries (CIA) at the level of L₄ to L₅. The CIA bifurcates into the internal iliac artery (IIA) or hypogastric artery and external iliac artery (EIA) at the level of the lumbosacral junction. At the level of the inguinal ligament, two small branches originate from the EIA: the inferior epigastric artery, which follows...
a medial and superior direction, and the deep iliac circumflex artery, which takes a lateral and superior direction. These vessels are important to visualize as they may be the source of post-procedure access site bleeding.

Once the EIA crosses the inguinal ligament, it becomes the common femoral artery (CFA), which courses medially over the femoral head. When it reaches the lower edge of the femoral head, the CFA divides into the superficial femoral artery (SFA) and profunda femoris artery (PFA), also known as the deep femoral artery. The PFA runs posterior and lateral along the internal aspect of the femur. A few centimeters after its origin, the PFA gives origin to two small branches—the lateral femoral circumflex and the medial femoral circumflex arteries—and, subsequently, to several small perforating arteries. The SFA continues down the anteromedial thigh, and in its distal portion runs deeper to cross the abductor (eg, Hunter’s) canal where it becomes the popliteal artery. The popliteal artery crosses the knee and gives origin to small muscular branches, 2 sural branches, and 3 geniculate arteries (superior, medial, and inferior).27

Below the knee, the popliteal artery gives rise to the anterior tibial (AT) artery and continues as the tibioperoneal trunk (TPT). The AT artery runs laterally and anterior to the tibia to the foot, and as it passes over the ankle onto the dorsum of the foot, and becomes the dorsalis pedis (DP) artery. The TPT, bifurcates into the posterior tibial (PT) and the peroneal arteries. The PT courses posteromedially in the calf, while the peroneal runs near the fibula between the AT and PT arteries. The peroneal artery then rejoin the PT above the ankle via the posterior division, and the anterior tibial through the anterior division. On the dorsum of the foot, the DP artery has lateral and medial tarsal branches. After the PT artery passes behind the medial malleus, it divides into medial and lateral plantar arteries. The lateral plantar and distal DP arteries join to form the plantar arch.27

**Angiography for the Pelvis and Lower Extremity**

Vascular access is equally effective from the arm or femoral arteries for diagnostic angiography. If the CFA is chosen, the less symptomatic extremity is preferred. A 4-Fr to 6-Fr pigtail catheter is positioned in the terminal aorta, below the IMA and above the aortic bifurcation at L₄ or L₅. A power injection of 8 mL to mL/sec for a total 80 to 100 mL is needed to image both legs (from the CIA to the feet) using a stepping table and DSA.
Selective angiograms in different angulations of a particular artery or arterial segments are useful when the non-selective angiogram shows possible stenoses or when further anatomic clarification is needed. If access has been obtained from the CFA and the arterial segment in question is located in the contralateral extremity, a diagnostic internal mammary catheter is positioned at the origin of the contralateral CIA. A Simmons Type I or II catheter can also be used in case of significant acute angulation between the origin of both CIA. A soft-tip straight steerable 0.035-in guidewire such as a Wholey wire, or an angled Glidewire (Terumo Interventional Systems, Somerset, NJ) is advanced to the CFA. The angiographic catheter is advanced over the guidewire to the area of interest, and angiography is obtained.

There are specific angiographic views which help to improve anatomical detail. In the AP view, there is significant overlapping of the origin of the EIA and the IIA, and ostial lesions in either vessel may be missed. In order to “separate” these 2 segments, the contralateral oblique 20° with 20° caudal view is very useful (Fig. 23-17 and Fig. 23-18). The proximal portions of SFA and the PFA are overlapping in the AP view. They are separated best with a 30° lateral angulation (Fig. 23-19). Finally, it is desirable to avoid overlapping of the SFA, popliteal, or infrapopliteal arteries with the dense cortical leg bones. Lateral oblique angulation (30°), with digital subtraction images offer an excellent separation of the vessels (Fig. 23-20 to Fig. 23-22).
FIGURE 23-17 Digital subtraction angiography of the left common iliac artery and its bifurcation in AP view, showing significant overlapping of the origin of the internal and external iliac arteries.
FIGURE 23-18 The same patient as Figure 23-17. Digital subtraction angiography of the left common iliac artery and its bifurcation shown in the right anterior oblique caudal view reveals a significant stenosis in the ostium of the left internal iliac artery not visualized in the AP view.
FIGURE 23-19 Angiography of the right common femoral artery (CFA) bifurcation in the AP view (left). A stenosis at the ostium of the profunda femoris artery (PFA) is noted in the ipsilateral oblique (20° right anterior oblique) view which was missed in the AP view (right).

COMPLICATIONS OF PERIPHERAL VASCULAR ANGIOGRAPHY

Complications leading to significant morbidity or mortality, although unusual, do occur, and the operator must remain vigilant during and after angiography in order to minimize them.

The registry of the Society for Cardiac Angiography and Interventions (SCAI) found an incidence of vascular complications for diagnostic angiography of 0.5% to 0.6%. When CFA access is used, the most common vascular complication is hematoma, which usually resolves within a few weeks after the procedure. If the hematoma remains in continuity with the arterial lumen due to inadequate sealing of the puncture site, a pseudoaneurysm may develop. This is usually manifested as a painful
pulsatile mass with an audible bruit. The diagnosis is easily confirmed with
duplex ultrasound. When the femoral arterial puncture (front or back wall) is
above the inguinal ligament, a hematoma may extend into the retroperitoneal
space, with bleeding not evident from the surface examination.

Retroperitoneal bleeding must be strongly suspected when a patient
becomes hypotensive after angiography from common femoral arterial
access, with or without flank pain. Aggressive volume replacement with
normal saline is indicated. If the patient remains hemodynamically unstable,
he must be taken for angiography of the vascular access to identify and stop
the bleeding with balloon inflation. Although the majority of retroperitoneal
hematomas resolve spontaneously, some require treatment. Percutaneous,
catheter-based modalities, may be effective for treating retroperitoneal
bleeding in selected patients. Other less frequent vascular complications
include arterial laceration, which requires a covered stent or surgical repair,
and symptomatic arteriovenous fistulas, which usually require surgical
treatment.

Stroke may occur as a rare but potentially devastating complication after
catheter placement in the aortic arch. The SCAI registry found a 0.07%
incidence of stroke during cardiac catheterization. The incidence of
neurologic events during carotid angiography is substantially higher,
identified as 0.78% to 1% in prospective studies. In general,
asymptomatic patients have a lower risk, whereas patients who undergo
angiography in the setting of transient ischemic events have a slightly higher
complication rate. The neurologic complication rate for patients with
severe bilateral carotid stenoses is 12.5%. In a review of cerebral
angiography performed by cardiologists, the risk of angiography was 0.05%.

Allergic and anaphylactoid reactions have substantially decreased with the
use of low/iso-osmolar contrast agents. Their reported incidence is less than
1%. The risk of developing CIN is highest in patients with baseline chronic
renal insufficiency (creatinine >2.1 mg/dL), diabetes mellitus, multiple
myeloma, and those who are receiving other nephrotoxic drugs such as
aminoglycosides, nonsteroidal anti-inflammatory drugs, and angiotensin-
converting enzyme inhibitors. Patients at higher risk for CIN must be
well hydrated before and after the procedure, and the volume of contrast
administered must be minimized. There is inconsistent and conflicting
data regarding the efficacy of the dopamine-1 receptor antagonist, fenoldopam in preventing CIN.\textsuperscript{48} There is also inconsistent evidence that the use of N-acetylcysteine (Mucomyst) is of benefit for preventing CIN.\textsuperscript{49,50} One small, randomized trial showed that and the use of hydration with sodium bicarbonate can prevent CIN; however, this needs to be confirmed in larger studies.\textsuperscript{51} At present, it is recommended that patients with a glomerular filtration rate of <50 mL/1.73 m\textsuperscript{2}, should avoid iodinated contrast agents if possible. If conventional angiography is required, a low/iso-osmolar agent should be used at the minimal dose, nonsteroidal anti-inflammatory drugs and diuretics should be withheld, and \(\sim 1\) mL/kg of 0.9% saline should be administered starting at least 3 hours prior to the procedure and continuing 12 hours after the procedure.\textsuperscript{52}

29. Beales JS, Adcock FA, Frawley JS, et al. The radiological assessment of

Although coronary angiography remains the reference standard for diagnosing critical epicardial coronary artery disease (CAD), it has a number of limitations. Identifying functionally significant intermediate coronary narrowings, characterizing plaque morphology, detecting moderate diffuse intimal thickening, evaluating the results of percutaneous coronary intervention (PCI), and assessing the status of the microvasculature all remain challenging with coronary angiography alone.\textsuperscript{1-6} Technologic advancements have made several adjunctive diagnostic techniques available that allow the interventional cardiologist to address the limitations of coronary angiography and more thoroughly assess the coronary circulation.

In this chapter we will focus on the role of the coronary pressure wire to measure fractional flow reserve (FFR) and guide decisions regarding coronary revascularization. The background and derivation of FFR were already covered in Chapter 6. We will briefly review the concept of FFR and then detail how to measure FFR, outline the clinical indications for FFR assessment, and present data supporting its role in the cardiac catheterization laboratory.

HISTORICAL BACKGROUND

The significance of intracoronary pressure gradients and their reflection of
the severity of underlying CAD has been appreciated for many years. However, it was not until the advent of miniaturized pressure sensors that allowed a wire-based approach to measuring coronary pressure and not until the development and validation of the FFR index by Pijls and De Bruyne that intracoronary pressure measurements have become a routine procedure in many catheterization laboratories.

DERIVATION OF FFR

FFR is defined as the fraction of maximal blood flow perfusing the myocardium in the presence of stenosis compared with the maximal blood flow that would reach the myocardium in the theoretical absence of the stenosis. Because the measurement is made at maximal vasodilation, resistance is minimized and flow becomes proportional to pressure. In a normal epicardial artery, there is little pressure decrement along the vessel, and distal pressure is roughly equal to proximal pressure. Therefore, in a diseased vessel, one can estimate the distal flow or pressure in the theoretical absence of the disease by measuring the proximal pressure. FFR then can be calculated easily in a diseased vessel by dividing the distal pressure, measured with a coronary pressure wire, by the proximal pressure, measured with the guiding catheter during peak hyperemia.

Compared with other techniques for determining the functional significance of a coronary narrowing, measuring FFR has several inherent advantages. It has an absolute normal value of 1.0 and a narrow range of normal values extending from 0.94 to 1.0. Because the measurements are made at maximal vasodilation, the effects of resting hemodynamics are eliminated, making FFR an extremely reproducible index, independent of blood pressure and heart rate. Compared with measuring CFR to evaluate intermediate coronary lesions, FFR is advantageous because it is epicardial artery-specific and independent of the microcirculation (Table 24-1). As described in more detail below, FFR has a narrow cutoff range for identifying ischemia-producing lesions. Numerous studies have shown that an FFR less than 0.75 to 0.80 correlates strongly with the presence of ischemia on a variety of noninvasive stress tests and predicts clinical outcome with or without percutaneous coronary intervention (PCI).

HOW TO MEASURE FFR: EQUIPMENT AND TECHNIQUE

The coronary pressure wire is a standard 0.014-in angioplasty guidewire with a high-fidelity pressure transducer mounted 3 cm from the tip of the wire, at the junction of the radiopaque and radiolucent segments. There are now multiple manufacturers of pressure wires, each of which have their own consoles which analyze and display the pressure recordings. The 2 oldest and most commonly used ones (St. Jude Medical Systems and Philips Healthcare) incorporate piezoelectric technology to measure intracoronary pressure. More recently introduced wires (Opsens and Boston Scientific) utilize optical sensors to measure pressure. The potential advantages of these newer wires are less propensity for pressure drift and improved wire handling characteristics. Finally, a micro catheter (Acist Medical Systems) with an optical pressure sensor mounted near its tip has been introduced and has the added advantage of allowing measurement of distal pressure by advancing the microcatheter over a workhorse wire. However, it has the theoretical disadvantage of increasing stenosis severity (because of its larger crossing profile compared to a 0.014-inch wire alone) and lowering FFR, particularly in smaller vessels and more severe lesions.

To measure FFR, it is traditionally necessary to connect the pressure console to the catheterization laboratory pressure monitoring system and to calibrate the guiding catheter and pressure wire. Newer wireless systems and
integrated consoles allow the pressure wire to communicate with the cath lab system without external connectors and facilitate this process. After administering intravenous heparin (or another antithrombotic agent) and intracoronary nitroglycerin (100-200 micrograms), the pressure wire should be advanced out of the guiding catheter so that the pressure transducer is positioned at the ostium of the guiding catheter. At this location, both the pressure wire and the guiding catheter should display identical pressures. One should flush the guiding catheter with saline to ensure an accurate pressure recording. If this is not the case, the pressure wire can be equalized to the guiding catheter. This step can be performed with the catheter and wire in the aorta in the presence of ostial coronary disease. The pressure wire is then advanced to the distal part of the vessel and a vasodilating agent such as adenosine is administered. It is important to start with the sensor in the distal two-thirds of the vessel so that not only the lesion in question, but also any other atherosclerosis in the vessel can be interrogated. The FFR of the vessel is the lowest value achieved by dividing the simultaneously measured mean distal pressure by the mean proximal pressure during maximal steady state hyperemia (Fig. 24-1). Occasionally with intravenous adenosine variability in the delivery of and/or response to adenosine results in fluctuations in the $P_d/P_a$ ratio. If this occurs, the lowest $P_d/P_a$ should be taken as the FFR. At times, the pressure wire console will record an inaccurate FFR because of an artifact in the pressure tracing, such as can occur when the manifold is open in order to inject intracoronary adenosine. For this reason, it is always important for the operator to review the tracing and determine the correct FFR.
FIGURE 24-1 Example of fractional flow reserve (FFR) determination. The upper red tracing represents the mean and phasic pressure recorded from the guiding catheter and the lower green tracing represents the mean and phasic pressure recorded from the pressure wire in a patient with a physiologically significant stenosis of the left anterior descending artery. The nearly horizontal yellow line above the 2 tracings represents the continuous distal pressure divided by proximal pressure calculation, and the vertical line marks the peak gradient and represents the FFR of 0.72.

If it is not possible to manipulate the pressure wire down the desired vessel, one can remove the pressure wire after equalization and wire the vessel with a more maneuverable wire through an exchange microcatheter. Once the wire and microcatheter have been advanced to the desired location, the more maneuverable wire can be removed. The pressure wire can then be advanced through the microcatheter to the desired location and the microcatheter can then be pulled back into the guiding catheter. At this point, FFR can be measured in the usual fashion. Alternatively, one can use the Navvus microcatheter (ACIST RXi) to measure pressure over the more maneuverable workhorse wire.

Achieving maximal hyperemia is critical in order to accurately measure FFR. If hyperemia is submaximal, the gradient across the stenosis in question will be underestimated and FFR will be overestimated. The reference standard agent for achieving peak vasodilatation is intravenous adenosine. Ideally, it is administered through a central vein or large bore peripheral line.
Peak hyperemia typically occurs within 1 minute and is signaled by the onset of chest pain (not due to ischemia) and or shortness of breath. These symptoms are generally well tolerated, particularly if the patient is forewarned and can be helpful in that they assure the operator that hyperemia has occurred. Because the hyperemia lasts as long as the infusion continues, intravenous adenosine is advantageous in that it allows more careful determination of the peak gradient. In addition, it affords the operator the ability to slowly pull back the pressure wire proximally in order to identify the area of stenosis. This can be particularly useful if there is diffuse disease or multiple lesions in the vessel (Fig. 24-2). Finally, in the setting of ostial left or right coronary lesions, it allows the operator time to remove the guide catheter from the ostium of the vessel in order to accurately measure FFR.
Intracoronary adenosine is another common method for measuring FFR which in the United States is less expensive and easier to administer. Its major drawback is its short peak effect, which is roughly 10 to 15 seconds. In addition, because it is given via the coronary artery, the potential exists for incomplete administration down the coronary artery and partial injection or reflux into the aorta. Recently, it has been shown that higher doses than previously used are necessary to achieve peak hyperemia, but typically 100 micrograms in the right coronary artery and 200 micrograms in the left coronary are adequate. If there is any doubt regarding adequate hyperemia, it is important to use either intravenous adenosine or an alternative agent, such as intracoronary papaverine.

Using intracoronary papaverine to measure FFR is advantageous because its peak effect is longer lasting than intracoronary adenosine, roughly 45 seconds, which makes more accurate determination of FFR possible and which allows time to perform a slow pullback of the pressure sensor. In addition, papaverine is inexpensive and easy to prepare and administer. Its major drawback is its potential arrhythmogenic effect. In an older series, the incidence of a serious arrhythmia (ventricular tachycardia or torsades de pointes) was approximately 1%. Fortunately, these arrhythmias were usually self-limited. Papaverine can precipitate in ionic contrast medium, which may induce the arrhythmia.

A newer hyperemic agent, regadenoson, has been recently introduced. It is an agonist specific for the adenosine A2A receptor and has the potential advantage of inducing less bronchoconstriction than adenosine. A recent study demonstrated equivalent hyperemia compared to intravenous (IV) adenosine with excellent reproducibility. An advantage is that it can be given as a single peripheral IV bolus. A potential drawback is that the hyperemic effect lasts between 45 seconds and 10 minutes, but its duration is unpredictable. A number of other agents are available for achieving hyperemia and are listed in Table 24-2.

Table 24-2  Agents for Inducing Hyperemia
If the FFR is abnormal and PCI is necessary, the operator can disconnect the pressure wire from the interface coupler and a balloon catheter or stent can be advanced over the pressure wire in the usual fashion. During balloon inflation the pressure wire can be reconnected and the coronary wedge pressure, a reflection of collateral flow, can be recorded. After completing the PCI, the pressure wire can be reconnected and FFR remeasured. Finally, it is important after measuring FFR, whether or not PCI has been performed, to reposition the pressure sensor at the ostium of the guiding catheter before removing the wire completely, to ensure that equal pressures are recorded from the guiding catheter and the pressure wire (ie, that no “drift” in either pressure recording system has occurred). If there is a difference greater than 0.05, then one should consider reequalizing the pressure wire and remeasuring FFR.

### INDICATIONS FOR MEASURING FFR

<tr>
<th>Agent</th>
<th>Route</th>
<th>Dose</th>
<th>Comments</th>
</tr>
</thead>
<tbody>
<tr>
<td>Adenosine</td>
<td>IV infusion</td>
<td>140 µg/kg/min</td>
<td>Reference standard. Side effects include dyspnea and chest pain. Prolonged hyperemia allows pressure wire pullback.</td>
</tr>
<tr>
<td>Adenosine</td>
<td>IC bolus</td>
<td>&gt;100-200 µg</td>
<td>Easy to use, inexpensive, and no significant side effects. Transient heart block at high doses. Hyperemia lasts only 10-15 seconds.</td>
</tr>
<tr>
<td>Adenosine</td>
<td>IC infusion</td>
<td>240-360 µg/min</td>
<td>Inconvenient set-up. Fewer side effects compared to IV infusion. Prolonged hyperemia allows pullback. Not well-validated.</td>
</tr>
<tr>
<td>Regadenoson</td>
<td>IV bolus</td>
<td>400 µg</td>
<td>Convenient, single IV bolus. Expensive. Side effects similar to IV adenosine but less severe and briefer. Hyperemia lasts 20 seconds-10 min.</td>
</tr>
<tr>
<td>Papaverine</td>
<td>IC bolus</td>
<td>10-20 mg</td>
<td>Easy to use, inexpensive. Rare, but significant side effect of polymorphic VT. Hyperemia lasts 30 seconds, allowing pullback.</td>
</tr>
<tr>
<td>Nitroprusside</td>
<td>IC bolus</td>
<td>0.3-0.9 µg/kg</td>
<td>Easy to use, inexpensive. Major side effect is hypotension. Hyperemia lasts 50 seconds allowing pullback. Not well-validated.</td>
</tr>
<tr>
<td>Dobutamine</td>
<td>IV infusion</td>
<td>50 µg/kg/min</td>
<td>Inconvenient as it takes time for onset an offset. Side effects include palpitations and hypotension. Not well-validated for FFR.</td>
</tr>
<tr>
<td>Nicorandil</td>
<td>IC bolus</td>
<td>2 mg</td>
<td>Not available in United States. Fewer side effects compared to IV adenosine. Hyperemia lasts 30 seconds. Not well-validated.</td>

IC: intracoronary; IV: intravenous; µg: microgram; mg: milligram; min: minute; VT: ventricular tachycardia.
Indications for measuring FFR are listed in Table 24-3. The most common indication for measuring FFR is to determine the physiologic significance of an intermediate coronary lesion. As many more patients present to the catheterization laboratory without a prior noninvasive assessment for myocardial ischemia and with an awareness of the limitations of angiography alone to identify functionally important moderate lesions, the role of a relatively simple method, such as measuring FFR, for interrogating this challenging subset has expanded. Pijls and colleagues performed a landmark trial comparing FFR with 3 noninvasive stress tests. They showed that an FFR less than 0.75 is 100% specific for predicting myocardial ischemia; the sensitivity was 88% and the predictive accuracy was 93%. Since this seminal report, clinical experience and subsequent studies have found a “grey zone” for FFR between 0.75 and 0.80. If the FFR falls in this range, one should use clinical judgment to decide if revascularization is warranted. If the patient has typical symptoms and a proximal lesion in a large vessel that is amenable to stenting, then revascularization should be performed. If the patient has no symptoms, atypical symptoms, and/or the lesion is located in a small or distal vessel, then medical therapy may be more appropriate. If the FFR is greater than 0.80, it is extremely unlikely that significant ischemia is present. FFR is not a dichotomous variable but a continuous one reflecting the fact that lower FFR values correspond with higher event rates in patients treated medically. This concept is an important one that has recently been highlighted.

Intermediate Lesions
To determine the safety of employing FFR to guide the operator’s decision to defer PCI, Bech and colleagues, in the DEFER trial, measured FFR in 325 patients with chest pain, no prior stress test, and intermediate coronary lesions who had been referred for PCI. One hundred and forty-four of these patients had an FFR less than 0.75, underwent PCI as planned, and formed a reference group. One hundred and eighty-one had an FFR of 0.75 or greater and were randomized to deferral of PCI (n = 91) or performance of PCI (n = 90). The deferral group had a greater freedom from major adverse cardiac events at 2 years, although not statistically significant, compared with the performance group: 89% versus 83%, respectively. The reference group had a significantly worse event-free survival compared with the deferral group (78% vs 89%, \( P = 0.03 \)), presumably because they had more significant CAD. Five-year follow-up from this study was reported and found that the rate of cardiac death or myocardial infarction (MI) in the deferral group was less than half of the rate in the performance group (3.3% vs 7.9%, \( P = 0.21 \)). Recently, the 15-year follow-up from this trial has been published, revealing no difference in long-term mortality between the two groups, but a significantly lower rate of MI in the patients assigned to deferral of PCI (2.2% vs 10%, \( P = 0.03 \)). This trial clearly showed that it is safe to defer PCI in stable patients with an intermediate lesion and an FFR of 0.75 or greater. Numerous other registries have confirmed the findings in the DEFER trial.

**Multivessel CAD**

The FFR versus Angiography for Multivessel Evaluation (FAME) trial established the role of routine FFR measurement for guiding PCI in patients with multivessel CAD amenable to PCI. In the FAME trial, 1005 patients with coronary lesions of >50% diameter stenosis in 2 or 3 major epicardial vessels which were amenable to PCI with drug-eluting stents were randomized to either the standard of care, angiography-guided PCI, or to FFR-guided PCI. Angiography-guided PCI was performed based on the noninvasive clinical data and the angiographic appearance of the lesions. For the FFR-guided PCI arm, FFR was measured across every stenosis and only if the FFR was \( \leq 0.80 \) was PCI performed on the particular stenosis.

There were approximately 3 lesions identified per patient in both groups, but the angiography-guided PCI group received significantly more stents per
patient, 2.7 ± 1.2 versus 1.9 ± 1.3, \( P < 0.001 \). In addition, significantly more contrast media was administered to the angiography-guided PCI patients, 302 ± 127 versus 272 ± 133 mL, \( P < 0.001 \). Importantly, the duration of the procedure was identical between the two groups—although measuring FFR adds time to the procedure, avoiding unnecessary PCI saves time. Despite the fewer stents, the percentage of patients free of angina at 1 year was numerically higher in patients randomized to FFR guidance (81.3% vs 77.9%, \( P = 0.20 \)).

The primary endpoint of the FAME trial was the 1-year rate of death, MI or repeat revascularization, which occurred in 18.3% of the angiography-guided PCI patients as compared to 13.2% of the FFR-guided PCI patients, \( P < 0.02 \) (Fig. 24-3). This significant reduction resulted from 30% to 40% relative risk reductions in each component of the composite endpoint. In addition, the rate of death and MI was reduced significantly in the FFR-guided PCI group (7.3% vs 11.1%, \( P = 0.04 \)). Subsequently, the 2-year results of FAME were reported and revealed a persistent reduction in the composite of death, MI and repeat revascularization (17.9% vs 22.4%, \( P = 0.08 \)). Importantly, the hard endpoints of death and MI remained significantly lower in the FFR-guided PCI patients (8.4% vs 12.9%, \( P = 0.02 \)). The Kaplan-Meier curves at 1 and 2 years showed that the benefit attributed to FFR guidance occurred early, due to fewer procedural-related events, and continued during follow-up, due to fewer late events. Recently, the 5-year follow-up from the FAME trial has been published and found continued separation of the curves with respect to major adverse cardiac events between the two groups, without any significant late catch-up in events in the FFR-guided PCI group.\(^{24}\)
FIGURE 24-3 One-year outcomes in the FFR versus Angiography for Multivessel Evaluation (FAME) 1 trial comparing angiography-guided percutaneous coronary intervention (PCI) to fractional flow reserve (FFR)-guided PCI.

The FAME trial further highlighted the limitations of coronary angiography alone for identifying lesions responsible for ischemia. Approximately 35% of the lesions graded between 50% and 70% narrowed had an ischemic FFR, while roughly 20% of the lesions between 71% and 90% narrowed had nonischemic FFR values (Fig. 24-4). This would suggest that all lesions between 50% and 90% narrowed could benefit from FFR measurement to accurately determine their functional significance.

FIGURE 24-4 A breakdown of lesions in the fractional flow reserve (FFR)-guided arm of patients in the FFR versus Angiography for Multivessel Evaluation (FAME) 1 trial demonstrating their FFR values based on their visual diameter stenosis on the
The FAME trial raised awareness about the differences between anatomic complete revascularization and “functionally” complete revascularization. In patients with multi-vessel coronary disease, this is particularly relevant because many of our treatment decisions regarding revascularization are made based on angiographic (or anatomic) assessment of the severity of coronary disease. For example, the SYNTAX score is an angiography-based scoring system designed to quantify the complexity of coronary disease; those patients with high SYNTAX scores tend to have better outcomes with coronary artery bypass graft (CABG) surgery, while those patients with low scores appear to do equally well with PCI.26

Because the SYNTAX score is based on visual interpretation of the angiogram, it is inherently limited by the inaccuracy of the angiogram. A substudy from the FAME trial asked whether incorporating FFR into the SYNTAX score and calculating a “Functional SYNTAX Score (FSS)” might convert higher-risk SYNTAX score patients to a lower risk, and whether it might improve the risk stratification of patients with multi-vessel coronary disease undergoing PCI.27

In the 497 patients in the FFR-guided arm of FAME, the SYNTAX score was calculated in the usual fashion and the patients were divided into tertiles, based on the SYNTAX score. The FSS was then determined by recalculating the SYNTAX score taking into account only those lesions with an FFR ≤0.80. More than one third of patients moved from a higher risk group to a lower one after calculation of the FSS. In addition, the FSS was a significant predictor of death or MI, while the classic SYNTAX score was not (Fig. 24-5). In this manner, the FSS simplifies the approach to PCI in many of these challenging multi-vessel disease patients and may make PCI a more appropriate treatment than CABG. This hypothesis is now being tested prospectively in the FAME 3 trial, comparing FFR-guided PCI to CABG in patients with 3-vessel coronary disease (www.clinicaltrials.gov: NCT02100722).
A comparison of the classic SYNTAX score and the Functional SYNTAX Score for their abilities to discriminate the risk for death and myocardial infarction. Of note, the percentage of patients falling into the highest risk functional SYNTAX score group is smaller than in the highest risk SYNTAX score group and the percentage of patients in the lowest risk group is much larger.

**Acute Coronary Syndromes**

The majority of PCI involves patients presenting with acute coronary syndromes (ACS). The role of FFR in these settings depends on whether the patient is presenting with ST segment elevation myocardial infarction (STEMI) or a non-ST elevation ACS (NSTEMI) and whether one is evaluating the culprit vessel or the nonculprit vessel. In the setting of STEMI, acute microvascular dysfunction can occur which will affect the peak flow achievable down the culprit vessel. This will result in a lower gradient and higher FFR for a given stenosis. Over time, some of the transient microvascular dysfunction can improve and the peak flow can increase leading to a larger gradient and lower FFR. For this reason, in the acute setting of a STEMI, measuring FFR in the culprit vessel is not recommended. Studies have shown that typically a number of days after STEMI, most of the transient microvascular dysfunction has resolved and one is left with chronic microvascular damage. In this setting, although the peak flow across a given stenosis may be lower, the gradient less and the FFR higher, the FFR remains accurate and is a reflection of the smaller amount of viable myocardium subtended by the vessel. Therefore, in the nonacute setting, FFR down the culprit vessel remains reliable.
There has been some concern regarding the role of FFR in the nonculprit vessel of patients presenting with STEMI. Older studies suggested that with STEMI, some degree of global microvascular dysfunction occurred which might affect the accuracy of FFR even in the nonculprit study. However, in a series of 101 ACS patients, Ntalianis and colleagues measured FFR in a nonculprit vessel in the acute setting and then repeated the measurement an average of 1 month later. They found only 2 cases in which the FFR was >0.80 in the acute setting and <0.75 at the time of follow-up, suggesting that in the vast majority of cases FFR can be measured accurately in the nonculprit vessel of a patient presenting with STEMI.

In a recent clinical trial, 627 STEMI patients with multivessel CAD were randomized to PCI of the culprit vessel only versus culprit vessel PCI and FFR-guided management of the nonculprit disease. These investigators found a significantly lower rate of the composite endpoint of death, reinfarction, and ischemia-driven revascularization of the nonculprit vessels at a median follow-up of 27 months in the functionally completely revascularized patients (13% vs 22%, \( P = 0.004 \)). This difference was primarily a result of lower rates of ischemia-driven revascularization in the patients with FFR guidance, but the study reinforces the safety and benefit of FFR guidance of nonculprit stenoses in the setting of STEMI.

**Tandem Lesions**

Tandem lesions or serial stenoses in the same vessel can be challenging to interrogate independent of each other with FFR. This is because each lesion affects flow across the other, and removal of one lesion may result in increased flow across the remaining lesion and a persistently low FFR. Predicting the contribution of each lesion to an FFR value is not practical because it requires complex equations and measurement of the coronary wedge pressure. For these reasons, when one is faced with serial narrowings, one should first measure FFR with the pressure sensor distal to both lesions. If the FFR is not ischemic, then the combination of the two lesions is not functionally significant and medical therapy is warranted. If the FFR is ischemic, then a slow pullback of the wire during maximal hyperemia (typically with IV infusion of adenosine) should be performed. Whichever lesion is responsible for more than 50% of the gradient (>0.10 contribution to the abnormal FFR) should be stented first, if technically feasible. It is then
critical to measure FFR again because with the increased flow down the vessel due to the relief of 1 stenosis, the FFR across the other lesion may still be in the ischemic range (Table 24-4).

Left Main Disease

Another challenging group of patients in which FFR measurement can be helpful is the subset with intermediate left main coronary disease. Left main disease is particularly difficult to evaluate with angiography and noninvasive testing. Intravascular ultrasound has been an alternative method for obtaining more anatomic information regarding lumen compromise; however, it provides no functional data and is hampered by the lack of a clear cutoff value applicable to all patients. FFR has been evaluated in a number of registries and found to be a safe method for deferring revascularization if the value is in the nonischemic range. In the presence of downstream disease in both the left anterior descending (LAD) and the circumflex arteries, isolating the contribution of the intermediate left main disease to an abnormal FFR can be difficult, just as occurs with tandem lesions not involving the left main. However, if downstream disease is present only in the LAD, for example, the operator can place the wire in the nondiseased downstream circumflex vessel
and measure FFR accurately in most cases. Studies have shown that if the LAD disease is severe (resulting in an FFR down the LAD < 0.50 range), then it may decrease flow across the left main and raise the FFR down the circumflex.\textsuperscript{36,37,38} If the operator stents the LAD and remeasures FFR of the left main down the circumflex, it may now be slightly lower. Fortunately, the clinical relevance of this effect appears to be small.\textsuperscript{38}

**Stable CAD**

Controversy exists regarding the appropriate initial management of patients with stable angina and CAD. Based on the COURAGE trial results, some argue medical therapy should be optimized in favor of performing PCI.\textsuperscript{39} However, others have criticized the COURAGE trial because it may have enrolled lower-risk patients without significant ischemia and because PCI may have been performed in a suboptimal fashion. The FAME 2 trial was designed specifically to ensure the inclusion of patients with a large burden of ischemia and utilizing current generation drug-eluting stents and PCI techniques, such as FFR.\textsuperscript{40} This was achieved by randomizing only patients with at least 1 lesion in 1 of the 3 major epicardial vessels with >50% narrowing and an FFR ≤0.80. Those patients with narrowings of >50% but with an FFR >0.80 were not included in the randomized portion of the study, but followed in a registry and treated with best medical therapy. The goal was to randomize roughly 1600 patients and follow them for 2 years with a primary composite endpoint of death, MI or unplanned hospitalization requiring urgent revascularization.

After 888 patients had been randomized, recruitment into FAME 2 was stopped prematurely by the data and safety monitoring board because of a highly significant difference in the primary endpoint between the 2 groups. After a mean follow-up of only 7 months, the primary endpoint occurred in 12.7% of patients in the best medical therapy arm compared to 4.3% in the PCI plus best medical therapy arm. There was no significant difference in death (0.7% vs 0.2%, \(P = 0.31\)) or MI (3.2% vs 3.4%, \(P = 0.89\)), but a highly significant difference in the rate of unplanned hospitalization requiring urgent revascularization (11.1% vs 1.6%, \(P < 0.001\)) between the best medical therapy arm and PCI arm, respectively. The rate of any revascularization was also significantly higher in the best medical therapy arm (19.5% vs 3.1%, \(P < 0.001\)).
Both groups in FAME 2 received excellent medical therapy, with the vast majority prescribed aspirin, a statin, a beta-blocker, and an angiotensin-converting enzyme (ACE) inhibitor in similar rates to what was seen in the COURAGE trial. The majority of the best medical therapy arm also received a calcium channel blocker and/or nitrate for refractory angina. Despite this, the hospitalization rate for an acute coronary syndrome requiring urgent revascularization in the best medical therapy arm was 11.1% at just 7 months. In comparison, in the COURAGE trial, the rate of an acute coronary syndrome at a median follow-up of 4.6 years was only 11.8%. This difference is likely because in the FAME 2 trial, by measuring FFR first, patients with a larger burden of ischemia were randomized.

The concept of more severe ischemia resulting in worse outcomes is supported further by the fact that stratifying outcomes in FAME 2 based on an FFR value of 0.65 demonstrated a significant interaction, meaning that those patients with more severe ischemia at baseline had even greater benefit with PCI as compared to medical therapy alone.

Importantly, there were 332 patients in the FAME 2 trial with angiographic coronary disease which was not significant based on FFR assessment and 166 of these were randomly assigned follow-up in a registry receiving best medical therapy alone. The primary endpoint occurred in only 3.0% of these registry patients with a 2.4% rate of urgent revascularization. This finding further emphasizes the importance of not only identifying angiographic evidence of coronary disease, but further characterizing whether the disease is responsible for ischemia. Patients with these types of lesions benefit from PCI, while patients with angiographic disease which is not functionally significant based on FFR respond well to medical therapy alone.

The complete 2-year follow-up of the FAME 2 study was recently published and showed a continued highly significant difference in the composite endpoint of death, MI, and urgent revascularization between the FFR-guided PCI arm and the medical therapy arm (8.1% vs 19.5%, \( P < 0.001 \)). Additionally, a landmark analysis evaluating the difference in the rate of death and MI alone, found that after 7 days (eliminating periprocedural MI from the FFR-guided PCI arm) there was a significantly low rate of death or MI in the FFR-guided PCI arm (4.6% vs 8.0%, \( P = 0.04 \)) (Fig. 24-6). These findings further highlight the increased risk for adverse events due to lesions with a low FFR which are treated with medicine alone.
FIGURE 24-6 Landmark analysis starting 1 week after treatment (and thereby eliminating periprocedural myocardial infarctions) from the FFR versus Angiography for Multivessel Evaluation (FAME) 2 trial. The data demonstrates an increased risk of death and myocardial infarction in the medical therapy arm compared to the percutaneous coronary intervention (PCI) arm.

An economic evaluation of the FAME 2 trial was performed.\textsuperscript{42} Although performing PCI initially costs more compared to medical therapy alone, because patients receiving PCI have significant improvement in quality of life and because they have fewer adverse events during follow-up, the incremental cost-effectiveness ratio for the PCI arm was favorable at $36,000 per quality-adjusted life year. This finding was robust in bootstrap replications and sensitivity analyses.

The role of routine measurement of FFR in stable patients undergoing coronary angiography also has been tested in two registries.\textsuperscript{43,44} Both found that the additional information from FFR measurement can have a dramatic impact on treatment strategies. For example, in one study of 1,075 patients, the final treatment strategy (medical therapy, PCI, or coronary artery bypass) was changed in 43% of cases after the operators were made aware of the FFR results.\textsuperscript{44} These findings further highlight the limitations of the coronary angiogram and argue for more routine utilization of FFR in the diagnostic setting.
**FFR After PCI**

A number of studies have compared FFR after stenting with intravascular ultrasound criteria for determining optimal stent deployment and have found a significant correlation between the two techniques.\(^45\)\(^-\)\(^47\) However, the strongest evidence supporting a role for measuring FFR after PCI comes from a registry in which 750 patients who had FFR measured after bare-metal stenting were followed for 6 months to determine the relationship between the post-procedure FFR and clinical outcomes.\(^5\) Multivariate analysis showed that FFR was the strongest predictor of major adverse cardiac events. In the 36% of patients with a final FFR of more than 0.95, the 6-month adverse event rate (after bare-metal stenting) was 4.9%, and in the 32% with a final FFR between 0.90 and 0.95, the event rate was 6.2%. In comparison, if the final FFR was less than 0.90, the event rate was 20.3%, and in the 6% of patients with a final FFR of less than 0.80, the event rate was 29.5%. Of note, angiographic results were not at all predictive of adverse events. Subsequent studies evaluating FFR measured after drug-eluting stenting have demonstrated similar findings, with low event rates if the final FFR is \(>0.90.\)\(^48\),\(^49\)

**LIMITATIONS OF FFR**

Although no invasive index for assessing the functional significance of a coronary stenosis is perfect, FFR is widely perceived to be the reference standard. There are some aspects related to the theory of FFR and to its actual measurement which have created controversy. First, FFR theory states that during maximal hyperemia, when myocardial resistance is minimized and coronary autoregulation abolished, coronary pressure becomes proportional to flow, and therefore myocardial flow in the presence of a stenosis can be determined by measuring distal coronary pressure. However, some have argued that this assumption is invalid because at low perfusion pressures the relationship between pressure and flow is no longer linear.\(^50\) In other words, coronary flow will stop before coronary pressure equals 0. This is because of the backpressure resulting from the myocardium and the coronary venous system. However, within the physiologic range of pressures where FFR is measured, the linear relationship between pressure and flow exists and
therefore this theoretical concern has not had clinical implications on the validity of FFR.

There has also been controversy over whether the minimal achievable microvascular resistance in the presence of a stenosis is equivalent to the resistance in the hypothetical absence of a stenosis.\textsuperscript{50,51} One study measuring microvascular resistance before and after uncomplicated PCI found lower levels of minimal resistance after PCI.\textsuperscript{52} This finding may be due to measurement error that occurred by not taking into account the contribution of collateral flow, which is greater in the presence of a stenosis and which, when neglected, leads to apparently higher levels of microvascular resistance. Earlier work\textsuperscript{53} and a number of follow-up studies performed by different investigators in both animals and humans have found that microvascular resistance is equivalent in both the presence and absence of an epicardial stenosis when collateral flow is incorporated into the measurement.\textsuperscript{54-57}

Another concern regarding the actual measurement of FFR is its theoretical reliance on achieving maximal hyperemia. If maximal hyperemia does not occur, the flow across the stenosis may be less, the pressure gradient lower and the FFR overestimated. For these reasons, it is critical that when FFR is measured the hyperemic agent is administered correctly and in an adequate dosage. If one is concerned that maximal hyperemia has not been achieved, an alternative pharmacologic agent can be delivered. If there is still concern, microvascular resistance can be measured simultaneously with the same pressure wire, for example, by calculating the index of microcirculatory resistance (IMR)\textsuperscript{58} using a thermodilution technique; in this manner, one can assess whether resistance is minimized and flow maximized. If the FFR is higher than expected based on the angiographic findings and the IMR is low, then one can be reassured that hyperemia has been achieved and the FFR result is valid. If FFR is high and IMR is high, then likely microvascular dysfunction is present, which may explain the presence of symptoms and/or ischemia. In this scenario, the use of IV adenosine is helpful because the symptoms and hemodynamic changes which often occur are reassuring that hyperemia has been achieved. FFR is still valid in that it informs the operator that there is little to be gained by performing PCI; a number of studies demonstrate that PCI of the epicardial stenosis in this setting does not improve outcomes.\textsuperscript{19,22,41} To circumvent this requirement for maximal hyperemia, combined pressure and Doppler flow indices have been
proposed. These require further validation and improvements in technology before they are used to augment FFR measurement.

Another issue raised about the need for maximal hyperemia concerns the fact that adenosine may not completely abolish autoregulation and minimize microvascular resistance. Prolonged coronary occlusion likely produces the greatest degree of hyperemia, but is not practical in the clinical setting. The addition of other vasodilators on top of adenosine has been proposed and may further reduce FFR; however, in theory this would require recalibration of the FFR cutoff value for identifying lesions capable of causing MI. It is unlikely that an additional agent would create enough additional hyperemia such that an FFR which with adenosine alone is >0.80 would drop to <0.75. This may explain why measuring FFR with adenosine alone has proven to be so useful clinically, despite the theoretical possibility that in a small proportion of patients truly maximal hyperemia was not achieved.

CONCLUSION

By providing information regarding the ischemic potential of a coronary stenosis, FFR measurement improves our management of patients with CAD. Is FFR required for all patients with coronary disease undergoing coronary angiography? In the culprit vessel of a patient with STEMI, FFR is not recommended. In a patient with angina, single-vessel CAD with an angiographically significant coronary stenosis, and a noninvasive stress test with ischemia in the territory subtended by the vessel with the stenosis, FFR is not necessary. But these scenarios occur less frequently than the patient with an equivocal noninvasive stress test, or the patient with multivessel coronary disease, where FFR measurement to guide PCI clearly improves outcomes and saves resources.

**MULTIPLE CHOICE QUESTIONS**

1. Which statement is correct with respect to the derivation of fractional flow reserve (FFR)?
   A. During maximal vasodilation, resistance is maximized and flow becomes proportional to pressure.
   B. In a normal epicardial vessel, there is little pressure loss along its course (ie, distal pressure is similar to proximal pressure).
   C. FFR is calculated as the proximal coronary or aortic pressure divided by the distal coronary pressure during maximal hyperemia.
   D. FFR is defined as the maximum flow in a diseased vessel compared to the maximum flow in an adjacent nondiseased vessel.
   E. FFR is defined as maximal flow down the vessel divided by resting flow down the vessel.

2. Which of the following is a feature of fractional flow reserve (FFR)?
A. It has a normal value of less than 0.80.
B. It is affected by changes in heart rate and blood pressure.
C. It is an index specific for epicardial coronary disease.
D. It has an ischemic cutoff value at 1.0.
E. It has high variability and is not very reproducible.

3. Which of the following is true when measuring fractional flow reserve (FFR)?
   A. The sensor is positioned just beyond the stenosis and not in the distal two-thirds of the vessel.
   B. Nitroglycerin is not routinely administered.
   C. The optimal dose of intracoronary adenosine is 12 micrograms (μg) for the right coronary artery and 16 μg for the left coronary artery.
   D. It is important to keep the guide catheter well-seated when assessing an aorto-ostial coronary stenosis.
   E. A continuous intravenous administration of adenosine has the advantage of allowing a slow pullback of the pressure sensor to identify the location of the most significant pressure drop.

4. The FFR versus Angiography for Multivessel Evaluation (FAME) trial did which of the following?
   A. Compared fractional flow reserve (FFR)-guided percutaneous coronary intervention (PCI) to angiography-guided coronary PCI in patients with stable, single-vessel coronary disease.
   B. Demonstrated that the FFR-guided procedure significantly prolonged the procedure compared to the angiography-guided strategy.
   C. Found that the angiography-guided arm received significantly fewer stents.
   D. Found that the FFR-guided arm utilized significantly more contrast media.
   E. Showed a significant reduction in major adverse cardiac events at 1 year in patients randomized to FFR-guided PCI.

5. The FFR versus Angiography for Multivessel Evaluation 2 (FAME 2) trial did which of the following?
   A. Compared fractional flow reserve (FFR)-guided percutaneous coronary intervention (PCI) to medical therapy in patients with acute
coronary syndromes.
B. Enrolled only patients with single vessel coronary artery disease.
C. Found that FFR-guided PCI led to significantly lower rates of the composite of death, myocardial infarction and urgent revascularization compared with best medical therapy alone.
D. Showed that medically treated patients without any lesion with an FFR less than or equal to 0.80 had higher event rates than medically treated patients with at least 1 lesion with an FFR less than or equal to 0.80.
E. Revealed an unfavorable cost-effectiveness ratio for FFR-guided PCI of greater than $100,000 per quality adjusted life year gained.

Adjunctive Diagnostic Techniques: Intravascular Ultrasound, Optical Coherence Tomography, and Spectroscopy

Yuhei Kobayashi
Peter J. Fitzgerald
Yasuhiro Honda

The limitations inherent to angiography served as a technological springboard for the development of other devices in search of better visualization, quantification, and identification of the coronary vasculature and assessment of the efficacy of subsequent clinical therapeutics. Intravascular ultrasound (IVUS) was invented and introduced to clinical practice in the late 1980s as an invasive intravascular imaging device. As a front-runner in this field, IVUS has greatly contributed to the investigation of the pathophysiology of coronary artery disease in symptomatic patients and to the guidance of percutaneous coronary interventions (PCI).

Since the early 2000s, optical coherence tomography (OCT), which was first introduced in the ophthalmology field, has been applied to human intravascular imaging. Apart from these intravascular imaging systems, spectroscopy has also begun to gather attention as a device to determine plaque components. Spectroscopy provides adjunctive information when used with IVUS, though current clinical applications are limited to the detection of cholesterol within the vessel wall.
This chapter will provide information related to concrete usage and tips of adjunctive intravascular imaging devices as well as to review evidence and rationale for use as a procedural guide in the cardiac interventional setting.

**INTRAVASCULAR ULTRASOUND**

After the first initial clinical experience by Yock et al. in 1988,\(^1\) IVUS has become established as an adjunctive diagnostic device as well as an essential research tool in the cardiac catheterization laboratory. Moreover, its development and findings have been a driving force in the expansion of the intravascular diagnostic field. With a miniaturized ultrasound probe equipped at a tip of an IVUS catheter, a high-frequency ultrasound beam ranging from 20 to 45 megahertz (MHz) is transmitted radially from the probe to a vessel wall and its reflection sound waves are reconstructed to depict a cross-sectional image. The higher frequency ultrasound beam (shorter wave length) than those utilized in noninvasive echocardiography (2-5 MHz, longer wave length) potentiates its high resolution to visualize vessel and intravascular structures, which leads to its low radial penetration of 4 to 8 mm from the IVUS catheter. To improve the resolution of IVUS images, adoption of ultrasound with higher frequency (55-60 MHz) than conventional IVUS is currently underway; this will possibly lead to better interpretation of gray-scale IVUS imaging by improving tissue and plaque differentiation.

There are several intermediate resolution/penetration ultrasound catheter devices for peripheral (15-20 MHz) or intracardiac (intracardiac echocardiography [ICE], 5-10 MHz) uses, specifically developed to guide catheter-based treatments of peripheral vessels and structural heart disease, or catheter ablation. Detailed descriptions of ICE can be found elsewhere in this textbook (see **Chapter 13**).

**Imaging Systems and Image Acquisition Procedure**

IVUS imaging systems consist of 3 components: an imaging catheter, a console for imaging reconstruction/display/recording/analysis, and a catheter interface unit with motorized transducer pullback capability. Specifically, 2 types of imaging acquisition processes are applied to commercially available IVUS catheters: a solid-state dynamic aperture and a mechanically rotating
single transducer system (Table 25-1). Currently, only 1 company (Volcano Corp., San Diego, CA) provides the solid-state catheter system that has 64 phased-array transducers mounted around the catheter tip. It utilizes a rapid-exchange design and the guidewire is inserted through a circumferential array of transducer elements. On the other hand, mechanical catheter systems are available from 4 companies with slightly varying configurations (Boston Scientific Corp., Marlborough, MA; Infraredx Inc., Burlington, MA; Terumo Corp., Tokyo, Japan; and Volcano Corp./Royal Philips). In mechanical systems, there is only one transducer equipped at the tip of the catheter, which rotates inside of a protective sheath, and it incorporates a rapid-exchange design with the guidewire running alongside the imaging window; therefore, this system can have several inherent artifacts from its structure (eg, non-uniform rotational distortion, guidewire shadow). In general, however, image quality is superior to the solid-state system because of the higher frequency ultrasound (40-45 MHz vs 20 MHz) and the larger effective aperture of a transducer element used in the mechanical system. In addition, longitudinal lesion length assessment is more accurate in the mechanical system, because the transducer pullback is performed within the stationary protective sheath.

Abbreviations: F, fluorescence profile; MHz, megahertz.
In terms of preparing the IVUS catheter prior to use, there are differences between the mechanical system and the solid-state system owing to their designs. The mechanical system requires a saline flush to remove air bubbles between the protective sheath and the transducer before IVUS catheter insertion, whereas the solid-state system requires a step to mask ring-down artifact before insertion of IVUS catheter into the coronary artery, which is usually performed in the aorta or in the left main. It is generally recommended that residual air bubbles should be flushed outside of the body so as to avoid an air embolization. Similar to standard interventional procedures, intravenous heparin (5000-10,000 units) and intracoronary nitroglycerin (100-200 micrograms) should be administered beforehand. Thereafter, a 0.014-inch guidewire is advanced distally to the target vessel, followed by IVUS catheter insertion. Pullback IVUS scan should be started from at least 10 mm distally to the target lesion and to the aorta for complete target vessel interrogation. Automated pullback speeds of 0.5 mm/sec and 1.0 mm/sec are available. When assessing an ostial lesion, it is important to disengage the guide catheter slightly from the ostium so that the target lesion can be fully visualized.

**Artifacts**

Differentiating among the types of artifacts and addressing them properly are important aspects to achieve precise interpretation of IVUS images. Artifacts of IVUS mainly derive from IVUS design, feature of ultrasound, or inappropriate preparations (Fig. 25-1).
FIGURE 25-1  Examples of common IVUS artifacts. A. Acoustic shadowing is an image blank behind strong ultrasound reflectors. B. Air bubbles are the artifact that blurs an IVUS image, when residual air bubbles exist between an outer sheath and a transducer in mechanical IVUS systems. C. Blood speckles can be observed as an unexpectedly high-echoic area within a lumen, and, as a result, the border between lumen and intima may become obscure. D. Multiple ghost images called reverberations (white arrowheads), spaced radially at regular intervals, can be observed in a calcified lesion with a smooth surface (red arrowhead) or a lesion with a metal stent. E. Non-uniform rotational distortion (NURD) is an artifact that can be seen as a partial or entire distortion of the cross-sectional image, resulting from mechanical binding of the drive cable that rotates the transducer inside the protective sheath. F. Ring-down artifact can be observed as a ring adjacent to an IVUS catheter and may be caused by residual air bubbles within the protective sheath or the sheath itself in mechanical IVUS systems, or by interference of ultrasound in the solid-state system. G. Side lobe artifact is an artifact observed laterally to stent struts or a calcification. When a strong reflector exists, a side lobe ultrasound can create a lateral ghost image. H. A guidewire can be the cause of acoustic shadowing (see Part A) called guidewire artifact, stemming from the reflection of the ultrasound beam by the guidewire.

A)  Acoustic shadowing (see Fig. 25-1A).
Acoustic shadowing is an image blank behind a calcification, a metal stent, or a guidewire. IVUS beam cannot penetrate such strong ultrasound reflectors, generating the image blank observed behind these structures.

B)  Air bubbles (see Fig. 25-1B).
Air bubbles are the artifact that blurs an IVUS image. When residual
air bubbles exist between an outer sheath and a transducer in
mechanical IVUS systems, adequate ultrasound beam emission and
image acquisition are inhibited. Repeat saline flushes are necessary to
fully remove the residual bubbles.

C) Blood speckles (see Fig. 25-1C).
Blood speckles can be observed as an unexpectedly high-echoic area
within a lumen, and, as a result, the border between lumen and intima
may become obscure. It is usually observed when using an ultrasound
system with higher frequency (>40 MHz), or in lesions with stagnant
coronary flow from severe stenosis where rouleaux formation of red
blood cells occurs. An injection of saline or contrast will help to
identify the lumen border.

D) Multiple reverberations (see Fig. 25-1D).
When analyzing a calcified lesion with smooth surface or a lesion with
a metal stent, multiple ghost images, spaced at radially regular
intervals, can be observed. These ghost images are called multiple
reverberations, and care should be taken to not misinterpret these
findings as true structures. This phenomenon is caused by multiple
reflections of the ultrasound beam between the transducer and a strong
reflector.

E) Non-uniform rotational distortion (NURD) (see Fig. 25-1E).
NURD is an artifact that can be seen as a partial or entire distortion of
the cross-sectional image. This artifact is unique to the mechanical
IVUS systems, resulting from mechanical binding of the drive cable
that rotates the transducer inside the protective sheath. This is usually
observed in a tortuous artery or from a kink in the imaging catheter. To
avoid this artifact, it is important to straighten the IVUS catheter
outside of body, or to unfasten the Y-connector to release torque.

F) Ring-down artifact (see Fig. 25-1F).
Ring-down artifact can be observed as a ring adjacent to an IVUS
catheter and may be caused by residual air bubbles within the
protective sheath or the sheath itself in mechanical IVUS systems, or
by interference of ultrasound in the solid-state system. This may be
treated with additional saline flushing in mechanical systems, or digital
mask adjustment in the solid-state system.
G) Side lobe artifact (see Fig. 25-1G). 
Side lobe artifact is an artifact observed laterally to stent struts or a calcification, which can possibly lead to an inaccurate assessment of a stent area because of pseudo-protruding struts to the lumen. When a strong reflector exists, a side lobe ultrasound can create a lateral ghost image.

H) Guidewire artifact (see Fig. 25-1H). 
A guidewire can be the cause of acoustic shadowing (see Fig. 25-1A), stemming from the reflection of the ultrasound beam by the guidewire, resulting in the blank image behind it. This artifact is only seen in the mechanical IVUS system, because a guidewire runs alongside the transducer.

**Image Interpretation**

Arterial three-layer structures (intima, media, and adventitia) correspond to high-low-high echoic findings by IVUS (Fig. 25-2). It is usually difficult to distinguish adventitia from extravascular matrix. In some cases, the media may appear artifactually thin because of “blooming”—an intense reflection from the intima. In other cases, the media can contrarily appear thick because of signal attenuation from the intima and the weak reflectivity of the internal elastic membrane (IEM). Particularly in younger normal subjects, the vessel wall may have a single-layer appearance, since the intima is thinner than the resolution of IVUS. IEM and external elastic membrane (EEM), just adjacent to the media, cannot be observed by IVUS. In some cases, the media may be destroyed partially in association with development of atherosclerosis, and it no longer appears as a distinct layer.
FIGURE 25-2 Typical cross-sectional IVUS image and its interpretation. A. A cross-sectional IVUS image with schematic diagram. B. Demonstrates the classic high-low-high, three-layered appearance. C. Histologic correlations with intima, media, and adventitia. The media has lower ultrasound reflectance owing to less collagen and elastin as compared with the neighboring layers. Because the intimal layer reflects ultrasound more strongly than does the media, there is a spillover in the image, which results in a slight overestimation of the thickness of the intima and a corresponding underestimation of the medial thickness.

In order to determine image orientation within the artery, recognition of perivascular structures (eg, branches, veins, pericardium, and myocardium) are of clinical importance, especially during interventional procedures or in repeated recordings over time (Fig. 25-3).

An IVUS image is reconstructed as a cross-sectional image as if the interpreters look down into a coronary artery in a proximal-to-distal direction. As an example in a typical case, a diagonal branch is located at approximately 90° to 120° clockwise to a septal branch. In contrast to side branches, veins are susceptible to compression during the cardiac cycle and do not merge with arteries when assessed longitudinally. While the pericardium appears to be a high echoic thick layer with pericardial space between an interrogated vessel and pericardium, the myocardium is viewed on an opposite side of the vessel as a low echoic homogeneous structure.
FIGURE 25-3 Perivascular structures. A. **Diagonal and septal branch** can be observed in the left anterior descending artery. A diagonal branch is located at approximately 90°-120° clockwise to a septal branch. B. While the **pericardium** appears to be a high echoic thick layer with pericardial space between an interrogated vessel and pericardium, the **myocardium** is viewed on an opposite side of the vessel as a low echoic homogeneous structure. C. **Right ventricular (RV) vein** overlying the right coronary artery. D. **Great cardiac vein (GCV)** observed from the left circumflex artery. In contrast to side branches, veins are susceptible to compression during the cardiac cycle and do not merge with
Quantitative Assessment

With an intrinsic distance calibration, diameter and cross-sectional area (CSA) can be measured in a cross-sectional IVUS image. Measurements will be repeated in the tightest cross-section within the lesion, and in proximal and distal reference segments. Reference segments are usually selected as the most “normal-looking” cross-section within 10 mm from the interrogated lesion without any major intervening side branches. The average area of proximal and distal reference is often used. Vascular remodeling, originally identified and proposed in autopsy specimens, can also be evaluated by IVUS. When serial IVUS images are available, vascular remodeling can be defined as a ratio of follow-up EEM CSA to baseline EEM CSA. When it is not available, it can be defined using a following formula: Remodeling index=lesion EEM CSA/reference EEM CSA. If the lesion EEM CSA exceeds the reference EEM CSA, remodeling index becomes >1.0, which is defined as positive remodeling of the vessel. On the other hand, negative remodeling is defined as a remodeling index <1.0. Instead of this cutoff, positive remodeling of >1.05 and negative remodeling of <0.95 can be employed.\(^5\)

After determination of the interface between the lumen and the leading edge of intima, lumen measurements can be performed. In addition to lumen CSA, minimum, maximum, and mean diameters as well as eccentricity can be obtained. Because the interface between the adventitia and extravascular matrix is usually obscure, EEM area is used as an alternative to vessel area. EEM area is defined as the area enclosed by the outermost interface between media and adventitia. Circumferential EEM may not be measured precisely, especially at a bifurcation or calcified lesion. Because IEM is not well delineated by IVUS, the area between the leading edge of the lumen and EEM is defined as atheroma, based on the fact that the media represents only a very small fraction of the atheroma CSA. Accordingly, the term “plaque plus media” is used to represent plaque in a cross-section. In terms of stent measurements, metallic stent struts are strong reflectors of ultrasound, and thus, high gain setting should be avoided to reduce side-lobe artifacts. Typical IVUS measurements for lumen, plaque, and stent are summarized in Figure 25-4 and Table 25-2.
FIGURE 25-4 Examples of quantitative IVUS assessment. Quantitative IVUS measurements for non-stented (A-D) and stented (E-H) segments. Area measurements are performed with computer planimetry. External elastic membrane (EEM) area is defined as the area enclosed by the outermost interface between media and adventitia (B), while lumen area (C and G) is determined by tracing the leading edge of the blood/intima border. Plaque + media area (D) is calculated as the difference between EEM and lumen areas. Stent area (F) is measured by tracing the leading edge of the stent struts, and neointimal area (H) is calculated as the difference between stent and lumen areas. For EEM, lumen, and stent, the maximum (solid arrows) and minimum (dotted arrows) diameters are determined. For plaque + media and neointima, the maximum (solid arrows) and minimum (dotted arrows) thickness are measured.

Table 25-2 Quantitative Assessment of Lumen, Plaque, and Stent by IVUS
In addition to cross-sectional assessments, longitudinal lesion length is an important aspect of a quantitative assessment. In mechanical IVUS systems, longitudinal lesion length can be measured automatically or manually by pulling back a transducer inside the protective sheath, whereas the solid-state system requires the pullback of the catheter itself. Care should be taken in assessing a tortuous lesion, where constant transducer pullback is not warranted. In addition, lesion length can be affected by the longitudinal catheter movement due to heartbeats. With the Eagle Eye® Platinum solid-state catheters (Volcano Corp.), 3 radiopaque markers at 1-cm intervals on the catheter shaft proximal to the transducer may be utilized to estimate the lesion length based on the angiogram.

**Qualitative Assessment by Gray-Scale IVUS**

With conventional gray-scale IVUS, plaques are typically classified into 4 types: (1) soft plaque; (2) fibrous plaque; (3) calcified plaque; and (4) mixed plaques.
plaque. However, this classification is fundamentally different from the histology, thus necessitates careful interpretation. Soft (echolucent) plaque refers to a low echoic plaque (lower than the adventitia) which derives from high lipid content and contrary low collagen and elastin (Fig. 25-5A). Fibrous plaque refers to an intermediate echoic plaque (echogenicity between the soft plaque and the calcified plaque) and represents the majority of atherosclerotic lesions (Fig. 25-5B). Usually, echogenicity increases according to the increment of fibrous tissue content. Calcified plaque has higher echogenicity than the adventitia and is accompanied by acoustic shadowing (Fig. 25-5C). Calcified plaque can be classified based on depth and its circumferential extent. Depending on the location of the leading edge of calcification, calcified plaque is categorized as superficial (within 50% of plaque plus media) or deep (deeper than 50% of plaque plus media). Because IVUS may not accurately delineate the border of calcification, and the angle is dependent of the distance from the center of the lumen, the extent of calcium may be semi-quantitatively expressed as 4 quadrants; 0°<90°, 90° to 180°, 180° to 270°, and >270°. If the extent of calcium is more than 90°, vessel contour should not be assessed. Calcification less than 90° is called spotty calcification, which is recognized as a feature of unstable plaque in acute coronary syndrome. It is worth noting that highly dense fibrous plaques may have acoustic shadowing and similar echogenicity with calcified plaques due to the high content of fibrous tissue. Some plaques consisting of multiple components are called “mixed plaques” (Fig. 25-5D), and are classified as fibrocalcific or fibrofatty plaques.
FIGURE 25-5 Examples of qualitative plaque characteristics assessment by gray-scale IVUS. With conventional gray-scale IVUS, plaques are typically classified into 4 types: A. soft plaque; B. fibrous plaque; C. calcified plaque; and D. mixed plaque. Soft (echolucent) plaque refers to a low echoic plaque (lower than the adventitia) which derives from high lipid content and contrary low collagen and elastin. Fibrous plaque refers to an intermediate echoic plaque (echogenicity between the soft plaque and the calcified plaque) and represents the majority of atherosclerotic lesions. Calcified plaque has higher echogenicity than the adventitia and is accompanied by acoustic shadowing. Calcified plaque can be classified based on depth and its circumferential extent. Depending on the
location of the leading edge of calcification, calcified plaque is categorized as superficial (within 50% of plaque plus media) or deep (deeper than 50% of plaque plus media).

**Tissue Characterization**

As IVUS-guided intervention matures, there is growing attention to acquiring more detailed plaque characterization. To date, 3 different tissue characterization techniques, which employ computer-assisted analysis of raw radiofrequency (RF) signals in the reflected ultrasound beam, are commercially available: Virtual Histology™ (VH) (Volcano Corp.), iMAP™ (Boston Scientific Corp.), and Integrated Backscatter (Terumo Corp.). A comparison of the 3 tissue characterization techniques and representative images are shown in Table 25-3 and Figure 25-6.

Clinical applications of tissue characterization techniques have been mainly focused on the prediction of future coronary events or slow-flow phenomenon after an interventional procedure by stratifying high-risk coronary plaques. In particular, among the three techniques, the VH-IVUS system has demonstrated the ability to predict future coronary events in a large-scale prospective multicenter trial (Providing Regional Observations to Study Predictors of Events in the Coronary Tree: PROSPECT) where 697 patients with acute coronary syndrome underwent three-vessel gray-scale and VH-IVUS after PCI. The 3-year cumulative rate of major adverse cardiac events was 20.4%, with nearly half of these events being associated with nonculprit lesions, most of which appeared to be mild by baseline angiography. On multivariate analysis, nonculprit lesions with recurrent events were significantly associated with 3 characteristics: (1) plaque burden of 70% or greater; (2) minimal luminal area of 4.0 mm² or less; and (3) VH-determined thin-cap fibroatheroma. In another study of investigating 190 consecutive patients with acute coronary syndrome (ACS), a no-reflow phenomenon was observed in 24 patients after stent implantation. VH-detected absolute and % necrotic core (NC) areas at the minimum lumen area (MLA) site as well as volumetric parameters of these variables were significantly greater in patients with no reflow. In the multivariable analysis, % NC volume was the only independent predictor of no reflow (OR=1.126, 95% CI: 1.045-1.214, $P = 0.002$).
There are several inherent limitations to these tissue characterization techniques: limited spatial resolution (100-250 μm) for detection of thin fibrous caps, no classification for thrombus or stent struts, and misclassification of plaque beyond severe calcification due to limited ultrasound signal penetration.

**Clinical IVUS Applications**

IVUS-guided PCI with both bare metal stents (BMS) and drug-eluting stents (DES) has demonstrated to be associated with better long-term outcomes compared to angiography-guided PCI. In the literature-based meta-analysis including nine studies, Casella et al. showed that IVUS-guided PCI with BMS reduced target lesion revascularization, major adverse cardiac events, and binary restenosis at 6 months, although deaths and nonfatal MI was similar between the two groups.\(^8\) In the recently published meta-analysis of IVUS-guided DES implantation including three randomized trials and 12 observational studies with 24,849 patients, Jang et al. found significant reduction of all-cause mortality (odds ratio [OR]=0.64, 95% confidence interval [CI] 0.51-0.81, \(P < 0.001\)), major adverse cardiac events (OR=0.79, 95% CI 0.69-0.91, \(P = 0.001\)), and stent thrombosis (OR=0.59, 95% CI 0.42-0.82, \(P = 0.002\)).\(^9\) It must be emphasized that careful and accurate interpretation of IVUS images is mandatory to maximize the benefit of IVUS-guided intervention. One additional aspect of IVUS-guided PCI is the potential to minimize the amount of contrast media during the procedure, which may also impact short- and/or long-term outcomes of our patients.

**Pre-Interventional Assessment**

In terms of preinterventional assessment, IVUS enables the interventionalist to determine the optimal device, its size, and other observations related to predicting favorable outcomes for a given procedure (Fig. 25-7). For example, if the IVUS catheter does not pass the target lesion, stent delivery and deployment may be affected. In this case, lesion preparation with balloon pre-dilatation or rotational ablation with the Rotablator® (Boston Scientific, Marlborough, MA) may be utilized, depending on the angiographic findings. After passing the target lesion, both qualitative and quantitative lesion morphology should be assessed. Additionally, when examining a tortuous
artery, a pseudo-stenosis caused by the accordion phenomenon should be kept to avert a misdiagnosis of a stenosis. On the IVUS image, a crescent-shaped lesion can be observed due to the folding of vessel wall. After removal of the IVUS catheter and guidewire, the lesion should be re-evaluated with an angiogram.

**FIGURE 25-7** Flow chart of preinterventional IVUS assessment.

### Qualitative Assessment

Common preinterventional qualitative assessment includes 1) high-risk features for distal embolization, 2) calcified plaque, and 3) plaque morphology with high risk of side branch occlusion. It is reported that plaque volume, a lipid pool-like image, ultrasound attenuation, and thrombus detected by IVUS are thought to be contributing factors to slow flow and no reflow. A lipid pool may be observed as an echolucent (or low echoic) zone inside the plaque in cases with high-quality images. However, detection of a lipid pool only by gray-scale IVUS imaging has low accuracy. Echo-
attenuated plaque can be identified by absence of the ultrasound signal behind the plaque that was either hypoechoic or isoechoic to the adventitia, despite absence of calcium, and is usually found in patients with acute coronary syndrome (Fig. 25-8A). One group recently reported that histopathologically, 91.4% of echo-attenuated plaques corresponded to either a fibroatheroma (FA) with an NC or pathological intimal thickening with a lipid pool; almost all segments with superficial echo attenuation indicated the presence of an FA with an advanced NC. Another group proposed that ultrasound attenuation with a longitudinal length of >5 mm and plaque rupture were significantly associated with no-reflow phenomenon. IVUS findings for a thrombus vary depending on the morphology; however, it is described as an intraluminal mass with a layered, lobulated, or pedunculated appearance (Fig. 25-8B). Adjunctive intracoronary drug administration or using a distal protection device may be warranted in this setting. In treating the heavily calcified lesion, especially circumferential calcification, called “napkin ring appearance” (Fig. 25-8C), application of the Rotablator device may be considered as an adjunctive therapy. The IVUS catheter position within a cross section will be useful to predict the impact of guidewire bias for the ablation procedure. After the ablation of calcium, multiple reverberations may be observed due to the smooth surface of the calcification. With respect to side branch occlusion, 2 IVUS findings were reported to have a predictive value. By observing a side branch ostium from a main vessel (Fig. 25-8D), presence of an atherosclerotic plaque at the side branch ostium was associated with 35% occlusion rate, whereas only 8% of the side branches without the ostial plaque resulted in occlusion. However, this finding may not be reliable, since an observation of the side branch ostium from the main vessel is not necessarily the same as the direct observation of the side branch ostium. One study investigating left main bifurcation lesions with IVUS pullback from the main vessel and the side branch showed that IVUS evaluation of the side branch ostium from the main vessel is only moderately reliable. Another finding is the “eyebrow” sign, which can be identified in the longitudinal view as a carina with a spiky morphology (Fig. 25-8E). Protection with a guidewire or predilatation may be utilized to avoid the side branch occlusion. Coronary aneurysm can be observed in preinterventional IVUS imaging or in postinterventional long-term follow-up IVUS imaging, as a consequence of an interventional
procedure (Fig. 25-8F). True coronary aneurysm is defined as more than 50% of lumen area enlargement than the proximal reference with an intact vessel wall. In contrast, pseudoaneurysm shows a loss of vessel wall integrity and damage to adventitia or perivascular tissue.

**FIGURE 25-8** Examples of preinterventional qualitative IVUS assessment. A. Echoattenuated plaque is characterized by absence of the ultrasound signal behind the plaque that was either hypoechoic or isoechoic to the adventitia, despite absence of calcium, and is usually found in patients with acute coronary syndrome. B. IVUS findings of a thrombus vary depending on its content and age; however, acute thrombus often presents as an intraluminal mass with a layered, lobulated, or pedunculated appearance. Adjunctive intracoronary drug administration or using a distal protection device may be warranted in this setting. C. In treating a heavily calcified lesion, especially with circumferential calcification called “Napkin ring appearance,” plaque modification with rotational atherectomy may be considered as an adjunctive therapy. D. Presence of an atherosclerotic plaque at the side branch ostium may be associated with an increased risk of occlusion after main vessel stenting. Accurate assessment requires direct imaging of the side branch. E. “Eyebrow” sign, defined in the longitudinal view as a carina with a spiky morphology, was also reported to predict side branch encroachment by main vessel intervention. F.
Coronary aneurysm can be observed in preinterventional IVUS imaging, or in postinterventional long-term IVUS follow-up as a consequence of an interventional procedure.

Quantitative Assessment

As stated previously, optimal device selection in terms of type and size are achieved with data acquired from quantitative IVUS assessment of the target lesion. Information obtained from earlier IVUS studies include the mechanism of luminal gain after percutaneous transluminal coronary angioplasty (PTCA) or stent deployment consist of vessel expansion (EEM expansion) and decrement of plaque volume (axial redistribution, compression, and distal embolization).\(^{15}\)

Clinical Outcomes with Ultrasound Trial (CLOUT) by Stone et al. was the first clinical investigation which demonstrated the safety and usefulness of IVUS-guided angioplasty compared to angiography alone, in which a balloon sizing protocol of the average of the lumen and media-to-media diameters at the reference segment for cases without extensive calcification was employed.\(^{16}\) A subsequent randomized, multicenter clinical trial (Balloon Equivalent to STent [BEST] study) comparing IVUS-guided angioplasty vs stenting employed a balloon sizing protocol of media-to-media diameter measured at the lesion.\(^{17}\) This aggressive balloon strategy resulted in a 56% reduction of stent usage (crossover of 44% patients from angioplasty strategy to stenting) with similar 6-month angiographic and clinical outcomes. In a contemporary DES trial of complex lesions, known as the Angiography Versus IVUS Optimization (AVIO) trial, the size of the post-dilatation balloon was selected based on the average of the media-to-media diameters at multiple sites within the stented segment.\(^{18}\) Precise vessel size measurement is also critically important for size selection of self-expanding or because these devices are not amendable once underdeployed in the lesion.

Angiographically “normal” reference segments can show 35% to 51% of plaque burden when evaluated by IVUS, and therefore, assessment of true lesion length by IVUS dictates the exact length of stent necessary to appropriately scaffold a lesion. To date, several IVUS studies of DES have identified greater reference plaque burden (inflow/outflow disease) as an independent predictor of subsequent stent edge restenosis or thrombosis.\(^{19-21}\)
The Impact of Stent Deployment Techniques on Clinical Outcomes of Patient Treated With the Cypher Stent (STLLR) trial also demonstrated that geographic miss (defined as the length of injured or stenotic segment not fully covered by the DES) had a significant negative impact on both clinical efficacy and safety at 1 year following sirolimus-eluting stent implantation.\textsuperscript{18} Thus, stent length is commonly recommended to be long enough to cover the entire lesion. Importantly, however, longer stent length has also been reported to be independently associated with DES restenosis and thrombosis. One practical approach was proposed in a single-center registry, where unique stepwise IVUS criteria (plaque burden <50% as the primary target zone) determined the optimal landing zone for DES.\textsuperscript{23} Spot stenting may also be an alternative option, which has shown favorable clinical outcomes in the DES era.\textsuperscript{24}

Detailed assessment of left main coronary artery disease is one of the most clinically important applications of IVUS, since left main disease is directly related to patient mortality. Angulations, calcification, or spasm in this location often lead to poor catheter engagement and confound angiographic interpretation. Several studies have shown that high percentages of patients that appear normal on angiography have left main coronary artery disease detected by IVUS.\textsuperscript{25-27} Conversely, another IVUS study has demonstrated that only less than half of angiographically ambiguous left main stenosis have a significant stenosis.\textsuperscript{28} This was especially true for ostial left main coronary disease where only 36% of the lesions had a significant stenosis and 41% had plaque burden <50% when assessed by IVUS. Furthermore, a recent study also reported a slight overestimation of fractional flow reserve (FFR) for the functional assessment of left main disease when a significant downstream stenosis coexists in the proximal left anterior descending or circumflex artery.\textsuperscript{29} Plaque distribution in left main bifurcation lesions can also be evaluated more accurately with IVUS compared with conventional angiographic classifications.\textsuperscript{30}

**PostInterventional Assessment**

Immediately after PTCA or stent deployment in a given lesion, the interventionalist should consider two perspectives in postinterventional IVUS assessment: the detection of complications following the procedure and the
optimization of the treatment (Fig. 25-9). In long-term follow-up, chronic stent problems and neointimal proliferation may also be assessed in details.

**FIGURE 25-9** Flow chart of postinterventional IVUS assessment.

**Qualitative Assessment**

Although spontaneous coronary dissection may be a primary cause for coronary events in some cases, coronary dissection (Fig. 25-10A) is usually seen after interventional procedures. IVUS is able to visualize the presence, longitudinal extent, and severity of the dissection, which is often difficult to assess precisely by coronary angiogram alone. In the IVUS image, dissection appears as a fissure or separation within the intima or plaque, and its severity can be quantified according to the depth (intimal, medial, or adventitial). After PTCA, dissection typically arises between 2 components with different compliance, such as soft and calcified plaque, whereas after stent deployment, it typically originates near the stent edge. Generally speaking, utilization of IVUS is preferable to OCT when injection of contrast media may possibly worsen the severity of dissection. Intramural (intravascular)
hematoma can arise often as a result of proximal dissection into the media (entry point) and distal dead end (a lack of reentry), leading to an accumulation of blood within the medial space (Fig. 25-10B). Maehara et al reported that in 29% of the hematomas detected by IVUS, there was no significant angiographic abnormality. Intramural hematoma is typically crescent-shaped, with straightening of the internal elastic membrane and with a homogeneous and hyperechoic lesion caused by blood accumulation. In contrast, extramural (extravascular) hematoma results from perforation of the coronary artery with extravasation to the adventitial tissue, typically observed after PCI, such as atherectomy or recanalization of chronic total occlusion (CTO) lesions. It appears as an irregularly shaped, echo-dim pattern, owing to the dilution of red blood cell concentration and dissemination throughout an echogenic adventitia with a separation of media. There may be less luminal compression in an extramural hematoma than in intramural hematoma.
FIGURE 25-10 Examples of postinterventional qualitative IVUS assessment and myocardial bridge. A. **Coronary dissection** is often seen after interventional procedures. In the IVUS image, dissection appears as a fissure or separation within the intima or plaque, and its severity can be quantified according to the depth (intimal, medial, or adventitial). B. **Intramural (intravascular) hematoma** can arise often as a result of proximal dissection into the media (entry point) and distal dead end (a lack of reentry), leading to an accumulation of blood within the medial space. Intramural hematoma is typically crescent-shaped, with straightening of the internal elastic membrane and with a homogeneous and hyperechoic region caused by blood accumulation. C. Even after stent
optimization, baseline incomplete stent apposition (ISA) can be observed by IVUS in 8% to 30% of drug-eluting stent (DES) cases. ISA is defined by IVUS as one or more stent struts incompletely attached to the arterial wall with evidence of blood speckle behind the strut(s) in a segment not associated with any side branches. **D. Myocardial bridge** is gaining attention as a functional cause of angina, myocardial infarction (MI), conduction disturbances, and sudden death. Myocardial bridge is defined on IVUS as an echolucent band (halo) corresponding to muscle tissue, partially surrounding the artery, with a variable degree of systolic arterial compression during cardiac cycle.

Even after stent optimization, baseline incomplete stent apposition (ISA) (Fig. 25-10C) can be observed in 8% to 30% of DES cases by IVUS. ISA is defined by IVUS as one or more stent struts incompletely attached to the arterial wall with evidence of blood speckle behind the strut(s) in a segment not associated with any side branches. Despite its theoretical concern, there are no data directly linking this finding with unfavorable clinical events in the long term, especially for minor baseline ISA under dual antiplatelet regimens. However, a “permanent” gap between stents and the vessel wall might become problematic when rewiring the vessel is needed at later interventions.32

**Quantitative Assessment**

Stent expansions defined by minimum stent diameter (MSD) or area (MSA) of both BMS and DES are frequently smaller than expected from the compliance charts provided by the manufacturers (MSD; 71%-80%, MSA 61%-66%).33 MSA is reported to be a consistent IVUS-based predictor of ISR and thrombosis, both in conventional BMS and contemporary DES. Utilizing IVUS assessment can confirm the achievement of larger acute gain, thereby contributing to better long-term outcome.8,9 Historically, the predicted risk of ISR was reported to decrease 19% for every 1 mm$^2$ increase of MSA in BMS.34 As a consequence, the so-called “bigger is better” theory is typically applied in the optimization of lesions with BMS. In other words, it is generally recommended to achieve maximal stent expansion in a given lesion when treating with BMS.

Given that the variability of neointimal proliferation is reduced by the eluting drug, the predictive value of MSA for long-term lumen patency is thought to be magnified in DES. In the SIRIUS (Sirolimus-Coated BX VELOCITY Balloon-Expandable Stent in Treatment of de Novo Native
Coronary Artery Lesions) trial, while a significant positive correlation was observed between baseline MSA and follow-up MLA in both BMS and sirolimus-eluting stent (SES) groups \((P < 0.0001\) for both), SES showed a higher correlation than BMS \((0.80\) vs \(0.65\)) with a higher regression coefficient \((0.92\) vs \(0.59\)).\(^{35}\) In a retrospective IVUS analysis of lesions with restenosis of various DES, despite excessive intimal hyperplasia still identified as the dominant mechanism of ISR, stent underexpansion at the MLA site was observed in a considerable percentage of ISR lesions \((35\%\) in lesions with stent length \(>28\) mm). Thus, stent underexpansion is considered as an important preventable mechanism of ISR, particularly in lesions with long stents.\(^{36}\) One practical question is whether any definitive target MSA exists to assure long-term stent patency. To date, several investigators have reported diagnostic thresholds of MSA to predict long-term DES patency by utilizing receiver–operator characteristic (ROC) analysis.\(^{32,35}\) While these analyses are useful to compare the performance of various types of stent devices, the cutoff values determined by ROC curves do not necessarily represent procedural endpoints, since the sensitivity and specificity for predication of ISR are not equivalently important from a clinical perspective. An ideal procedural endpoint should be a clinically reasonable agreement of MSA in maximizing the probability of long-term stent patency while minimizing increased risk of complications associated with aggressive stent dilatation.\(^{37}\) The target MSA should also be modified based on clinical (eg, diabetes, renal failure) and targeted lesion characteristics (eg, lesion location, amount of downstream myocardium).

For left main stenting using either single- or 2-stent strategy, Kang et al proposed optimal stent areas to predict angiographic ISR. Among 403 patients enrolled in this study, MSA cutoffs to best predict ISR on a segmental basis were \(5.0\) mm\(^2\) for the ostial left circumflex artery, \(6.3\) mm\(^2\) for the ostial left anterior descending artery, \(7.2\) mm\(^2\) for the polygon of confluence, and \(8.2\) mm\(^2\) for the left main. Stent underexpansion was again an independent predictor for major adverse cardiac events \((\text{adjusted HR}=5.56, 95\% \text{ CI}, 1.99-15.49, P = 0.001)\).\(^{38}\) Another clinical study reported the impact of IVUS-guided stent implantation on long-term mortality of left main disease, using propensity-score matching. In 145 matched pairs of patients treated with DES, IVUS-guidance was associated with a significantly lower 3-year mortality as compared with angiography-guidance \((4.7\%\) vs
Follow-Up Assessment

The primary mechanism of restenosis can be accurately identified by IVUS, which significantly affects the treatment strategy in patients with restenotic lesions. An IVUS study of in-stent ISR lesions following BMS demonstrated that 20% of lesions had an MSA <5.0 mm$^2$ and an additional 4.5% had other mechanical problems that contributed to restenosis. In most of these cases, stent underexpansion or other mechanical problems were not suspected angiographically at the time of reintervention. In another IVUS study of DES restenosis, 21% of lesions had an MSA <5.0 mm$^2$, 38% of which were not associated with significant neointimal hyperplasia. For this type of ISR, mechanical optimization is the first priority, and IVUS can be helpful to differentiate mechanical issues from exaggerated neointimal proliferation that may truly require DES implantation within the original restenotic stent.

Serial IVUS studies have added the concept of classification of ISA according to the time course. At follow-up, baseline ISA may have resolved or may persist. Therefore, ISA observed at follow-up could be either persistent baseline ISA (persistent ISA) or newly developed ISA in the segment where struts were completely apposed to the vessel wall after the procedure (late-acquired ISA [LISA]). At present, however, it is still debatable whether LISA independently contributes to the occurrence of late adverse events: the majority of clinical trials failed to show a prospective association between LISA and later thrombotic events, whereas multiple IVUS studies have demonstrated that LISA is frequently observed in lesions of late DES thrombosis. This discrepancy clearly represents a multifactorial process of this phenomenon. Also, most prospective studies were underpowered to detect a possible relationship of LISA with rare thrombotic events. A literature-based meta-analysis, recently conducted to circumvent this issue, suggested a significantly higher risk of late or very late DES thrombosis in patients with LISA (persistent or late-acquired) compared with those without LISA (OR: 6.51, $P = 0.02$). Another potential methodological issue in investigating the clinical impact of LISA is lack of appropriate grading or classification: LISA consists of a wide spectrum ranging from tiny
ISA to extensive aneurysm formation, whereas thrombosis-associated LISA is often at the extreme end of this spectrum. Finally, the late development of ISA may simply represent a pathologic process within the arterial wall, such as chronic inflammation with endothelial dysfunction weakening the vessel structure, rather than serving as a direct cause of thrombosis. To accurately identify LISA posing a risk for future events across the spectrum, a better understanding of this phenomenon is essential.

Another IVUS-detected condition that may be of importance in DES is stent strut fracture after implantation. IVUS imaging can directly visualize stent struts, offering more detailed morphologic assessment and classifications of this phenomenon. By IVUS, strut fracture is defined as longitudinal strut discontinuity and can be categorized based upon its morphologic characteristics: (1) strut separation, (2) strut subluxation, or (3) strut intussusceptions. Another proposed classification focuses on potential mechanisms of the strut fracture, categorizing them on the basis of the presence or absence of aneurysm at the fracture site (type I and II, respectively). Theoretically, strut fracture of the DES can reduce the local drug dose delivered to the arterial wall, as well as affecting the mechanical scaffolding of the affected lesion segment. In addition, the irregular edge of the fractured struts may give chronic stimuli to the vessel wall under cardiac movement. Conversely, deployment of long and rigid stents in angulated lesions with hinge motion can lead to significant alteration of local physiology, and therefore, the strut fracture may help restore the original dynamic state in at least some cases. The exact incidence and clinical implications of strut fractures remain to be investigated in large clinical studies.

**Other Clinical Applications**

When treating a CTO lesion, IVUS has the potential to improve its success rate with real-time procedure guidance. In contrast to OCT, IVUS does not require contrast flush that may possibly aggravate subintimal dissection. If there is a branch located near the entry point of the CTO lesion, the IVUS catheter can be inserted into the side branch to examine the target for wire penetration. Also, the IVUS catheter can possibly be inserted into the subintimal space to determine the direction of the true lumen, to guide penetration of the 2nd guidewire, or to determine the balloon diameter in
order to make a connection between the intimal and the subintimal space. For this application, the short-tip solid-state catheter is often preferred. In addition, the longer monorail design of the solid-state catheter may offer better trackability and less frequent catheter trapping, which can occasionally be caused by separation of the IVUS catheter and guidewire. Finally, intramural or extramural hematoma (or perforation) can occur not infrequently during the CTO procedure. Early detection and precise assessment of these conditions are crucial for safe and effective treatment of patients with CTO.

Recently, myocardial bridge is gaining attention as a functional cause of angina, myocardial infarction (MI), conduction disturbances, and sudden death. Among 331 patients with de novo coronary lesions located in the left anterior descending artery, myocardial bridge was reported to be detected in 23% of patients by IVUS, whereas in 3% of patients by angiogram. Myocardial bridge is defined on IVUS as an echolucent band (halo), corresponding to muscle tissue, partially surrounding the artery (Fig. 25-10D). The direct assessment of muscle tissue by IVUS regarding length, thickness, and location, in combination with a functional measurement of systolic arterial compression, may enhance our understanding of this anomaly, provide prognostic information in specific patients, and determine the indication and strategy of treatment, especially when unroofing surgery is considered.

Assessment of vasculopathy after heart transplant is another common application of IVUS, since angiography often fails to detect diffuse progression of vasculopathy that involves the entire coronary tree. Rapidly progressive vasculopathy, defined by IVUS as an increment of >0.5 mm in intimal thickness within the first year after transplantation, was demonstrated to predict worse long-term outcome up to 5 years.

**Safety**

The IVUS procedure can be performed safely with general cautions for interventional procedures and careful catheter manipulation. The most frequently observed complication during the IVUS procedure is coronary spasm (2.9%), followed by other rare problems, such as acute occlusion, embolism, dissection, or thrombus formation (0.4%). Regarding possible endothelial injury and disease progression as a chronic complication of
intracoronary instrumentation, no acceleration in the progression of atheroma or allograft vasculopathy of arteries imaged by IVUS has been demonstrated compared with noninstrumented arteries.48

OPTICAL COHERENCE TOMOGRAPHY

Since the first description in 1991,49 the OCT technology has been applied clinically in ophthalmology, dermatology, gastroenterology, urology, and cardiology. By utilizing backscattered reflections of infrared light, the catheter-based OCT system generates real-time tomographic images with significantly higher resolution than conventional IVUS (10 times or more). However, this leads to a relatively low penetration ability and necessitates removal of blood during the image acquisition procedure. Thus, the relation between IVUS and OCT is thought to be complementary rather than alternative. The integration of IVUS and OCT on a single catheter is currently under investigation.

While OCT provides microscopic assessment of coronary artery disease, the impact of its application for PCI on clinical outcomes is yet to be demonstrated. Currently, an international multicenter registry (n=3,000) with 5 years clinical follow-up is underway to address its evidence in clinical utility. In addition, a multicenter randomized trial (n=800) comparing OCT-guided versus IVUS-guided PCI is ongoing.

Imaging Systems and Image Acquisition Procedure

OCT employs light in the near infrared (NIR) range, typically with wavelengths of approximately 1.3 micrometers (μm). Light emitted from the OCT system is split into 2 portions, so that 1 portion travels through tissue and the other portion travels through a predetermined distance as a reference. Reflected light from tissue is then collected and combined with the reference light to obtain an interference pattern between the 2 portions of light, which are then analyzed by the OCT system to determine the amount of backscattering as a function of delay time or depth within the tissue (A-line). First-generation OCT systems, called time domain (TD)-OCT, and 2nd
generation OCT systems, called frequency domain (FD)-OCT or optical frequency domain imaging (OFDI), employ similar systems. Second-generation systems have vastly improved the capability of obtaining A-lines at much higher speeds, facilitating rapid 3D pullback imaging. Both FD-OCT and OFDI systems have an axial resolution of 10 to 20 μm and a lateral resolution of 25 to 30 μm at the focus.

TD-OCT and FD-OCT/OFDI have different catheter configurations. The TD-OCT employs a wire type catheter with 0.016-in thickness and an imaging core at the tip of the wire. The FD-OCT/OFDI uses a rapid-exchange catheter that enables pullback imaging performed within a protective sheath, similar to the configuration of mechanical IVUS catheters.

For accurate measurements, the OCT image should be properly calibrated for the refractive index of the flushing media and Z offset. Since the refractive index differs among various flushing media, calculated distances in the images can vary, thus the distances need to be corrected. This correction is readily available in the OCT console provided by the manufacturer. Z offset refers to slight variations in the optical path length of the optical fiber within the catheter. Calibration can be achieved by adjusting the optical path length in the sample and/or reference arm, which can be performed automatically or manually before each OCT examination. Since the fiber length can also change during a single pullback, resulting in a varying z-offset across the OCT dataset, OCT images should be evaluated to verify the z-offset and to adjust it, if necessary, prior to quantitative analysis.

Unlike IVUS, OCT image acquisition mandates blood removal, since light emitted from the imaging core is strongly scattered/absorbed by red blood cells. Conventionally, the proximal balloon occlusion method has been used for TD-OCT, whereas continuous flushing technique is the standard for FD-OCT/OFDI. In the former method, the occlusion balloon catheter is advanced over a standard 0.014-in guidewire, followed by replacement of the guidewire to the "ImageWire". Careful manipulation is required when using the TD-OCT catheter because this imaging wire is fragile. In FD-OCT/OFDI, the monorail imaging catheter is inserted along a 0.014-in coronary guidewire. Owing to the much higher image acquisition rate of the FD-OCT/OFDI system enabling a rapid pullback of the imaging core, blood removal using a bolus injection of contrast media results in satisfactory image quality. Some operators prefer low-molecular weight dextrose or lactated Ringer’s solution to reduce the amount of contrast media for OCT imaging.
In contrast, using saline to flush the vessel is not generally recommended since QT-elongation or ventricular arrhythmia may occur during the procedure. Comparisons of different OCT systems are provided in Table 25-4.

**Artifacts**

Similar to IVUS, OCT has several inherent artifacts from its catheter configuration and nature of light (Fig. 25-11).
FIGURE 25-11 Examples of common OCT artifacts. A. The OCT image can be blurry when the flushing of the catheter is insufficient. Repeat flushing with saline is necessary to fully remove the residual bubbles or blood inside the catheter. B. With residual blood inside the vessel lumen, high-density, variably shaped structures within the lumen are observed, precluding visualization of entire vessel structures. This artifact often results from insufficient injection of flushing media. C. In the FD-OCT/OFDI system, the guidewire artifact is always observed as a point artifact with signal void behind it. In contrast, the guidewire artifact is not observed in the TD-OCT system, since the original guidewire is exchanged with the image wire. D. When assessing a lesion with a metal stent, multiple ghost images of stent struts, radially spaced at regular intervals, can be observed. These ghost images are called reverberations. Unlike with intravascular ultrasound (IVUS), this phenomenon is observed beyond metal struts but not beyond calcium, since OCT light can penetrate the calcium. E. Saturation artifacts are linear streaks of high and/or low intensities seen along the axial direction. This phenomenon occurs when a strong reflector of light, such as a guidewire or metal stent struts, backscatter at too high intensity to be accurately detected by the system. F. Seam-line or sew-up artifact appears as an axial discontinuity at the location of the transition between the first and the last A-line. This is caused by catheter motion during acquisition of a single cross-sectional image. G. Eccentric catheter position within the lumen may result in an artifact termed “sunflower” or “merry-go-round” artifact, where stent struts form a pinwheel pattern, appearing to face the imaging probe. H. Tangential signal dropout occurs when the optical beam is directed nearly parallel to the tissue surface and can resemble the OCT appearance of thin-cap fibroatheroma (TCFA). Careful interpretation is necessary so as not to misdiagnose this finding as a TCFA.
A) Bubbles or blood inside the catheter (see Fig. 25-11A).
The OCT image can be blurry when the flushing of the catheter is insufficient. Repeat flushing with saline is necessary to fully remove the residual bubbles or blood inside the catheter.

B) Blood within the lumen (see Fig. 25-11B).
With residual blood inside the vessel lumen, high-density, variably shaped structures within the lumen are observed, precluding visualization of entire vessel structures. This artifact often results from insufficient injection of flushing media. In some cases, a severe stenosis proximal to the imaging core may cause this phenomenon. It is important to ensure proper engagement of the guide catheter prior to increasing the injection speed of flushing media.

C) Guidewire artifact (see Fig. 25-11C).
In the FD-OCT/OFDI system, the guidewire is always observed as a point artifact with signal void behind it. This artifact is derived from its rapid-exchange design at the distal portion of the catheter, and is also seen in the reconstructed 3D image. In contrast, the guidewire artifact is not observed in the TD-OCT system, since the original guidewire is exchanged with the image wire.

D) Multiple reverberations (see Fig. 25-11D).
When assessing a lesion with a metal stent, multiple ghost images of stent struts, radially spaced at regular intervals, can be observed. These ghost images are called multiple reverberations. This phenomenon is caused by the multiple reflections of light between the transducer and a strong reflector. Unlike IVUS, this phenomenon is observed beyond metal struts but not beyond calcium, since OCT light can penetrate the calcium.

E) Saturation (see Fig. 25-11E).
Saturation artifacts are linear streaks of high and/or low intensities seen along the axial direction. This phenomenon occurs when a strong reflector of light, such as a guidewire or metal stent struts, backscatter at too high intensity to be accurately detected by the system.

F) Seam-line (sew-up) (see Fig. 25-11F).
Seam-line or sew-up artifact appears as an axial discontinuity at the location of the transition between the first and the last A-line. This is caused by catheter motion during acquisition of a single cross-sectional
image.

G) Sunflower (merry-go-round) (see Fig. 25-11G). Eccentric catheter position within the lumen may result in an artifact termed as “sunflower” or “merry-go-round” where stent struts form a pinwheel pattern, appearing to face the imaging probe.

H) Tangential signal dropout (see Fig. 25-11H). This occurs when the optical beam is directed nearly parallel to the tissue surface and can resemble the OCT appearance of thin-cap fibroatheroma (TCFA). Careful interpretation is necessary so as not to misdiagnose this finding as a TCFA (see below).

I) Non-uniform rotational distortion (NURD). NURD is an artifact which can be seen as a partial or whole distortion of the cross-sectional image, as occasionally seen with mechanical IVUS. This artifact results from mechanical binding of the drive cable that rotates the imaging core inside the protective sheath, and is usually observed in a tortuous artery or from kinking of the imaging catheter. To avoid this artifact, it is important to straighten the OCT catheter outside of body, or to unfasten the Y-connector to release torque.

**Image Interpretation**

In a normal coronary artery, three-layer vessel wall structures (intima, media, and adventitia) correspond to high–low–high backscattering layers by OCT image, similar to that seen with IVUS (Fig. 25-12). Owing to much higher resolution than IVUS, OCT can visualize microscopic vessel layer structures, such as IEM or EEM seen as a thin high-intensity layer, and periadventitial adipocytes as large, clear structures. In contrast, lower signal penetration of OCT than IVUS may inhibit observation of the entire vessel wall or perivascular structures (eg, branches, veins, pericardium, and myocardium).
FIGURE 25-12 **Typical cross-sectional OCT image and its interpretation.** A cross-sectional OCT image (A) with schematic diagram (B) demonstrates the classic high–low–high, 3-layered appearance. Histologic correlations with intima, media, and adventitia are also shown (C). Owing to much higher resolution than intravascular ultrasound (IVUS), OCT can visualize microscopic vessel layer structures, such as internal elastic membrane (IEM) or external elastic membrane (EEM) seen as a thin high-intensity layer, and periadventitial adipocytes as large clear structures. In contrast, lower signal penetration of OCT than IVUS may inhibit observation of the entire vessel wall or perivascular structures.

---

**Quantitative Assessment**

Quantitative assessment methods of OCT are generally similar to those for IVUS. Current OCT systems provide automatic lumen contour detection and subsequent measurements of lumen area and diameter (minimum and maximum diameters) of every cross-section immediately after image acquisition, owing to better delineation of lumen contour by blood removal and higher resolutions. On the other hand, its low signal penetration within the tissue often results in difficulty assessing plaque burden or vessel remodeling precisely. To optimize the high-quality imaging of OCT, complete blood removal and calibration of the catheter are necessary. Also, care should be taken when assessing the lesion with the TD-OCT system, since the vessel may shrink by obstructing the blood with a proximal balloon.

Unlike IVUS, either or both the IEM and EEM may be visualized in the OCT image. By employing the EEM for measurements, the definition of plaque area is the same as IVUS measurement, whereas by employing the IEM, plaque volume will be more accurate in terms of the pathologic definition of atherosclerosis.
Qualitative Assessment

A fibrous plaque (Fig. 25-13A) has high backscattering and a relatively homogeneous OCT signal, which mainly derives from collagen. Unlike ultrasound, OCT signal can penetrate a calcified plaque (Fig. 25-13B) without shadowing, thus it is defined as a well-delineated, signal-poor region with sharp borders. Kume et al demonstrated that OCT is superior to IVUS in quantifying the calcification area within a cross-sectional image as referenced to histology specimen.\(^{51}\) A lipid plaque (Fig. 25-13C) is visualized as a signal-poor region with a diffuse border by which a calcified plaque can be differentiated. Due to signal attenuation from the lipid plaque, quantitative assessment of lipid volume is usually difficult in OCT.

A thin-cap fibroatheroma (TCFA) is defined as an OCT-delineated lipid or NC with an overlying thin fibrous cap, which is thought to be one of the features of unstable plaque. E. Thrombus appears as a lobulated structure that attaches to the luminal
surface or is floating within the lumen. Red thrombus (red blood cell-rich) is typically observed as a high backscattering and high attenuation structure, whereas white thrombus (platelet-rich) is seen as a less backscattering and homogeneous mass with less attenuation. **F. Cholesterol crystals** are high backscattering, thin, and linear structures within the plaque, typically accompanied with a fibrous cap or necrotic core. **G. Intimal vasculature** can be observed as signal-poor voids that are delineated clearly and can be identified in multiple continuous frames. **H. Macrophage accumulations** are seen as signal-rich, distinct, or confluent punctate regions that exceed the intensity of background speckle noise. Since macrophages attenuate the light significantly, superficial accumulations of macrophages may be falsely interpreted as a TCFA in some cases.

A fibrous cap is visualized by OCT as a signal-rich tissue layer overlying a signal-poor region such as a lipid pool or calcium. One important aspect of OCT image interpretation is the diagnosis of vulnerable plaque. A TCFA (Fig. 25-13D) is defined as an OCT-delineated lipid or NC with an overlying thin fibrous cap, which is thought to be one of the features of unstable plaque. With respect to the thickness of a “thin-cap,” 65 μm is proposed as a cutoff from a pathological study. However, the pathological cutoffs may require some adjustments when applied to in vivo OCT images, since tissue shrinkage of 10% to 20% can occur during histopathologic processing. One OCT study reported that, in ruptured plaques, the median thinnest cap thickness was 54 μm (50-60), and that the thinnest cap thickness was <80 μm in 95% of ruptured plaques. In several studies, an additional parameter was used for the diagnosis of OCT-defined TCFA, such as distribution of lipid (or NC) of >90° or involvement of more than one quadrant of the vessel circumference. As described earlier, misdiagnosis can happen when the tangential signal dropout artifact is observed.

Thrombus (Fig. 25-13E) appears as a lobulated structure which attaches to the luminal surface or is floating within the lumen. Depending on the content of thrombus, the OCT image will appear differently. Red thrombus (red blood cell-rich) is typically observed as a high backscattering and high attenuation structure, whereas white thrombus (platelet-rich) is seen as a less backscattering and homogeneous mass with less attenuation. Minute structures such as cholesterol crystals, intimal vasculature, or macrophage accumulations can also be seen by OCT (Fig. 25-13F-H). Cholesterol crystals are high backscattering, thin, and linear structures within the plaque, typically accompanied with a fibrous cap or NC. Intimal vasculature can be observed as signal-poor voids that are delineated clearly and can be identified in
multiple continuous frames. Association of this finding with active inflammation and the vasa vasorum are currently under investigation. Macrophage accumulations are seen as signal-rich, distinct, or confluent punctate regions that exceed the intensity of background speckle noise. Since macrophages attenuate the light significantly, superficial accumulations of macrophages may be falsely interpreted as a TCFA in some cases.

Clinical OCT Applications

Preinterventional Assessment

OCT may offer unique preinterventional information regarding vulnerable plaque, culprit lesion assessment of patients with acute coronary syndrome, and the extent of calcification. Several studies have demonstrated the relation between OCT-defined TCFAs and distal embolization during intervention. Its high resolution feature often enables the operator to identify the culprit lesion of acute coronary syndrome by visualizing the ruptured plaque. Detailed assessment and quantification of calcified plaque by OCT may help determine the appropriate treatment strategy of calcified plaque, including the employment of aggressive preprocedural lesion modification with Rotablator® or cutting balloon. On the other hand, there is a possibility that device sizing based on OCT imaging tend to be smaller than IVUS-guided intervention, because the low penetration of OCT light makes the determination of true vessel size difficult in cases with large plaque burden.

Postinterventional Assessment

Higher resolution of OCT than IVUS contributes to more precise detection of coronary dissection (Fig. 25-14A), tissue protrusion (Fig. 25-14B), and ISA after stent implantation; however, its impact on clinical outcomes has yet to be determined. For example, the minor abnormal findings noted only on OCT (not detectable by IVUS) were reported to be healed or resolved without any restenosis or thrombus formation (Fig. 25-14C). Also, while the higher resolution of OCT can enhance the detection of those abnormal morphologies, interobserver variability of qualitative analysis may also increase for less experienced analysts.
FIGURE 25-14 Examples of post-interventional OCT assessment. Higher resolution and contrast of OCT than intravascular ultrasound (IVUS) contribute to more precise detection of coronary dissection (A), tissue protrusion (B), thrombus formation (C), and incomplete strut apposition after stent implantation. At long-term follow-up of drug-eluting stent (DES), multiple interstrut hollows (D) defined as multiple hollows (the maximum depth >0.5 mm) existing between and outside well-apposed stent struts, can be observed.

After stent deployment, stent strut apposition is precisely assessed by
direct measurement of the distance between the stent strut and the lumen border. Because OCT light can create a blooming artifact of the stent strut both proximally and distally, the highest intensity point within the strut image is often used as the endoluminal surface of the stent strut. The measured distance is compared with the nominal strut thickness (metal plus polymer thickness in DES) to distinguish incomplete from complete strut apposition. The latest OCT systems can also provide immediate 3-dimensional stent reconstruction in the catheterization laboratory, which potentially facilitates appropriate guidewire insertion through the jailed orifice of a side branch for further bifurcation intervention.

Quantitative OCT analysis for polymeric bioresorbable vascular scaffolds (BRS) may slightly be different from conventional analysis methods for permanent metallic stents. For example, the scaffold area is often measured by tracing the backside of struts, while the stent area of metallic devices is drawn by connecting the endoluminal surface of strut. Strut core area and flow area can also be measured since polymeric struts appear on OCT as a black-box region surrounded by bright reflecting frames without shadowing, enabling the direct measurement of the strut core area as well as the precise assessment of luminal area even behind the struts. In addition, unlike the apposition assessment of metallic struts using the distance measurement, apposition of polymeric struts can be assessed directly owing to its optical transparency. To compare these two different implantation devices, a standardized comparative methodology should be applied to avoid systematic analysis biases.

**Follow-Up Assessment**

The definition of ISA described above is also applied to the assessment of chronic stent apposition, combined with tissue coverage of the struts: (i) apposed and covered; (ii) apposed and uncovered; (iii) non-apposed (protruded) but covered; (iv) non-apposed and uncovered (Fig. 25-15). At long-term follow-up of SES, an angiographic finding named peri-stent contrast staining (PSS) has been identified as an important imaging marker of very late stent thrombosis, possibly reflecting chronic inflammatory response of the vessel wall after the implantation. Two OCT findings of PSS lesions were reported in the literature; one is ISA, and the other is multiple interstrut hollows defined as multiple hollows (the maximum depth >0.5 mm) existing
between and outside well-apposed stent struts (Fig. 25-14D). On the other hand, conflicting results were also reported in an OCT study of acute and late ISA, in which OCT-detected LISA was not significantly associated with adverse clinical outcome.

Another unique and potentially important application of OCT at follow-up is the detailed characterization of neointimal tissue after stent implantation. Unlike homogeneous neointimal proliferation typically seen after BMS implantation, neointimal tissue within DES can be heterogeneous, representing proteoglycan-rich tissue, organized thrombus, smooth muscle cells, atheroma, inflammatory cells, or fibrinoid. Particularly, advanced neoatherosclerosis of neointimal tissue observed by OCT may be predisposed to late coronary events after DES implantation. In a study investigating 50 lesions with in-stent DES restenosis, 52% of lesions had at least 1 OCT-defined in-stent TCFA and 58% had at least 1 in-stent neointimal rupture.
within median follow-up of 32.2 months. In addition, fibrous cap thickness measured by OCT negatively correlated with follow-up time ($r = -0.318$, $P = 0.024$).\textsuperscript{58}

In BRS, minute structural changes of polymeric struts over time, such as the processes of strut degradation and absorption, and their interaction with the vessel wall can readily be monitored by OCT.\textsuperscript{59}

**Other Applications**

OCT is now being utilized for the assessment of cardiac allograft vasculopathy as well. In a prospective observational study of heart transplant patients, prevalence of vulnerable plaque features (ie, TCFA, macrophages, and microchannels) and complicated coronary lesion morphologies (ie, intimal laceration, intraluminal thrombus, layered complex plaque, and plaque rupture) increased over time, suggesting the development of atherosclerosis beyond the typical concentric and fibrosing vasculopathy changes.\textsuperscript{60}

By utilizing OCT, conformational changes of arterial layers in vasospastic lesions can also be investigated in detail. An OCT study of lesions with vs without spasm suggested that medial contraction occurs even in an asymptomatic state and facilitates the formation of an intimal bump in patients with vasospastic angina.\textsuperscript{61} Luminal narrowing during spasm was associated with intimal gathering, but without alteration of intimal area.

**Safety**

The safety of TD-OCT has been reported in a multicenter retrospective registry.\textsuperscript{62} Among 468 patients undergoing OCT examination, 54.7% of examinations were performed utilizing the balloon occlusion technique, whereas 45.3% were performed with the non-occlusive flush technique with a mean contrast volume of 36.6±9.4 mL. Although minor adverse events of transient chest pain (47.6%) and electrocardiographic changes (45.5%) were frequently observed, major complications were rare. Ventricular fibrillation occurred due to balloon occlusion and/or deep guide catheter engagement in 5 cases (1.1%), air embolus in 3 cases (0.6%), and vessel dissection only in 1 case (0.2%). No coronary spasm or major adverse cardiac event was
As for FD-OCT, a single center registry of 90 patients reported no major complications in terms of death, MI, emergency revascularization, embolization, life-threatening arrhythmia, coronary dissection, prolonged and severe vessel spasm, and contrast-induced nephropathy.

Compared with IVUS, additional considerations are required specific to OCT imaging procedures. First, additional contrast media usage should be taken into account when using OCT in patients with renal dysfunction or heart failure. Second, if there is coronary dissection in the investigating artery, there is a possibility of extending the dissection when flushing contrast media during the imaging.

SPECTROSCOPY

Spectroscopy, developed within the field of analytical chemistry for identification of mixed samples or unknown molecules, has recently been adapted for tissue characterization in interventional cardiology. Analyzing the spectra induced by the interaction of electromagnetic radiation or light with tissue materials, spectroscopy enables the determination of the chemical composition of plaque substances. Several forms of photonic spectroscopy have been applied for the characterization of atherosclerotic plaques, represented by diffuse reflectance near-infrared, Raman, and fluorescence spectroscopy.

Among these newly developed optical techniques, the diffuse reflectance near-infrared spectroscopy (NIRS) is the frontrunner for invasive intracoronary imaging, for which an FDA-approved catheter-based NIRS system (Infraredx, Inc., Burlington, MA) is clinically available in the US. Since its initial experience with detecting lipid content of an atherosclerotic plaque in an experimental animal study in 1993, its usefulness to identify lipid core plaque (LCP) has been validated with human atherosclerotic plaques in autopsy specimens through blood and in vivo. NIRS provides a two-dimensional map of the vessel, called a “chemogram,” to demonstrate the lipid component in atherosclerotic plaques.

Other spectroscopic techniques are still under preclinical evaluation. Raman spectroscopy has a theoretical advantage in direct quantification of individual plaque components. Recently, a prototype of an intravascular
Raman spectroscopy catheter system and diagnostic algorithms for high wave number Raman spectra have been developed.\(^{65}\) Ongoing efforts are also directed at the application of fluorescence molecular imaging to catheter-based diagnostics by adopting intravascular near-infrared fluorescence (NIRF) techniques.

**Imaging Systems and Image Acquisition Procedure**

The commercially available NIRS system (Infraredx, Inc.) incorporates a dual-modality imaging catheter that provides simultaneous gray-scale IVUS and NIRS imaging for co-registered acquisition of structural and compositional information. NIRS-IVUS is the first clinically available hybrid intravascular imaging system, which is an area of growing attention in the field of coronary imaging. Combined data are obtained with a rapid-exchange 3.2F imaging catheter system (TVC Insight™) on which both ultrasound and NIRS probes are equipped. The catheter design and image acquisition procedure are similar to conventional IVUS systems. The imaging catheter is compatible with a 6-Fr guide catheter and can be inserted using a 0.014-in guidewire. After insertion of the catheter distally to the target lesion, catheter pullback is performed at 0.5 mm/s via an automated rotational pullback unit. Unlike other light-based imaging techniques such as OCT and angioscopy, NIRS does not require removal of blood from the imaging field.

The current NIRS system is specialized to detect lipid-rich plaque (cholesterol) that is displayed as yellow on a two-dimensional map of the vessel (called a “chemogram”) with spatial (circumferential and longitudinal) information (Fig. 25-16). A color scale from red to yellow indicates increasing algorithmic probability of a lipid component in the vessel wall. The chemogram data, laid in a halo surrounding the cross-sectional IVUS image, is readily applicable in a real-time manner on a dedicated console (TVC Composite™). A summary of the results for each 2-mm section of artery is presented as a block chemogram, which also is portrayed in the central catheter artifact of the cross-sectional IVUS image. In addition, a lipid core burden index (LCBI) is computed as the fraction of valid pixels within the scanned region that exceed a lipid probability of 0.6, multiplied by 1,000. Since the chemogram lacks depth information, precise assessment of lipid core plaque volume as well as the depth of lipid core (thickness of fibrous cap) is currently limited. However, a new algorithm to differentiate the cap
thickness of lipid core plaque using the amount of collagen signal contribution has recently been developed and is under preclinical validation.

**FIGURE 25-16** Example images of combined IVUS/NIR spectroscopy. A. The current NIRS system is specialized to detect lipid-rich plaque (cholesterol). A color scale from red to yellow indicates increasing algorithmic probability of a lipid component in the vessel wall. The color-coded data laid in a halo surrounding the cross-sectional IVUS image is readily applicable in a real-time manner. B. On a two-dimensional map of the vessel called “chemogram,” the spatial distribution of lipid is displayed with circumferential and longitudinal information. C. A summary of the results for each 2-mm section of artery is presented as a block chemogram, which is portrayed in the central catheter artifact of the cross-sectional and longitudinal IVUS images.

**Clinical NIRS Applications**

Other than research applications of NIRS-IVUS, three primary areas are being investigated for clinical applications: (i) in vivo detection and quantification of lipid-rich vulnerable plaque as well as guidance for PCI such as prediction of periprocedural distal embolization, (ii) determination of optimal stent length to avoid residual lipid-rich plaques at the treatment margins, and (iii) the risk stratification for side branch compromise during PCI based upon NIRS findings of plaques located in proximity to the side branches.
Madder et al demonstrated that target lesions of ACS patients were more frequently composed of LCP than those with stable angina (84.4% vs 52.8%, \( P = 0.004 \)). LCPs remote from the target lesion were also found more frequently in ACS patients (73.3% vs 17.6%, \( P = 0.002 \)). In another study of culprit lesions of ST-segment elevation MI, the maximal LCBI measured for each of the 4-mm longitudinal segments in the treatment zone (maxLCBI4mm) was 5.8-fold higher than in nonculprit segments within the same vessel (523 vs 90, \( P < 0.001 \)) and 87-fold higher than in autopsy segments free of large LCP by histology (523 vs 6, \( P < 0.001 \)). Based on these findings, this investigator group proposed the maxLCBI4mm=400 as a cutoff to detect the culprit segments of ST-segment elevation MI.\(^67\)

With respect to PCI applications, a substudy of the COLOR (Chemometric Observations of Lipid Core Plaque of Interest in Native Coronary Arteries) registry proposed the maxLCBI4mm=500 as a useful cutoff to stratify patients with high risk of periprocedural MI. In this study, periprocedural MI occurred in 7 of 14 patients (50%) with the maxLCBI4mm ≥500, compared with only 2 of 48 patients (4.2%) with the lower maxLCBI4mm \( (P=0.0002) \).\(^68\) This preliminary finding was further evaluated in the CANARY (Coronary Assessment by Near-infrared of Atherosclerotic Rupture-prone Yellow) study in which a moderate relationship was again demonstrated between the automated NIRS lipid parameters and periprocedural MI. In this cohort, 31 patients with a maxLCBI4mm ≥600 were further randomized to PCI with vs without distal protection. Although this small study failed to demonstrate a significant reduction of periprocedural MI with the adjunctive distal protection, the potential utility of NIRS in this application warrants further investigation.

Unlike other modalities such as OCT or VH-IVUS, NIRS offers automated lipid-rich plaque detection that can be easily interpreted, both in a cross-sectional image and in longitudinal distribution on chemogram. This feature may possibly reduce interobserver variability between experienced and less experienced interventional cardiologists. Accordingly, LCBI may be used as an objective surrogate marker for assessing the efficacy of anti-atherosclerotic drug therapeutics, such as intensive statin therapy.\(^69\) In-stent thin-cap neoatheroma as a mechanism for late DES failure may also be assessed using this technology.\(^70\)
Safety

The safety of catheter-based spectroscopy has been reported in a standalone NIRS system. The SPECTACL (SPECTroscopic Assessment of Coronary Lipid) study that examined 106 patients with the standalone NIRS catheter showed no major adverse events related to NIRS imaging. On the other hand, a relatively high rate of failure (16%) to obtain adequate data was reported in this early clinical experience. The safety and performance of the newer dual-modality NIRS–IVUS system are currently being evaluated in the SAVOIR (Simultaneous Acquisition of Intravascular Ultrasound and Near Infrared Spectroscopy Data in the Coronary Artery) study.

ACKNOWLEDGEMENT

The authors appreciate Heidi N. Bonneau, RN, MS, CCA, and Teruyoshi Kume, MD, PhD, for the review and figure preparation of this chapter.

**MULTIPLE CHOICE QUESTIONS**

1. Which of the following statements is correct in terms of intravascular ultrasound (IVUS) findings of the coronary artery?
   A. Arterial 3-layer structures (intima, media, and adventitia) generally correspond to a high–low–high echoic appearance of the arterial wall on IVUS images.
   B. The thickness of intima decreases with age.
   C. The media is clearly observed as a distinct layer, especially in atherosclerotic lesions.
   D. Plaque vulnerability can be accurately evaluated by conventional gray-scale IVUS.

2. An intravascular ultrasound (IVUS) image was obtained within a stented segment from a patient who underwent stent implantation 12 months ago. What is the area indicated in yellow?
A. Stent area
B. Neointimal hyperplasia (or thrombus) area
C. Lumen area
D. Plaque plus media area

3. In comparison of features between intravascular ultrasound (IVUS) and optical coherence tomography (OCT), all of the following statements are true, EXCEPT:
   A. OCT has higher resolution than IVUS.
   B. OCT requires blood removal whereas IVUS does not.
   C. Fibrous cap thickness can be measured by both IVUS and OCT.
   D. IVUS is more suitable for assessment of vessel remodeling than OCT.

4. In this optical coherence tomography (OCT) image, the coronary lumen is mainly occupied by which of the following?
   A. Thrombus
   B. Contrast medium
   C. Ruptured plaque material
   D. Residual blood
5. This is a representative image of combined intravascular ultrasound (IVUS)/near-infrared spectroscopy (NIRS). What does the yellow color represent in a halo surrounding the cross-sectional IVUS image?

A. Calcified plaque
B. Lipid-rich plaque
C. Stent struts
D. Neointima
E. Thrombus

ANSWERS

1. A
Interpretation of intravascular ultrasound (IVUS) images relies on the fact that arterial wall structures can be identified as separate layers. Typically, the differences in acoustic impedance of intima, media, and adventitia of coronary arteries give rise to a characteristic 3-layered (high–low–high) appearance on IVUS images (choice A). In muscular arteries such as the coronary tree, the media generally stands out as a thin dark layer since it contains much less echo-reflective material (collagen and elastin) than the neighboring intima and adventitia. However, this layered appearance may be undetectable in truly normal coronary arteries wherein the intimal thickness is below the effective resolution of IVUS. Also, with progression of atherosclerosis and/or patient age, the intima/plaque layer increases in thickness (choice B), and the media may be destroyed so that it may not appear as a distinct layer around the full circumference of the vessel (choice C). With respect to plaque vulnerability assessment, visual interpretation of conventional gray-scale IVUS images is limited in the precise detection and quantification of specific plaque components (choice D). Low echogenicity of plaque may represent its lipid content, but a similar appearance can result from other conditions, such as acoustic shadowing from microcalcifications or an adjacent region of calcification or fibrosis.

2. B
On intravascular ultrasound (IVUS) scan, metallic stent struts are visualized as bright, focal points in a circular-arrayed pattern, and the stent area measurement is performed at the leading edge of these distinct echoes (a blue line on the right panel). Neointimal hyperplasia within the stent has low echo-reflectivity at follow-up IVUS imaging, and the area is calculated as the difference between stent and lumen areas (choice B and C). Differential diagnoses include plaque prolapse, stagnant blood flow, and thrombus. Acute thrombus usually appears as a relatively echo-dense intraluminal mass often
showing a layered, lobulated, or pedunculated appearance with speckling, scintillation, clefts or microchannels, while old organized thrombus may have a darker, more homogenous ultrasound appearance, similar to that of neointimal hyperplasia. Plaque and media are located outside the stent area (choice D).

3. C

By utilizing backscattered reflections of infrared light, intravascular optical coherence tomography (OCT) systems generate real-time tomographic images similar to intravascular ultrasound (IVUS) but with significantly higher resolution (choice A). Thus, OCT is more suitable for microscopic assessment such as the thickness of a thin fibrous cap (choice C). On the other hand, this advantage is achieved at the expense of limited beam penetration within the tissue, often resulting in insufficient visualization of vessel area for the assessment of vessel remodeling (choice D). The imaging procedure of intravascular OCT is similar to that of IVUS, except that blood must be displaced by optically transparent liquid (e.g., contrast medium) while imaging, since red blood cells cause significant scattering of infrared light, leading to very large signal loss (choice B).

4. D

Unlike intravascular ultrasound (IVUS), optical coherence tomography (OCT) image acquisition mandates blood removal from the lumen, since light emitted from the imaging core is strongly scattered/absorbed by red blood cells. With residual blood inside the vessel lumen, high-density, variably-shaped structures within the lumen are observed, precluding visualization of entire vessel structures, as seen in this image (choice D). This artifact often results from insufficient injection of flushing media; therefore, operators should be careful not to interpret this artifact as real tissue structure. Contrast medium is optically transparent and is typically used to remove blood from the lumen (choice B). Thrombus, or plaque rupture complicated with thrombus accumulation, often appears as a lobulated intraluminal mass that attaches to the lacerated plaque surface or is floating within the lumen (choices A and C). Red thrombus (red blood cell-rich thrombus) is typically observed as a high backscattering and high attenuation structure, whereas white thrombus (platelet-rich thrombus) is seen as a less backscattering and
homogeneous mass with less signal attenuation.

5. B

The commercially available coronary spectroscopy system incorporates a dual-modality imaging catheter that provides simultaneous intravascular ultrasound (IVUS) and near-infrared spectroscopy (NIRS) imaging for co-registered acquisition of structural and compositional information. The current system is specifically designed for the detection of lipid-rich plaque that is exhibited yellow on a color-coded halo surrounding the cross-sectional IVUS image. The color scale from red to yellow indicates increasing algorithm probability of a lipid component of the vessel wall (choice B). At present, the ability of coronary spectroscopy to detect and differentiate various other plaque components or pathological features of plaque vulnerability remains to be determined.
INTRODUCTION

Adjunctive physiologic and intravascular imaging modalities as described in Chapters 24 and 25 enable operators to 1) direct ischemia-guided revascularization; 2) diagnose microvascular disease, coronary vasospasm, diffuse endothelial dysfunction, myocardial bridging or any combination of these entities; 3) characterize plaque morphology and severity; and 4) optimize acute and long-term percutaneous coronary intervention results. Herein we describe emerging clinical applications of in vivo physiologic and imaging modalities in the settings of stable ischemic heart disease, symptomatic myocardial ischemia without obstructive epicardial atherosclerosis, and acute coronary syndromes.

STABLE ISCHEMIC HEART DISEASE

Physiologic Evaluation of Intermediate Stenoses
As discussed in Chapter 24, fractional flow reserve (FFR) can accurately assess the hemodynamic significance of intermediate coronary lesions (40%-80% diameter stenosis) and guide coronary revascularization in patients with single vessel, multi-vessel, and left main disease. Physiologic assessment can also help simplify and determine the overall interventional approach for complex bifurcation lesions by converting them into a predominantly single lesion. In addition, FFR can be used to assess the need for intervention of jailed side-branches.

Considered the gold standard for invasive physiologic assessment, FFR has been preferred over other coronary indices such as hyperemic stenosis resistance (HSR), coronary flow reserve (CFR) and the instantaneous wave-free ratio (iFR) because it has a normal reference value of 1.00, is reproducible and relatively easy to perform, and has robust literature supporting its use for safely deferring and guiding revascularization.\(^1\)-\(^4\) While HSR may be even more accurate in predicting the hemodynamic significance of an epicardial lesion, it requires both pressure and flow sensors for measurement and currently does not have substantial data supporting its clinical use.\(^5\),\(^6\)

In patients with contraindications to adenosine use, non-hyperemic indices such as whole cycle distal pressure to aortic pressure ratio (Pd/Pa) or iFR may be preferable for intermediate lesion assessment. Although predictive of FFR with a diagnostic accuracy of 75% to 85%, Pd/Pa has a narrower gradient window and smaller signal-to-noise ratio, resulting in less robustness for ischemia prediction. For example, a pressure wire drift of ±2 mm Hg resulted in 31% of misclassified study lesions using Pd/Pa, compared to 21% for FFR (\(P < 0.001\)).\(^7\)

Another non-hyperemic index, iFR measures the difference between distal and aortic coronary pressure during a specific mid to late diastolic period of the cardiac cycle, known as the wave-free period, when the resting resistance is relatively constant and low. Several studies have suggested that iFR has a diagnostic accuracy of 75% to 85% for identifying a hemodynamically significant FFR.\(^8\)-\(^11\) The VERIFY study, however, reported a weaker correlation between iFR and FFR and recommended against its use for clinical decision making.\(^12\) Due to the variability of reported correlations between FFR, iFR, and Pd/Pa, the RESOLVE study was undertaken with analysis in a core laboratory to help settle questions surrounding the
diagnostic accuracy of iFR and Pd/Pa compared to FFR. In this retrospective multi-center study, an optimal iFR cut point of 0.90 and Pd/Pa cut point of 0.92 demonstrated overall accuracies of 80.4% and 81.5%, respectively, when compared with FFR.\textsuperscript{13} The ADVISE II study, a prospective multicenter trial, also observed similar diagnostic accuracies for an iFR cut point of 0.89 and Pd/Pa cut point of 0.91 (82.5% vs 83.2%).\textsuperscript{14,15} The role of iFR was recently clarified following the results of two studies: DEFINE-FLAIR (Functional Lesion Assessment of Intermediate Stenosis to Guide Revascularisation)\textsuperscript{16} and iFR-Swedeheart (Instantaneous Wave-free Ratio versus Fractional Flow Reserve to Guide PCI).\textsuperscript{17} Both studies prospectively compared intermediate lesion assessment between FFR- and iFR-guided percutaneous coronary intervention. Two thousand four hundred patients were enrolled in the DEFINE-FLAIR trial and the primary endpoint was the 1-year risk of major adverse cardiac events which were a composite of death from any cause, nonfatal myocardial infarction, or unplanned revascularization. At 1-year, the primary end point occurred in 6.8% in the iFR group and 7.0% in the FFR group (difference in risk, −0.2 percentage points; 95% confidence interval [CI], −2.3 to 1.8; \( p<0.001 \) for noninferiority; hazard ratio, 0.95; 95% CI, 0.68 to 1.33; \( p=0.78 \)) indicating for the first time that iFR guided revascularization is non-inferior to FFR-guided revascularization. This finding was further illustrated with the iFR-Swedeheart where 2037 patients with stable angina or acute coronary syndrome were randomized to undergo revascularization guided by either iFR or FFR. The primary end point was the rate of a composite of death from any cause, nonfatal myocardial infarction, or unplanned revascularization within 1-year after the procedure. The primary endpoint in the iFR group occurred in 6.7% vs. 6.1% in the FFR group. Following completion of these randomized trials, it became evident that iFR is a promising non-hyperemic index and the technology appears to be quicker and as safe as the established FFR.

**Intravascular Imaging for Intermediate Stenoses**

The pressure gradient across a stenosis depends on the reference vessel area, stenosis area and length, blood flow velocity and viscosity, entrance effects, and flow separation (Fig. 26-1).\textsuperscript{3} One might thus expect an imperfect correlation between stenosis geometry and FFR.\textsuperscript{18-22} Therefore, it is now
accepted that physiologic evaluation is more reliable than anatomic evaluation for assessing intermediate lesion severity. Nevertheless, we discuss below the evidence derived from anatomic lesion assessment.

**FIGURE 26-1 Factors producing resistance to coronary blood flow.** The angiographic 2-dimensional images cannot account for the multiple factors that produce resistance to coronary blood flow and loss of pressure across a stenosis. The eccentric and irregular stenosis (upper panel) shows arrows designating entrance effects, friction, and zones of turbulence accounting for separation energy loss. The calculation of pressure loss ($\delta P$) across a stenosis (lower right panel) incorporates length ($l$), areas stenosis ($A_s$), reference area ($A_n$), flow ($Q$), and coefficients of viscous friction and laminar separation ($f_1$ and $f_2$) as contributors to resistance and hence pressure loss. (Reproduced from Kern MJ, Samady H. Current Concepts of Integrated Coronary Physiology in the Catheterization Laboratory. *J Am Coll Cardiol.* 2010;55(3):173-185. Copyright © 2010, with permission from American College of Cardiology Foundation.)

**Non-Left Main Lesions**
In a study of 167 patients with intermediate lesions randomized to undergo PCI based on cutoff values of FFR 0.80 or intravascular ultrasound (IVUS)-derived minimum lumen area (MLA) 4.0 mm$^2$, neither cohort had increased incidence of major adverse cardiac events, but the IVUS group underwent significantly more revascularization procedures. While studies suggest that an IVUS-MLA ≥4.0 mm$^2$ can accurately identify non-ischemic lesions for which PCI can be safely deferred, further investigations have supported the importance of considering additional vessel information beyond MLA. A meta-analysis of 11 clinical trials demonstrated that the mean MLA of non-left main lesions was 2.6 mm$^2$, with a pooled sensitivity of 0.79 and specificity of 0.65. Use of IVUS-MLA was observed to misclassify up to 20% of coronary lesions. Given the aforementioned discordances, physiologic evaluation remains superior to anatomic assessment with imaging for intermediate coronary lesions. Anatomic measurements with optical coherence tomography (OCT) imaging are smaller than those with IVUS and correlate better with true anatomic representations from phantom measurements.

**Bifurcation Lesions**

Coronary bifurcations are challenging lesion subsets accounting for 20% of interventional procedures. Pre-intervention intravascular imaging can help select the optimal bifurcation PCI strategy by visualizing the spatial distribution of the mother and daughter vessels as well as identifying carina shifts as a mechanism for side branch compromise. Koo et al have demonstrated that jailed side branches with <75% diameter stenosis are almost never hemodynamically significant and therefore often do not need further assessment or treatment. Similarly, provisional side branch PCI can usually be deferred if the pre-intervention side branch IVUS-MLA is ≥2.4 mm$^2$.

**Left Main Lesions**

In addition to difficulty in accurate angiographic assessment as demonstrated by substantial interobserver variability, decision making regarding the hemodynamic significance of left main lesions are often more critical.
Therefore, adjunctive imaging and physiology modalities have emerged as highly useful tools allowing operators to more confidently and accurately evaluate lesions and direct revascularization. Initial studies suggested that left main MLA <7.5 mm² was hemodynamically significant. A subsequent study observed that left main FFR cut point of 0.75 correlated with IVUS-MLA cut point of 5.9 mm². More recent data suggest that an IVUS MLA ≤4.5 mm² in the left main artery of Asian patients may correspond to an FFR value of ≤0.80, and that ruptured left main plaque and plaque burden also correlate with FFR. An observational outcomes study found that using an IVUS-MLA cut point of 6 mm² to direct or defer revascularization was safe.

Most of the support for the use of IVUS and FFR in left main disease has been derived from small trials and observational studies, so there remain several unanswered questions regarding optimal ischemic cut-off values and long-term safety, efficacy and cost-effectiveness. Nevertheless, even for intermediate left main lesions, FFR is considered the gold standard and can be used to guide decision making with regard to the need for revascularization. Importantly, the FFR of left main artery has to be taken in the context of tandem daughter vessel disease (see Chapter 25). Randomized clinical trials directed toward invasive physiologic and anatomic assessment for left main disease are warranted. In the interim, it may be appropriate to start with FFR for angiographically indeterminate left main lesions. If the FFR value is greater than 0.80, then PCI should be deferred, while if it is less than 0.75, the lesion should be revascularized. If the FFR value falls in the grey zone between 0.75 and 0.80, IVUS or other noninvasive functional testing may be helpful (Fig. 26-2).
Physiologic and intravascular ultrasound assessment of left main lesions. In this algorithm of left main assessment, we recommend performing fractional flow reserve (FFR) for indeterminate left main lesions. If the FFR value is greater than 0.80, then PCI should be deferred while if it is less than 0.75 the lesion should be revascularized. If the FFR value falls between 0.75 and 0.80, intravascular ultrasound (IVUS) or other non-invasive functional testing may be helpful. In particular, we recommend revascularization for an IVUS minimum luminal area (MLA) of <4.5 mm² and deferring if the MLA is >6.0 mm². For those lesions that fall in the grey zone of IVUS MLA 4.5 to 6.0 mm², the clinical context should be considered with respect to revascularization or further non-invasive testing.

MYOCARDIAL ISCHEMIA IN THE ABSENCE OF OBSTRUCTIVE EPICARDIAL CORONARY ARTERY DISEASE

Patients with anginal syndromes in the absence of significant epicardial disease (<40% diameter stenosis by visual assessment with angiography)
likely have myocardial ischemia derived from coronary microvascular disease, vasospasm and/or endothelial dysfunction, or from structural abnormalities such as myocardial bridging, coronary aneurysms, or coronary artery anomalies. Patients with non-obstructive atherosclerosis have longterm outcomes similar to those with obstructive coronary artery disease; anginal symptoms in these patients have been associated with increased mortality, higher frequency of emergency room visits and hospitalizations, increased costs, and worse quality of life when compared to normal subjects.\textsuperscript{33,34} Obtaining a definitive diagnosis in such patients can guide targeted intensified lifestyle modification counseling and medical treatment.\textsuperscript{35} Figure 26-3 outlines a diagnostic approach in the cardiac catheterization laboratory.

\textbf{FIGURE 26-3} Testing algorithm for patients with mild stenoses. For patients presenting with angina but no flow limiting coronary lesions, we recommend coronary reactivity testing, first with acetylcholine and then with adenosine. Normal coronary arteries vasodilate in response to acetylcholine. Therefore, observations of vasoconstriction in combination with symptoms or electrocardiogram (ECG) changes are highly suggestive of endothelial dysfunction and vasospastic disease. Additionally, patients with coronary flow velocity reserve <2.5 are considered to have microvascular disease. If this occurs without notable findings in response to acetylcholine, then the patient has endothelium-independent microvascular dysfunction. On the other hand, if it occurs with vasoconstriction to acetylcholine, then the patient is considered to have both endothelial and microvascular dysfunction. Abbreviations: CFR, coronary flow reserve; FFR, fractional flow reserve. (Based on
Endothelium-independent microvascular assessment is performed with adenosine to induce hyperemia through smooth muscle cell relaxation and microcirculatory vasodilatation. Several indices have been developed to evaluate microvascular function in patients with and without epicardial disease. One established index is CFR, which reflects the combined ability of the epicardial artery and the microcirculation to achieve maximal blood flow in response to stress. In the absence of significant epicardial disease (FFR >0.80), CFR may be used as an index of predominantly microvascular disease, with a CFR <2.0 suggestive of coronary microvascular disease.

There are other indices that have been developed in recent years to assess microvascular function in patients with or without epicardial lesions. The index of microcirculatory resistance (IMR) can be assessed using a pressure wire and reproducibly measures microvascular function in patients with or without epicardial stenosis; although there are no established cut-off values for IMR, it is emerging as a very practical invasive tool for microvascular testing. Hyperemic microcirculatory resistance (HMR) is also an attractive index that can measure microvascular function independently of epicardial stenosis, but it relies on a combination of pressure and Doppler velocity wire that requires some technical expertise and does not account for collateral reserve. Microvascular assessments with IMR or HMR are primarily utilized in research cases only.

Endothelial dysfunction is a common cause of microvascular disease and angina in patients with no significant coronary atherosclerotic lesions. Endothelial function testing requires pharmacological interrogation of the endothelium using intracoronary acetylcholine (off-label use) and thus is generally performed in specialized centers or in research protocols. The healthy endothelium in the presence of acetylcholine induces vasodilatation through stimulation of nitric oxide and cyclic guanosine monophosphate. In patients with endothelial dysfunction, acetylcholine paradoxically fails to cause vasodilatation and may even result in vasoconstriction through interaction on muscarinic receptors of arterial smooth muscle cells. Endothelial dysfunction is therefore characterized by the vessel response to intracoronary acetylcholine: epicardial if there is no change or a decrease in
diameter as visualized by angiography; and microvascular if there is no change or a decrease in coronary blood flow as determined by angiography in combination with a Doppler velocity wire.\textsuperscript{37,38}

During acetylcholine administration, vasospasm is identified by reproduction of symptoms or ischemic electrocardiogram changes and classified as epicardial or microvascular depending on the degree of coronary artery diameter reduction in response to acetylcholine. Patients with severe vasospasm may demonstrate complete obliteration of the coronary artery that can be quickly reversed with nitroglycerin.

\textbf{Myocardial Bridging}

While only a minority of myocardial bridges will cause myocardial ischemia, identification of those with hemodynamic relevance is of paramount importance in the diagnosis and management of symptomatic patients.\textsuperscript{36,39} Angiography likely underestimates the prevalence of myocardial bridges given its lower detection rate (0.5%-16.0%) compared to autopsy (40%-80%).\textsuperscript{36} Angiographic manifestations of myocardial bridges include the characteristic step down/step up “U” sign on lateral projections and “coronary milking,” a periodic decrease in luminal dimensions that can be amplified with administration of intracoronary nitroglycerine. Compared to angiography, IVUS is more sensitive in detecting myocardial bridges and can more accurately assess lumen dimensions of the intramyocardial segment.\textsuperscript{40-43} IVUS frequently reveals a hypoechoic “half-moon” image adjacent to the arterial wall within the tunneled segment and has been instrumental in demonstrating the prolongation of luminal obliteration in myocardial bridging during the early- and mid-systolic phase of the cardiac cycle.

Similar to fixed coronary stenoses, the angiographic severity of myocardial bridge does not correlate well with its functional relevance. On the other hand, the physiology of myocardial bridging is significantly different and more complex compared to that of fixed stenoses. During systole, myocardial compression results in highly resistive microcirculation and markedly higher intracoronary pressure, which is observed as a negative pressure gradient across the myocardial bridge where distal pressure is higher than aortic pressure.\textsuperscript{44} Although myocardial bridges exert extravascular coronary compression primarily during systole, this compression also extends
into diastole resulting in compromised luminal area and blood flow with
positive pressure gradients during the early- and mid-diastolic phases.\textsuperscript{36,44,45} Since conventional FFR calculation is based on time-averaged pressures, the
negative systolic pressure gradients will invariably affect the detection of the
positive diastolic ones if only mean pressures are used.

As a myocardial bridge is a dynamic stenosis that depends on the
contractile status of the myocardium and the length of diastole, the
hemodynamic consequences of myocardial bridging may only get expressed
under stress during increased inotropy and tachycardia, which shortens the
diastolic period. Therefore, the hemodynamic significance of a myocardial
bridge with FFR should include a dobutamine challenge, which increases
coronary blood flow and ionotropy but does not modify epicardial vessel or
stenotic dimensions.\textsuperscript{44,46} Still, when using conventional FFR, a negative
result even after dobutamine challenge does not preclude the possibility of a
false negative, and should be interpreted with caution.

In myocardial bridging, this problem can be circumvented by using
diastolic FFR with an optimal cutoff value of 0.76.\textsuperscript{44,47} The restriction of
measurements to diastole not only avoids the influence of negative systolic
gradients on overall pressure measurements, but also allows identification
and quantification of the effect of the myocardial bridge on the diastolic
coronary blood flow.

Intracoronary Doppler has been used to evaluate vessels with myocardial
bridging.\textsuperscript{41,42,48,49} Flow velocity immediately proximal to the myocardial
bridge shows systolic flow reversal, resulting from epicardial blood being
squeezed from the compressed coronary segment.\textsuperscript{40} Characteristic abrupt
eyearly diastolic flow acceleration has been documented within the myocardial
bridge segment in Doppler tracings, reflecting the decreased luminal
dimensions caused by the myocardial bridge at that stage of the cardiac
cycle.\textsuperscript{49} Additionally, the velocity waveform within myocardial bridge shows
a characteristic “fingertip” spike pattern, which denotes a higher flow
velocity during early-mid diastole resulting from decreased luminal
dimensions during extravascular vessel compression.\textsuperscript{36,45} CFR has been
observed to be decreased as a consequence of the hemodynamic effect of the
myocardial bridge.
ACUTE CORONARY SYNDROMES

Intravascular imaging has been increasingly used in the management of patients presenting with acute coronary syndromes (ACS). Both IVUS and OCT can help the operator identify the location and morphology of the culprit lesion, appropriately select the stent size and optimize stent deployment. Furthermore, innovations in hybrid intravascular imaging and multi-modality fusion may facilitate precise morphologic visualization and phenotypic characterization of culprit lesions. These advances enable decision-making strategies during PCI which potentially reduce rates of late cardiovascular events such as myocardial infarction related to clinical restenosis or stent thrombosis.

Assessing Pathogenesis of the Culprit Lesion

Intravascular imaging has allowed in vivo evaluation of ruptured thin cap fibroatheromas and plaque erosions, which are the most common precursors of coronary occlusions resulting in fatal acute myocardial infarctions. For anatomic assessment, intravascular OCT with its superior spatial resolution (10 vs 100 microns for IVUS) allows accurate measurement of the fibrous cap thickness. In contrast, OCT’s lower image penetration depth (1-3 vs 4-8 mm for IVUS) limits its ability to reliably evaluate the entire plaque/media area and vessel remodeling. Clinical OCT observations demonstrate that 50% of culprit lesions in STEMI patients are due to plaque rupture and 25% to plaque erosions (Fig. 26-4).
Culprit plaque phenotype underlying coronary thrombosis stratified by sex. Optical coherence tomography (OCT) can highlight the different etiologies for the presentation of acute coronary syndrome. In the Optical Coherence Tomography Assessment of Gender Diversity in Primary Angioplasty (OCTAVIA) trial of 140 age-matched men and women undergoing percutaneous coronary intervention (PCI) for ST-Elevation myocardial infarction (STEMI), there was no significant difference in culprit plaque morphology between men and women. About 50% were plaque rupture, 25% plaque erosion and 25% unclassifiable. A total of 2 spontaneous dissection cases were observed in this study. (Reproduced from Guagliumi G, et al. Mechanisms of Atherothrombosis and Vascular Response to Primary Percutaneous Coronary Intervention in Women Versus Men With Acute Myocardial Infarction Results of the OCTAVIA Study. JACC: Cardiovascular Interventions. 2014;7(9):958-968. Copyright © 2014, with permission from American College of Cardiology Foundation.)

Several clinical applications of intravascular imaging have emerged to better identify high-risk atherosclerotic plaques. Advancements in IVUS technology to improve plaque morphological characterization include virtual histology IVUS, which uses radiofrequency backscatter analysis, and near-infrared spectroscopy, which estimates the lipid content through a lipid core burden index. An interesting advancement in OCT technology is the hybridization of OCT with near-infrared autofluorescence, which allows high resolution plaque morphologic visualization with accurate phenotypic characterization.

The quest for modalities with spatial resolution sufficient for cell level visualization has introduced micro-OCT, which uses ultra-broadband light
sources and common-path spectral-domain OCT to achieve an axial resolution of less than 1 micron. Micro-OCT can visualize the cellular and subcellular features of the coronary artery wall associated with atherogenesis and thrombosis as well as responses to interventional therapy, suggesting that it can complement existing diagnostic techniques for investigating progressive atherosclerotic lesions.

**Spontaneous Coronary Artery Dissection**

Spontaneous coronary artery dissection (SCAD) is an uncommon ACS presentation, with a reported prevalence of approximately 0.3% in patients undergoing angiography for the first time. Angiography can detect SCAD; however, when angiography is inconclusive, OCT can enhance the diagnostic accuracy by visualizing a double-lumen or an intramural hematoma, identifying the rupture site and measuring the extent of thrombi, true and false lumens. A potential concern when performing OCT in patients suspected with SCAD is the propagation of the dissection through contrast injection. Nevertheless, an algorithm has been proposed (Fig. 26-5) to utilizing intravascular imaging in identifying and managing SCAD.

FIGURE 26-5 SCAD Algorithm with the roles of IVUS and OCT. In patients with suspected spontaneous coronary artery dissection (SCAD), intravascular imaging such as optical coherence tomography (OCT) or intravascular ultrasound (IVUS) can help enhance the diagnosis accuracy. Depending on the clinical setting, a conservative approach of medical management and watchful waiting with possible imaging follow up has been shown to have excellent clinical and angiographic outcome. For those with acute, ongoing or recurrent ischemia, revascularization is indicated to restore the coronary blood flow and reduce infarct size. There are 3 options: 1) conservative stenting to cover only the entry door and segments showing severe lumen compromise, which may result in residual distal dissection, 2) aggressive stenting that may result in a “full metal jacket” due to propagation of an intramural hematoma, or 3) coronary artery bypass grafting for unstable patients with left main involvement or multiple severe and long dissections. Abbreviations: CABG, coronary artery bypass
STENT DEPLOYMENT AND OPTIMIZATION STRATEGIES

Physiologic evaluation can help the operator determine which coronary lesion to intervene upon. As mentioned previously, both FFR and iFR can guide PCI decision making in intermediate stenoses. In critical angiographic stenosis (>90% diameter stenosis by visual assessment), particularly in a symptomatic patient with evidence of myocardial ischemia, further intravascular physiologic testing is not required to decide on hemodynamic lesion severity. On the other hand, both FFR and iFR have been proposed to help perform spot stenting in patients with tandem lesions or diffuse severe disease. Whether physiologically guided spot stenting or anatomically guided “normal to normal” stenting results in superior outcomes has not been prospectively investigated.

In addition to physiology, IVUS and OCT can help guide and optimize PCI. Intravascular imaging co-registered with angiography can accurately measure required stent diameter and length, inform the decision of how aggressively to prepare the lesion prior to stenting, and direct poststent optimization with noncompliant balloon dilatation or adjunctive stenting. Intravascular OCT may be particularly helpful for selecting debulking strategies toward optimal stent expansion in patients with calcified coronary lesions. At the time of stent implantation, intravascular imaging can identify stent underexpansion, edge dissections, strut malapposition, tissue prolapse and incomplete lesion coverage.60,61

**Bifurcation and Left Main PCI**

Intravascular imaging can assist during bifurcation PCI by: 1) estimating the degree of carina shift and daughter-vessel pinching after main branch stenting; 2) assessing the neocarina when 2-stent techniques are implemented
such as culotte or crush stenting; and 3) selecting the most distal stent cell to postdilate when optimization techniques are needed after stent deployment. In a propensity-matched analysis of patients undergoing PCI of non-left main bifurcations with drug-eluting stents, the IVUS-guided PCI strategy was associated with larger poststent lumen diameters as well as lower rates of death or myocardial infarction compared to the angiography-guided PCI strategy.\textsuperscript{26,62}

OCT excels at identifying which strut to rewire when reaccessing bifurcation side branches.\textsuperscript{63} This is particularly true with bioresorbable scaffolds, where OCT is superior to IVUS in detecting polymer-based struts. Bioresorbable scaffolds due to their larger strut size, are associated with a higher incidence of postprocedural side branch obstruction. This was recently demonstrated in the ABSORB—Extend trial where BVS-treated vessels demonstrated a higher incidence of postprocedural side branch obstruction compared with Xience V-treated vessels in small side branches with reference vessel diameters ≤0.5 mm (10.5% vs 3.9%, \(P = 0.03\)).\textsuperscript{64,65}

In unprotected left main coronary artery PCI, the adverse consequences related to suboptimal stent deployment are more dramatic and thus increase the utility of IVUS-guided PCI. During lesion preparation, IVUS can highlight the degree of calcification as well as the distribution, burden, and composition of atherosclerotic plaque within the left main and at the branch areas. Several observational studies have reported a wide range of clinical benefit of IVUS-guided PCI in unprotected left main disease.\textsuperscript{32,66-68} In particular, a post-hoc analysis of the multicenter MAIN-COMPARE registry, patients undergoing IVUS-guided unprotected left main PCI suggested a trend toward lower 3-year mortality compared to those undergoing angiography-guided PCI.\textsuperscript{67} Although OCT is not usually used to guide left main PCI, limited data suggest that it is comparable to IVUS in assessing and guiding left main PCI with respect to 1-year clinical event rates.\textsuperscript{69}

**Post-PCI Impairment of the Microvasculature**

There has been significant concern about the microcirculatory functional status after PCI in acute myocardial infarction patients because microvascular dysfunctions can occur in up to half of these patients and are associated with adverse ventricular remodeling and poorer patient prognosis.\textsuperscript{70} Impaired
microvascular function can include microvascular obstruction, myocardial compression, or hemorrhage. On angiography, microvascular obstruction can be observed as reduced or no-reflow and can be semiquantitated using the TIMI flow and/or blush grade.

While there is currently no consensus on the best way to detect and quantify microvascular dysfunction after PCI, IMR might provide more accurate measurements of the impairment and, thus, better prognostication. Defined as distal coronary pressure multiplied by the hyperemic mean transit time, IMR is measured using the thermodilution technique with a pressure sensor/thermistor-tipped wire. Several small studies have suggested that higher IMR values are associated with more microvascular obstruction. In 29 patients undergoing primary PCI for STEMI, IMR value >32 U was a predictor of acute and 3-month followup microvascular damage after STEMI. Another study of 50 patients undergoing elective PCI demonstrated that pre-PCI IMR values ≥27 U compared to lower values were associated with higher risk of developing periprocedural MI (HR 22.7, 95% CI 3.9-133.9). It has also been observed in patients undergoing PCI for STEMI that IMR values >36 U compared to lower IMR values were associated with higher rates of microvascular obstruction (93% vs 39%, \( P = 0.001 \)). Other physiologic indices such as zero-flow pressure and HMR measured at the time of primary PCI have been suggested to be superior to IMR for predicting the extent of myocardial infarction and warrant further investigation.

**Stent Underexpansion**

Several standardized criteria have been proposed to define stent underexpansion. These include the Multicenter Ultrasound Stenting in Coronaries (MUSIC) criteria and the more aggressive AVIO criteria (Table 26-1). The recent ADAPT-DES, a prospective non-randomized study of 8,583 patients undergoing PCI, found that IVUS caused the operator to alter the PCI strategy in 74% of cases, either by choosing a larger or longer stent, using higher balloon inflation pressures, performing additional post-stent dilatation, or implanting an additional stent. At 1-year follow up, the IVUS-guided cohort experienced lower rates of myocardial infarction (adjusted HR 0.66; 95% CI 0.49-0.88; \( P = 0.004 \)), definite or probable stent thrombosis.
(adjusted HR 0.40; 95% CI 0.29-0.73; \( P = 0.003 \)), and major adverse cardiovascular events (adjusted HR 0.70; 95% CI 0.55-0.88; \( P = 0.002 \)). Several studies have now suggested significant benefit of IVUS-guided PCI compared to angiography alone in patients presenting with complex target lesions.\(^{60,81-83} \)

2. Proximal in-stent segment  
3. In-stent of maximal narrowing |
| Symmetrical stent expansion defined by minimum lumen diameter divided by maximum lumen diameter \( \geq 0.7 \) |  |

Compared to IVUS-guided PCI, OCT guidance result in smaller lumen dimensional measurements, leading to smaller stent sizing and less lumen gain.\(^{84} \) The ILUMIEN studies have shed additional information on the use of OCT in stent optimization. ILUMIEN-1 was a prospective multicenter observational study to determine which OCT parameters were most useful for improving near-term clinical outcomes.\(^{85} \) Of the 418 patients enrolled in this study, 65 patients (16%) underwent both OCT-guided pre-PCI lesion assessment and post-PCI optimization and had significantly reduced rates of myocardial infarction at 1-year followup compared to those without OCT guidance (0% vs 12%, \( P = 0.03 \)). Interestingly, the post-PCI MLA was significantly smaller in those procedures guided by OCT compared to those with angiographic guidance without pre- or post-OCT guidance (5 ± 2 vs 6 ± 3 mm\(^2\), \( P = 0.004 \)). This conundrum spurred the design of ILUMIEN-2, a post-hoc study of ILUMIEN-1 and ADAPT-DES, comparing the relative degree of stent expansion from OCT- and IVUS-guided PCI.\(^ {86} \) This analysis determined that there were no major differences between OCT and IVUS
with respect to post-PCI stent expansion (73% vs 71%, $P = 0.84$), in-stent MLD (2.5 vs 2.6 mm, $P = 0.78$), in-stent acute gain (1.6 vs 1.6 mm, $P = 0.60$). The ILUMIEN-3, a prospective randomized clinical trial (NCT02471586) which was completed in 2016 and is pending analysis and publication, randomizes patients undergoing PCI to 1 of 3 arms: 1) OCT pre- and post-PCI guidance, 2) IVUS pre- and post-PCI guidance, or 3) angiography guidance. Patients in all arms will undergo post-PCI OCT to allow blinded core lab comparison of OCT measurements of the post-PCI minimal stent areas achieved from angiography-, IVUS-, or OCT-guided PCI.

**Strut Malapposition**

Malapposition, also known as incomplete stent apposition, occurs when there is no contact between the stent struts and the lumen wall. The extent of strut malapposition can be measured as the distance between the strut and the vessel wall, taking into account strut thickness and intravascular imaging resolution limits. Malapposition can occur acutely after stent deployment or develop over time from positive arterial remodeling or thrombus resolution, and are categorized accordingly. Acute malapposition is detected immediately after stent implantation and attributed to suboptimal stent implantation. Late–persistent malapposition is an acute stent malapposition that remains malapposed at follow-up evaluation, and late–acquired malapposition is malapposition identified at follow-up assessment despite complete strut apposition during the initial procedure. ILUMIEN II demonstrated that, compared to IVUS, OCT post-PCI imaging detected more malapposition of any type (14% vs 27%, $P = 0.0002$) but comparable major malapposition with a >20% distance-to-lumen ratio (0.7% vs 1.4%, $P = 0.69$). Clinically, it is debatable how malapposition affects future healing and long-term outcomes, as there have been several conflicting studies on the relationship between acute or late malapposition and the rates of stent thrombosis. Regardless of this uncertainty, most operators strive to achieve full apposition of all stent struts after stent deployment, thereby minimizing acute and late-persistent malapposition.

**Tissue Prolapse**
Tissue prolapse occurs after stent implantation where the tissue of the arterial wall and plaque protrudes between the stent struts. In postmortem and OCT studies, the observed rates of tissue prolapse immediately after stent implantation was 94% to 97%. Most cases of tissue prolapse detected immediately after PCI were found to have resolved during the study follow-up periods and do not appear to significantly impact clinical outcomes. However, large natural history studies of tissue prolapse are not available and are warranted.

**Edge Dissections**

A classification system for intimal tears was proposed by the Coronary Angioplasty Registry to help manage dissections observed after balloon angioplasty. This angiographically-based system has evolved into the National Heart, Lung, and Blood Institute (NHLBI) grading system for coronary dissections. Minor tears are categorized as type A or B dissections and are considered to be clinically benign. Higher-grade intimal tears include types C-F dissections, which have been associated with greater rates of acute closure or stent thrombosis early after PCI. With the improved resolution of intravascular imaging, higher incidences of edge dissections have been reported; however, most of these fall into the lower grade edge dissection categories have thus far have not been associated with higher rates of adverse events. The CLI-OPCI II Study evaluated 1,002 lesions in 832 patients by OCT, which showed suboptimal stent implantation in 31% of these lesions. On regression analysis, dissection >200 microns at the distal stent edge was associated with increased adverse cardiac events (HR 2.54, \( P = 0.004 \)) but not those at the proximal edge (HR: 0.83, \( P = 0.65 \)). While high-grade edge dissections continue to be intervened upon, there is no consensus on the optimal management of low grade and angiographically silent edge dissections, so it remains to be seen whether edge dissections that are observed only on intravascular imaging are clinically relevant.

**Stent Failure**

**In-Stent Restenosis**
Smaller minimal stent area is commonly associated with target vessel failure at follow-up, and larger post-PCI areas consistently predict lower rates of restenosis. Smaller minimal stent areas may represent stent underexpansion, which can be detected on IVUS or OCT and treated with appropriate post dilatation. Additionally, intravascular imaging can assist in the differentiation of restenosis related predominantly to intimal hyperplasia versus mechanical complications such as stent fracture or stent underexpansion, which can help the operator determine which approach to take to treat the in-stent restenosis.

**Stent Thrombosis**

Smaller stent areas have consistently been associated with higher rates of stent thrombosis, implicating stent underexpansion in the pathogenesis of both early and late stent thrombosis. Stent underexpansion and malapposition with uncovered struts are hypothesized to be more likely to incite thrombosis within the stent. IVUS studies have agreed with autopsy studies linking in-stent thrombosis with uncovered malapposed struts, while OCT has demonstrated that patients presenting with unstable angina are more likely to have stents with uncovered struts than those with stable angina. Clinically, intravascular imaging-guided PCI may reduce rates of stent thrombosis by identifying and managing suboptimal stent deployment.

**Neoatherosclerosis**

Within implanted stents, atherosclerotic changes of neointimal tissue has been hypothesized to contribute to late in-stent restenosis and stent thrombosis. In the SIRTAX-LATE OCT study, in-stent neoatherosclerosis was assessed by OCT 5 years after the initial PCI procedure with either sirolimus- or paclitaxel-eluting stents (SIRTAX trial conducted in 2003-2004). Defined as the presence of fibroatheroma or fibrocalcific plaque within the neointima of stented segments on OCT, neoatherosclerosis was identified in 16% of follow-up lesions and determined to be more common among patients with angiographic and clinical evidence of native atherosclerosis progression. OCT may therefore be a useful adjunctive tool in
distinguishing between in-stent restenosis and neoatherosclerosis.

**Stent Fracture**

Fracturing of metallic stents is relatively uncommon with a reported rate of about 4%;\textsuperscript{113} however, there are heightened concerns about stent fractures in the bioresorbable scaffolds.\textsuperscript{114} Because visualization of the stent on fluoroscopy can be limited and variable, the use of intravascular imaging increases the rate of stent fracture detection and provides additional information such as neointimal tissue formation, vascular remodeling, or strut characteristics that may help deduce the mechanism of stent fracture. Traditionally, IVUS has been used to evaluate suspected stent fracture cases; however, with the novel bioresorbable scaffolds, OCT may prove the better modality to visualize the non-metallic struts.

**CONCLUSION AND FUTURE DIRECTIONS**

Coronary angiography remains a cornerstone assessment for patients with coronary artery disease; however, given its inherent limitations, there is a strong rationale for incorporating adjunctive diagnostic tools for lesion assessment and PCI optimization. The use of physiological indices, especially FFR measurements, to direct coronary revascularization is seeing growing use in routine clinical practices as well as in more complex cases. Patients with recurrent angina symptoms and non-obstructive coronary artery disease may benefit from microvascular function testing and endothelial function assessment to guide targeted medical therapy. Intravascular imaging plays an important role in visualizing plaque characteristics and optimizing stent deployment to reduce the risk of in-stent stenosis and thrombosis. OCT may also be helpful to visualize plaque erosion or coronary dissection in patients presenting with ACS. It has therefore become critical for clinicians to understand the potential applications of adjunctive diagnostic tools in the cardiac catheterization laboratory in order to best incorporate these modalities into their current practice.
COMPETENCY STATEMENTS

ACS-MK1—Know the epidemiology, causes, pathophysiology, and natural history of ACS, including the roles of plaque rupture or erosion and platelet activation and thrombosis.

INV/INT-MK7—Know the angiographic features of coronary artery disease and how to assess its anatomic and physiologic severity.

ISCHEM-MK15—Know the anatomic and physiologic catheterization findings indicating significant coronary artery obstruction and the coronary angiographic features indicative of a high-risk state.

**MULTIPLE CHOICE QUESTIONS**

1. Which of the following describes the best use of intravascular imaging in a patient presenting with acute myocardial infarction?
   A. Intravascular ultrasound (IVUS) to measure the fibrous cap thickness of a fibroatheroma
   B. IVUS to assess for myocardial bridging
   C. IVUS to detect edge dissections
   D. Optical coherence tomography (OCT) to measure the total plaque volume
   E. OCT to identify plaque erosions

2. Which of the following statements is correct regarding fractional flow reserve (FFR)?
   A. FFR requires more fluoroscopy and total procedure time compared to regular angiography, thus making it an overall less cost-effective solution over a 15-year period.
B. FFR can be accurately measured in patients presenting with acute myocardial infarction complicated by cardiogenic shock.
C. FFR can simplify and direct the revascularization approach to complex coronary bifurcation lesions.
D. FFR is normal if its measurement is 0.80 or above.
E. FFR should not be used to assess left main disease.

3. Which of the following statements is correct regarding left main lesions?
   A. Left main lesions may hide on angiography significant amounts of complex atherosclerotic plaque that increase the risk of a future adverse event.
   B. Left main lesions should almost always be treated with coronary artery bypass grafting.
   C. Left main lesions can be accurately evaluated with coronary flow reserve.
   D. Left main lesions do not benefit from intravascular ultrasound guided percutaneous coronary intervention.
   E. Left main lesions can be reliably assessed on angiography with respect to disease severity if one is a very experienced operator.

4. Which of the following statements is correct regarding stent underexpansion?
   A. Stent underexpansion can be readily detected using intravascular ultrasound.
   B. Stent underexpansion can be readily detected using fractional flow reserve.
   C. Stent underexpansion has little impact on stent thrombosis rates.
   D. Stent underexpansion has little impact on in-stent restenosis rates.

5. Which of the following statements is true regarding edge dissections detected on optical coherence tomography?
   A. There are fewer edge dissections detected on optical coherence tomography compared to intravascular ultrasound.
   B. Edge dissections detected on optical coherence tomography are considered National Heart, Lung, and Blood Institute (NHLBI) type E dissections.
   C. Most edge dissections detected only on optical coherence tomography
can be deferred from further intervention.
D. Edge dissections detected only on optical coherence tomography have higher event rates than those detected on angiography.

**ANSWERS**

1. E
2. C
3. A
4. A
5. C
Appropriate selection and manipulation of equipment is critical to successful percutaneous coronary intervention (PCI) outcomes and low complication rates. The guidewire is the first piece of interventional equipment to contact the lesion to be treated. Proper intraluminal advancement of the guidewire through the lesion and into the distal vessel allows the coronary guidewire to serve as the backbone for the safe delivery of diagnostic and therapeutic devices while maintaining secure and safe access to the vessel lumen. Although the current standard 0.014-inch wires are suitable for the majority of interventions, operator familiarity and facility with guidewire selection and manipulation are still paramount. The advent of specialty guidewires, such as those designed for chronic total occlusions (CTOs), has furthered our ability to successfully treat more complex lesions, but the use of these wires requires an understanding of specific wire performance features and the possible complications that can result from their use. Given the wide variety of guidewires that are available, knowledge of their design, materials and structure aids the operator in understanding unique differences in performance and ultimately in making the proper selection for an individual patient or lesion.

In this chapter, we will review specific characteristics of coronary guidewires including their construction and properties that favor different clinical situations. In order to optimize guidewire selection, we have developed a general classification scheme based on wire performance
features. We will discuss techniques for guidewire manipulation in selected subsets of coronary lesions with the caveat that minimal comparative literature is available. As with other aspects of interventional cardiology, there are multiple guidewires that can be used for each lesion, and operator selection may change with experience or as technologic advances are made.

**HISTORY OF THE GUIDEWIRE**

More than 30 years have passed since the introduction of a catheter system allowing an independently movable, flexible-tipped guidewire for coronary intervention. Unlike the initial balloon catheters with fixed-wire tips, the 2 component balloons and independent, steerable guidewire systems greatly enhanced coronary artery and lesion accessibility. Guidewires are designed to allow the tip to be shaped or curved so that the wire could be purposefully directed into the desired artery and across the target lesion using rotation and advancement. The independent catheter–guidewire system also brought increased safety with the ability to exchange devices without recrossing the coronary lesion.

The first guidewire for angioplasty, available from 1979 to 1982, was a 0.018-inch standard wire (Cook Group Inc.). This wire had a safety wire at its tip—a precursor to the shaping ribbon—that allowed it to be shaped but resulted in added tip stiffness. The next wire to be developed (ACS) was a standard wire that replaced the safety wire with a metal ribbon. This change made the tip more flexible while retaining the ability for shaping. Further advances included construction of a floppier wire, which lacked a shaping ribbon, and had greater flexibility and safety but sacrificed some directional control. Thus the objective was to develop wires that combined flexible and safe tips while maintaining shapability and torsional control. Currently, as no guidewire meets all needs or preferences, several manufacturers offer a line of coronary guidewires, many with subtle variations, to allow artery- or lesion-specific guidewire selection.
Knowledge of the underlying construction of a guidewire provides an understanding of the expected performance features including steerability and trackability. *Steerability* relates to the ability to direct the wire to a desired location within an artery or lesion. *Trackability* is the ability of a wire to follow the course of an artery during advancement with minimal resistance or buckling. Multiple characteristics including flexibility, radiopacity, torquability and kink resistance, and the frictional resistance of the guidewire within the system it is used, all contribute to the fundamental properties that result in maneuverability of guidewires (Fig. 27-1). *Torquability* is a term that describes the relationship between rotational movement of the proximal wire (the site where the operator grasps the wire) to the tip. Torquability that is 1:1 means that for every degree rotation by the operator, a similar rotation will occur at the tip.

**FIGURE 27-1** Guidewire performance. Multiple characteristics contribute to the fundamental properties that result in the steerability and maneuverability of a guidewire.

Coronary guidewires are composed of 3 main components, a central core that tapers distally, a flexible tip which includes a spring, and the external surface or coating (Fig. 27-2). These components all influence the ability of a
wire to reach and cross a lesion and also to support the delivery of balloon catheters and other devices to the lesion. For example, the core provides the support for device advancement but is also integrally related to trackability, steerability, and torque transmission.

**FIGURE 27-2** Coronary guidewires are composed of 3 main components: a central core, a flexible tip, and a lubricious coating.

The core may be constructed as a single continuous unit or have more than one segment. As the core extends distally, the diameter tapers and the degree of tapering and the location of tapering vary. These variations in core diameter, length and degree of tapering affect performance. Cores that extend to the distal wire tip provide extra support and torque transmission but are stiff. Cores that do not extent to the distal tip and that gradually taper are more flexible and retain more trackability than wire cores that abruptly end. For this reason, wires that have a single core construction have the smoothest transition into the flexible preshaped tip and provide a high degree of steerability and trackability. The core strength also varies with the core material and diameter, and as stiffness increases, flexibility may be compromised, but vessel straightening and device delivery improve. The core
wire is commonly composed of stainless steel or alternative alloys such as nitinol. The nitinol core increases wire trackability, including the ability to traverse acute artery angulations without wire prolapse. Nitinol wires, therefore, might be more capable of entering a retroflexed circumflex takeoff than a stainless steel core wire.

The tip of the wire is composed of a coil or spring that provides a flexible leading tip that enhances safety and steerability. The ability to shape the tip into a retainable and variably shaped curve is accomplished with a shaping ribbon. This thin metallic strip that runs parallel to the longitudinal axis of the wire allows the tip to retain a curved shape or “J” configuration that provides directionality to the guidewire. The degree to which the tip retains its shape during use relates to the properties of the shaping ribbon, the material of the distal tapered core, and, additionally, to the coatings, which are discussed below. Wires with straight tips and shaping ribbons can be shaped to more acute angles, or sequential bends can be placed to negotiate unusual or severe (<90°) instances of vessel tortuosity. Wires that have preshaped tips are also available. These wires lack a shaping ribbon, which results in less ability to alter the tip shape.

The wire tip also varies in stiffness. Highly flexible tips are termed floppy or soft and these wires are particularly safe and atraumatic in that the likelihood of subintimal dissection or vessel perforation is very low. Commonly such wires include a core of moderate flexibility and support and are accordingly used as “workhorse wires.” Because of enhanced tip flexibility, they can prolapse or form a large “J” configuration when advanced. Such a configuration, if it occurs after the wire crosses the lesion to be treated, is an advantage in that the wire can be readily and safely advanced into the distal artery without the need for steering.

Other potential features of the wire tip that may be manipulated include the distal diameter and weight of force, or tip load. Guidewire tips can have a tapered coil from the shaft of 0.014-inch down to 0.009-inch. There are also lines of wires that are designed with incremental tip loads, or grams of force at the wire tip. These wires with reduced profile or increased tip load, discussed below, are designed to improve crossing of subtotally or totally occluded arteries. Caution must be exercised with these wires to avoid coronary dissection or perforation.

The distal coil segment is constructed of platinum, tungsten, or an alternative radiopaque material. Radiopacity is critical for monitoring fine
wire manipulation and advancement. The standard wire has a radiopaque tip of 2 to 3 cm in length, and although the entire wire is visible with fluoroscopy, the entire length of the wire may be difficult to follow. Problems with the wire such as kinks or the development of loops, particularly outside the guiding catheter and within the aorta, may be difficult to detect. These situations, however, are usually recognized by accompanying clues such as loss of 1:1 torque, pushability, guide stability, or the ability to deliver devices. The benefit of a short radiopaque tip is that it can be advanced past the target lesion so as not to influence the identification of devices or evaluation of the targeted lesion. The radiopaque segment may also interfere with the ability to perform quantitative coronary angiography. Certain wires have longer radiopaque tips of 11 to 40 cm. This “high radiopacity” feature is found on more aggressive wires where more force may be applied to wire advancement, and intense monitoring of the entire length of the wire in the coronary and guiding sheath is needed for safety. Besides the safety issue, the longer radiopaque tip does not offer additional benefits.

The third component of the coronary wire is the coating, which can be silicone, Teflon, polytetrafluoroethylene (PTFE), or a hydrophilic polymer. The coating decreases the friction, making the surface lubricious within the device lumen and across lesions, and improves wire and device tracking in tortuous vessels. The hydrophilic wires are well suited for severe stenoses and total occlusions, but they may create vessel dissections or perforations if not manipulated cautiously. As with other aspects of wire construction, each feature may improve one or more clinical aspects of the wire, but at the expense of another.

**GENERAL GUIDEWIRE FEATURES**

The majority of coronary wires are 0.014-inch diameter for compatibility with low-profile coronary balloon and stent systems. Larger diameter specialty wires such as the Glidewire® Gold 0.016 to 0.018 inch (Boston Scientific Corporation) and the Magnum wire (Schneider) 0.021 previously used for recanalization of chronic total occlusions (CTOs), have been replaced by 0.014 wires engineered specifically for CTOs. Wires come in 2 general lengths. Standard length guidewires are 175 to 190 cm and exchange length wires are 270 to 300 cm. Longer wires, 335 to 350 cm, are available.
for specific procedures that require guidewire externalization such as retrograde CTO interventions. The choice of wire length depends largely on operator preference and the balloon catheter system chosen, single operator or rapid exchange (RX) versus over the wire (OTW). Details of these techniques are discussed in the next section. Importantly, most, but not all, standard length guidewires can be extended with compatible extension wires if conversion to an OTW technique is required. If a standard length wire is not compatible with an extension wire, there are techniques, discussed below, that can be used to remove OTW devices or to exchange the wire without uncrossing the target lesion or losing access to the distal vessel. Additional features on some wires include marker bands that can reduce fluoroscopy time. These bands are generally placed at 90 and/or 100 cm, the length of a guiding catheter, to allow passage of the wire through the guide or balloon to the appropriate distance without fluoroscopy, ensuring that the wire has not exited from the guide catheter. Wires can also be designed with radiopaque markers at the distal tip that are a known distance, apart allowing for estimation of lesion length. These wires are termed marker wires.

GUIDEWIRE TECHNIQUES FOR OVER-THE-WIRE AND RAPID-EXCHANGE SYSTEMS

**OTW Systems**

In an OTW system the wire traverses the entire length of the balloon catheter lumen, which is generally 135 to 150 cm. Standard coronary balloon and stent catheters are designed for 0.014-inch wires. Often the tolerances of the balloon catheter lumens and the guidewires overlap such that there is little clearance between lumen and wire. There are 2 approaches to using an OTW system. In the more common approach, the operator first places the guide wire through the balloon lumen and then the guidewire-loaded device is advanced into the guiding catheter to the coronary ostium. The guidewire is manipulated through the vessel across the target lesion, and, with the wire fixed in place, the balloon can be advanced across the lesion for dilation. The
advantage of this technique is that the balloon catheter can be advanced over
the wire into the coronary for more precise guidewire manipulation.
Additionally, if the operator requires a different guidewire, the balloon
catheter can be left in place within the coronary to maintain access. For
example, OTW balloon catheters are of special value when attempting
difficult anatomy including calcified, tortuous, or highly stenotic vessels and
especially chronic total occlusions. The greatest challenge for successfully
treating such lesions is to cross the lesion with a guidewire, and, accordingly,
an assortment of different guidewires is often necessary in these cases. The
OTW catheter can be positioned directly proximal to a total occlusion to
facilitate guidewire exchanges.

Either a standard length wire (175-100 cm) or an exchange length wire
(300 cm) can be used to cross the lesion with the OTW system. If a standard
wire successfully crosses the target lesion, the wire can be extended with an
extension wire to remove the balloon catheter or the balloon can be advanced
distal to the lesion and the wire can be exchanged through the balloon for an
exchange-length wire prior to balloon withdrawal. Another method for
removing an OTW device from a standard length wire is to use a trapping
balloon. This method is commonly used in CTO interventions, where
meticulous care is required to prevent vessel injury or perforation from
unintended migration of stiff or polymer coated wires. To perform this
technique, a rapid exchange balloon is advanced to the distal tip of the
guiding catheter on its own, not over a wire. For an 8-French (Fr) guiding
catheter, a 3.0-mm balloon is used, and, for 7-Fr or smaller, a 2.5-mm balloon
is recommended. The OTW device is retracted proximal to the trapping
balloon, then the trapping balloon is inflated to 14 atmospheres, pinning the
wire against the guiding catheter to maintain position. Then, the OTW device
is withdrawn from the guide, followed by deflation and removal of the
trapping balloon. During the trapping, the guidewire pressure will be damped,
and, following device removal, the system should be cleared of potential
trapped air. Another advantage of this method is that fluoroscopy can be
minimized and radiation exposure reduced. An alternative technique to
preloading the guidewire in the OTW device is one where the operator
advances a guidewire alone into the guiding catheter and across the target
lesion. In this “bare-wire technique,” the balloon or stent is then advanced
over the wire into the lesion. This approach allows better visualization in
smaller diameter guiding catheters, but given the low profile of current OTW
balloons, the advantage of this approach is minimized. Passage and removal of OTW balloon catheters over standard length wires has been reported using other techniques, such as the hydro-glide method. This method uses hydrostatic pressure applied to the central lumen of the balloon catheter with a saline-filled syringe or inflation device.\textsuperscript{8,9} Loss of wire position is the main drawback of this approach. Since this situation can lead to loss of vessel access it should be avoided, and a rapid-exchange catheter or trapping balloon should be used in these situations.

**Rapid Exchange Systems (RX)**

The RX system is commonly referred to as a single-operator exchange system. The coronary balloon and stent catheters are labeled \textit{RX} (for rapid exchange) or \textit{Monorail} and are compatible with 0.014-inch wires. The catheters were modified from the OTW type and the distal portion is similar, with the guidewire traversing through the balloon lumen. The OTW segment, however, is short, and the remainder of the wire tracks outside the catheter adjacent to the balloon lumen. The RX system is ideal for the single operator and can reduce fluoroscopy time. A standard length guidewire can be used for all RX intracoronary catheters. Initially, the bare wire technique is used to cross the lesion, and then the balloon catheter is loaded on the distal end of the guidewire. The catheter is advanced until the wire exits the catheter lumen and the wire is then fixed in place as the remainder of the catheter is advanced across the lesion. Although the RX catheters may have less pushability and trackability and cannot act as a device for exchanging wires, the current balloon catheters are low profile, easy to deliver, and can be used in the majority of cases.

When using an RX system, the operator must be prepared to change to an OTW system when necessary. In certain situations, such as inability to cross a lesion with a wire or balloon or an unanticipated non-dilatable lesion, the wire may need to be exchanged for a specialty wire, such as an extra support wire or rotational atherectomy wire. If balloon inflations have been performed, and, in particular, if a dissection in the vessel is present, maintenance of distal wire position is essential. Normally these situations pose no problem, as the majority or standard length wires can be extended to exchange length with extension wires, and a microcatheter or OTW balloon catheter can be used to secure position during the wire exchange. Another
option is to use a dual lumen catheter such as the Twin-Pass (Vascular Solutions, Minneapolis, MN) which has both an RX and OTW lumen. The Twin-Pass can be placed on the standard length wire through the RX lumen and advanced distal to the lesion, then a long wire can be placed in the OTW lumen of the catheter.

GUIDEWIRE SELECTION

There may be many appropriate guidewire choices for each coronary intervention. Categorizing the guidewires into groups according to their general performance features and becoming familiar with a few wires from each group is a sound initial approach. Subsequently, each operator may find subtle differences among the guidewires in each group and develop a personal preference for a specific guidewire. Most operators will choose an “all-purpose” guidewire for the majority of cases and then have preferred wires for circumstances where “extra support” is needed or for specific lesion subsets. A guidewire classification grouping according to the general performance features is given in Table 27-1.

**Specialty Wires for Total Occlusions**

There are many wires that have been developed to cross severely narrowed or totally occluded coronary stenosis. These wires are generally classified by the coating and tip characteristics such as style and stiffness (Table 27-2). This section will review examples of these types of wires.

**Polymer-Coated Wires**

Several polymer jacketed wires are available for use in challenging anatomy, and are particularly suited for CTO interventions. The wires either have a standard 0.014-inch tip or taper to a .009- to .010-inch tip to assist in probing microchannels. The Asahi Fielder XT wire (Abbott Vascular, Lake Bluff, IL) is an example of a tapered-tip wire that can be manipulated in a CTO in
attempt to cross non-visible microchannels. The drawback of these types of wires is the potential for subintimal dissection. The Fielder FC (Abbott Vascular), which has a non-tapered tip, is suited for crossing small vessels, such as septals and collaterals, with less risk of dissection (Fig. 27-3). The Pilot series of wires (Abbott Vascular) come in 3 different tip loads and are stiffer than the Fielder wires. The increasing stiffness results in greater ability to penetrate occlusions with the negative consequence of risk of complications. Several additional polymer-coated wires are available with tip stiffness ranging from 0.8 g to 7.0 g (Table 27-2).

FIGURE 27-3 Cineangiograms from a percutaneous coronary intervention in a
patient with a chronic total occlusion of the right coronary artery (RCA) treated with a retrograde approach. A. A Fielder FC wire and Corsair microcatheter were used to atraumatically cross the septal collaterals. B. A Pilot 200 wire was used for retrograde subintimal tracking. A ViperWire was used for guidewire externalization (not shown). C. Final result after overlapping drug-eluting stents to the RCA.

**Open Coil Non-Polymer Coated Wires**

Stiff- tipped non-polymer coated wires may be more steerable than the “glide” type wires and are well suited for total occlusions. They also offer more secure positioning for device delivery. As with other wire types, the tip configuration may tapered or non-tapered with a range of stiffness. The Asahi SION wire (Abbott Vascular) was designed for small vessels. It tracks well through tortuosity and is used for septal and collateral wiring. The CROSS-IT wire (Abbott Vascular) has the lowest tip stiffness, and is tapered and can be used to probe visible microchannels in CTOs. Wire escalation to wires with increasing stiffness is a reasonable strategy but operators should be cautious not to extend fluoroscopy time by continuing to work with a wire that does not have the characteristics needed to cross the occlusion.

**Asahi MiracleBros and Confianza Line**

The Asahi Miraclebros line (Abbott Vascular) of 0.014-inch wires is also designed for highly stenosed or occluded vessels. The wires have a single continuous core construction with a jointless spring coil for tracking; silicone, fluororesin, and hydrophilic coatings to reduce friction; and a highly radiopaque 11-cm tip. The wires are manufactured according to a tip load—or the weight of force required to deflect the tip—with 3-g, 4.5-g, 6-g, and 12-g size available (ie, Miraclebros 3 has a tip load of approximately 3 g). The wires have reduced flexibility and increased support as the tip weight increases. The progression in tip load translates to greater retention of tip shape, responsiveness, and ability to push the wire in a desired direction. The Asahi Confianza wires (Abbott Vascular) which come in 9-g and 12-g tips, have tapered tips and high penetration ability for CTO caps. The radiopaque segment is 20 cm long to allow visualization of movement and wire displacement with manipulation. Use of these wires is based on a strategy of crossing total occlusions that differs from the conventional approach where emphasis is placed on detecting the original lumen and slipping through that
segment of the total occlusion. The Asahi concept features blunt but highly
direct dissection. This technique is more complex and technically demanding,
but may achieve success when others fail. If the course of the vessel is
unknown, the risk of complications from these aggressive wires is increased.

Externalization Wires

The retrograde approach to CTOs requires that a guidewire have sufficient
length for externalization outside the body. There are 2 wires available in the
United States. The R350 wire (Vascular Solutions) is 0.013 inch in diameter,
350 cm in length, and has a 5-cm radiopaque platinum coil tip. The Viper
Advance wire (CSI) is 0.014 inch in diameter and 335 cm in length.

GUIDEWIRE SHAPING TECHNIQUES

The majority of wires have a straight tip that can be shaped; however, some
are available with a preshaped curve. The advantage of the straight wire is
that the tip shape can be customized for the vessel morphology. In general,
the thumb and index finger are used to place rotational traction on the distal
wire over a mandrel or through the introducer tool (Fig. 27-4). For the
majority of interventions, a 30° to 60° smooth curve over the distal 4 to 5 mm
of the wire is sufficient. For larger or more angulated vessel, a longer curve, a
larger angle, or a secondary curve may be required. A different technique is
used when stiff-tipped wires are needed for severely stenosed or chronically
occluded vessels. A bend rather than a curve is placed on the distal 1.0 to 1.5
mm of the wire with an angle 30° to 45°.
GUIDEWIRE MANIPULATION TECHNIQUES

Universal Techniques

The “workhorse” wires are flexible tipped 0.014-inch wires that are often the initial wires of choice as they offer adequate support, excellent steerability, and are atraumatic. Some vessels and lesions, however, are particularly challenging and require alternative wires and techniques. The operator should be familiar with alternative wires and have a logical stepwise approach planned to accomplish a complicated intervention. In addition to wire choice, appropriate selection of additional equipment such as a guiding catheter with sufficient back-up is needed. Common lesion subsets are discussed below.

Tortuous Vessels and Distal Lesions

Severely angulated or tortuous vessels and distal lesions may be technically difficult to access. Even proximal lesions may pose a challenge if the origin of the left anterior descending artery, or more commonly the left circumflex, arises from the left main at an extreme angle. Although the tip of the flexible guidewire can be shaped to accommodate increased angulation, the guidewire will often prolapse into the alternative artery or branch rather than advance into the target branch. Stiffer-tipped or nitinol wires may prolapse less in >90° angulation, but even these wires will have poor tip steerability.

Distal lesions in tortuous arteries may represent the greatest challenge for access, because as the wire traverses curved segments, steerability is lost. For these reasons, additional support and ability for wire exchange is offered by an OTW approach. A low-profile OTW balloon can be advanced near the guidewire tip to decrease wire prolapse and to make wire removal and reshaping easier. The OTW system will also increase the torque responsiveness and decrease frictional drag of the wire. On occasion even
low profile OTW balloons cannot be advanced without compromising guide or wire position. Alternatively placing a second wire adjacent to the initial wire, the “buddy wire” technique may augment access. A third option advocated by many operators is the use of a more flexible system in these cases. Microcatheters have been used successfully in these difficult cases.\textsuperscript{10-12} There are currently several low-profile microcatheters available, including the FineCross (Terumo) which has a hydrophilic coating and tip that tapers to 1.8-Fr for crossing tortuous vessels. Delivery of devices such as balloons and stents may also be difficult in tortuous arteries or distal lesions. Vessel straightening and increased support can be achieved by exchanging the initial wire for an extra-support wire. The use of dual wires, or a buddy wire, can also be used in tortuous vessels to keep the balloon tips free.

**Chronic Total Occlusions**

Approximately 10% of percutaneous coronary interventions are for CTOs.\textsuperscript{13} The success rate for these lesions is lower than for other lesion subsets and ranges from 40% to 80% in various studies.\textsuperscript{14-19} The most common reason for failure in a CTO is inability to cross the lesion with a guidewire.\textsuperscript{20} Careful evaluation of the pre-intervention angiogram should help determine the appropriate course of the occluded vessel segment. If a previous angiogram was done prior to vessel occlusion, this should be reviewed to gain information regarding the vessel course and characteristics. Dual coronary injection is often required to simultaneously visualize antegrade and collateral flow.\textsuperscript{21,22} Recanalization of CTOs requires the availability of a broader range of coronary wires as discussed above. An example of a left anterior descending CTO case in which contralateral coronary injections and the Asahi Confianza wire (Abbott Vascular) were used is shown in Figure 27-5.
FIGURE 27-5 Cineangiograms from a percutaneous coronary intervention in a patient with a chronic total occlusion of the left anterior descending artery (LAD) treated with an antegrade approach. A. Simultaneous injections of the left and right coronary arteries allow visualization of the length of the LAD occlusion. The small arrow shows antegrade filling from the left and the large arrow shows retrograde filling from the right. B. Double arrows show the tip of the Asahi Confianza wire partially through the coronary total occlusion through an over-the-wire (OTW) balloon (*). C. Guidewire exiting LAD into diagonal artery demonstrated by contralateral injection. D. The Confianza wire was redirected into the distal LAD successfully. Note the long radiopaque segment of the wire (double arrows). E. The wire was exchanged to a floppy wire using the OTW balloon so that the LAD could be better visualized. A dissection was seen by angiography (**) that was confirmed by intravascular ultrasound. F. Several drug-eluting stents were delivered over a floppy guidewire (tip in distal LAD, arrow).

Hydrophilic wires have been used successfully in lesions previously attempted with conventional wires. In several series, lesions previously uncrossable with conventional wires were crossed with clinical success in 39% to 79% of cases.\textsuperscript{23,24} Coronary perforations were higher than previously reported at approximately 2%. In a larger series of 106 patients with CTOs
and previous PCI failure, a hydrophilic wire was employed and 42% of these attempts were successful. In a multivariate regression analysis, TIMI flow grade and occlusion age were independent predictors of success. In 5 cases, pericardial contrast staining due to vessel perforation occurred.\textsuperscript{25} Whether to use a hydrophilic wire as the initial wire in CTOs is debatable, but in one small randomized study of 88 patients, this strategy resulted in a lower number of guidewires being used, a trend toward shorter procedural and fluoroscopy times, and decreased use of contrast media compared to a strategy of using 1 or 2 0.014-inch soft or intermediate tip guidewires.\textsuperscript{26} Since that time, many non-hydrophilic wires suitable for CTOs have been developed and may offer the same success rate in crossing CTOs as the hydrophilic wires with more directability and less risk for dissection or perforation. These include wires such as the CROSS-IT and Asahi MiracleBros series (both from Abbott Vascular).

Since multiple wires are generally needed for a CTO intervention, microcatheters are often used. The Corsair microcatheter (Asahi Intecc USA), designed for CTO interventions, is a proprietary braided catheter that can track wires into microchannels or collaterals and provides support for wire manipulation or exchanges.

**Stents**

Advancing the guidewire through new or previously placed stents must be done cautiously. Even in situations of in-stent restenosis, the guidewire may exit through the stent struts, which will prohibit delivery of balloons and other devices and may even lead to stent avulsion.\textsuperscript{27} One manipulation technique that may decrease the chances of the wire advancing through stent struts is to place a large “J” curve on the wire in attempt to loop or prolapse the wire through the stent. Another option is to use a Wiggle Wire (Guidant, Inc.), which is manufactured with a distal core that has multiple undulations or bends, a shapeable flexible tip, and a low friction coating. This wire may be more trackable and prevent wire tip entrapment within stent struts.

**Bifurcation Lesions and Side Branch Access**

Dual coronary guidewires are often needed for bifurcation lesions. If provisional stenting is going to be used for the side branch, then the side
branch wire should be removed prior to stenting the main artery to avoid wire entrapment. Some operators, however, believe this cautionary step is not necessary and that leaving the side branch wire in place improves side branch patency during stent placement. A non-polymer coated, core-to-tip wire is preferred when wire jailing behind a stent is planned to prevent embolization of the coating and reduce the risk of wire tip separation during removal from behind-the-stent struts. With either method, removal or jailing, the side branch must be rewired prior to performing a final kissing balloon inflation of the main and side branch.

A complication that may occur with dual wires in bifurcation lesions or with the use of a buddy wire is wire braiding. This occurs when the two wires become entwined and cannot be manipulated independently. This phenomenon occurs mostly with RX systems and must be recognized to avoid inadvertent removal of both wires.

GUIDEWIRE COMPLICATIONS

Recognition and management of guidewire-related complications are critical to patient safety and successful procedural outcomes.

Coronary Vasospasm and Pseudostenosis

Coronary vasospasm occurs in <5% of interventions and is mostly at the target lesion or the distal vessel. Vessel closure secondary to spasm is uncommon—less than 2%—even with rotational atherectomy. Guidewire-induced vasospasm is uncommon and the presentation is not uniform. Rare instances of diffuse coronary vasospasm solely due to guidewire insertion and responsive to nitrates has been described. Additionally, wire-induced spasm may accompany angioplasty, making the recognition of the vasospasm more difficult. Multiple sites of spasm remote for the target lesion occur and may be due to wire or equipment manipulation. Most vasospasm is responsive to intracoronary vasodilators such as nitroglycerin 100 to 200 μg, but some patients may require higher doses or a continuous intravenous infusion. The calcium channel blockers verapamil, 100 μg/min up to 1.0-1.5 mg, and diltiazem, 0.5-2.5 mg over 1 minute, up to 5-10 mg, have also been
Vasospasm distal to the dilated lesion during PTCA may be refractory to vasodilators if the guidewire is contributing to the spasm, and, in that case, guidewire removal is necessary. Distinguishing newly acquired coronary narrowing due to vasospasm from coronary dissection is important. Removal of the guidewire, a potential therapy for wire-induced spasm, may be detrimental if a dissection, thrombus, or other mechanical complication is not recognized. Intravascular ultrasound may be helpful in this situation to rule out a dissection prior to wire removal. The recognition of this phenomenon of guidewire-induced vasospasm is important so that it does not interfere with selection of appropriate balloon and stent sizes or result in unnecessary interventions for “pseudolesions.”

Another well-described cause of coronary narrowing attributable to a guidewire is pseudostenosis. Tortuous vessels including the right coronary, left circumflex, and internal mammary arteries are prone to these artifacts. Pseudostenosis results from the creation of pleats or kinks in the artery due to artificial straightening induced by passage of the straight section of the guidewire through a tortuous or redundant arterial segment. In addition, stiffer guidewires, which are often used for the purpose of improved device delivery in more complicated cases such as calcified or tortuous vessels, are more likely to cause these false lesions. The lesions often appear as a linear defect and may be difficult to distinguish from a dissection, thrombus, or vasospasm. Pseudostenosis will usually resolve once the guidewire is removed, however, it can also result in erroneous hemodynamic measurements or incorrect assessment of stenosis severity.

Prior to complete removal of the wire, a few approaches can be taken to evaluate for a true lesion. If a stiff or extra-support wire is being used, it can be exchanged for a floppy wire to see if less vessel straightening resolves the lesion. Relief of pseudostenosis may occur with a transit catheter or OTW balloon catheter. The catheter can be placed distal to the lesion in question and the wire removed. This technique is particularly useful if the catheter has been used during the case so that an additional wire is not needed. Another approach is to partially withdraw the wire so that the flexible tip enters the segment of concern and the pseudostenosis disappears as the segment assumes its normal tortuous configuration (Fig. 27-6). Such an approach is not suitable for clarifying multiple lesions. If the etiology is still unclear,
IVUS can be helpful.\textsuperscript{49}

\textbf{FIGURE 27-6} Procedural cineangiograms of a right coronary intervention. A. Diagnostic angiography shows a tortuous right coronary artery (RCA) with a culprit lesion mid vessel (\textit{arrow}). B. After the stent was delivered over an extra-support wire (radiopaque floppy tip, \textit{double arrows}) 2 lesions were noted proximally (*). C. The diagnosis of pseudo-lesions was made by progressively withdrawing the guidewire until its floppy segment rested equally on either side of the suspect lesion(s).

\textbf{Wire Perforations}

Coronary perforations are a rare complication of PCI, occurring in 0.3% of patients in 12,658 cases, more with debulking devices (1%) than with balloon angioplasty and stent techniques (0.2%).\textsuperscript{50} Importantly, this study observed that 51% of the coronary perforations were guidewire-related. The majority of guidewire perforations result from distal migration and buckling of the wire during exchanges and delivery of devices. In this situation, the wire is advanced through progressively smaller arterial branches until it exceeds the lumen diameter and penetrates the thin wall of the distal branch. Perforations can also occur attempting to cross a CTO. Guidewires that have a distal hydrophilic polymer coating are more prone to cause perforations because of the wire properties and that they are generally used in more complex lesions. Operator experience is also a factor. In fact, reports of perforation often follow the release of new wires.\textsuperscript{51} As with other coronary perforations, wire perforations are can be classified as type I through III with an increasing risk of tamponade with higher classification. Importantly, wire perforations may not be readily apparent during or at the end of the PCI procedure. Patients with undetected perforations may present with features of cardiac tamponade,
notably hypotension, several hours after they completed what was judged to be an uncomplicated intervention. A high index of suspicion is essential for the prompt diagnosis and management of these patients.

Initial treatment of perforation should consist of a prolonged balloon inflation—up to 15 minutes—which in the case of a distal or CTO perforation should not result in significant ischemia. Wire-induced perforations typically do not require a covered stent. An OTW balloon should be used if time allows so that the wire can be removed, but, if an RX balloon is in place, the wire can be withdrawn into the distal balloon lumen. Further management is individualized, but if a significant pericardial effusion or tamponade is present, a pericardiocentesis should be performed.

For perforations that persist despite prolonged inflations, particularly when immediate reversal of anticoagulation is not possible such as with administration of a glycoprotein (GP) IIb/IIIa inhibitor, several unique treatment strategies have been reported. In 2 cases, a small dose (100-300 IU) of thrombin was injected via the lumen of a balloon catheter during prolonged low-pressure balloon inflation, just proximal to the wire perforation site. The thrombin can be prepared at a concentration of 50 to 00 IU/ml with a delivery of 2 to 5 ml and a 10- to 20-min balloon inflation following the thrombin injection to prevent retrograde effects of the activated thrombin. In one case report, 2-mm pieces of GelFoam (Pfizer, New York, NY) soaked in contrast were injected into the distal vessel via a transit catheter, with successful sealing of the perforation. Microcoil embolization, distal delivery of polyvinyl alcohol, or the patient’s organized thrombus has also been used successfully to treat wire perforations.

Wire Fractures, Emboli, and Retained Fragments

Guidewire entrapment or embolization is a rare complication of PCI that may be related to operator technique or, less commonly, to manufacturing flaws or wire component failure. Tip entrapment may occur when the wire is advanced into a small side branch or distal vessel due to resultant vessel vasospasm or with excessive rotation in total occlusions. Initially, an attempt to release the wire should include administration of intracoronary nitroglycerin with gentle retraction. Another possible technique is to advance a low profile over the wire balloon close to the wire tip and then retract the
wire into the balloon catheter. After removal of the wire, angiography should be performed to exclude vessel perforation. Attempts to remove an entrapped wire may lead to fracture and unwinding of the distal tip ribbon or wire embolization. Another situation that can lead to wire entrapment is the use of a wire to maintain side branch patency during stenting, as discussed above. A wire may also become inadvertently trapped behind a stent if a loop in the non-radiopaque segment goes unrecognized. The authors had this experience once during treatment of a bifurcation lesion and the stent entrapped wire fractured during attempted removal. Fracture of a coronary guidewire during thrombectomy of an occluded coronary bypass graft with the X-Sizer catheter (Genç Medikal, Ankara, Turkey) has also been reported and resulted from entrapment with a coronary stent. \(^{59}\) Guidewire transection can also occur during rotational atherectomy if the wire prolapses or kinks in the path of the rotoburr. \(^{60}\)

The optimal strategy for retrieval of wire fragments and the consequences of retained fragments are unclear, as the largest series reported outcomes in only 8 patients. \(^{61}\) Four of five extraction procedures were successful, including retrieval of a wire segment totally contained within a distal coronary artery. Retrieval of wires with segments extending into the coronary guide or aorta has been achieved with bioptomes, or compression of the wire in the guiding catheter by inflation of a balloon within the guide and simultaneous withdrawal of the balloon and catheter. \(^{62}\) Guidewire segments retained totally within the coronary circulation can be removed with improvised or commercially available snares that can be looped around the wire fragment. \(^{63}\) Some retained fragments may be benign, particularly if within the coronary or in total occlusions. At late follow-up in the observations of Hartzler et al \(^{61}\) up to 5 years, 5 patients with retained wire segments had no sequela attributable to the PTCA component debris.

**SUMMARY**

The guidewire is one of the most critical instruments in coronary intervention. This chapter reviewed the construction and fundamental physical properties of guidewires, general manipulation techniques, and potential guidewire complications. As coronary anatomy becomes more challenging, an understanding of the advantages and limitations of available
guidewires can complement operator experience and increase successful outcomes.

**MULTIPLE CHOICE QUESTIONS**

1. Which of the following statements is true about guidewire cores?
   A. Those that extend to the tip add wire flexibility.
   B. Tapering detracts from trackability.
   C. Cores that extend to the tip provide better torque transmission.
   D. A wire with a nitinol core is less trackable than one with a stainless steel core.

2. Which of the following wire features is not helpful for crossing a total occlusion?
   A. Very flexible tip
   B. Polymer jacket
   C. Tapered tip
   D. Continuous core

3. Which of the following lesion locations would be the most difficult to cross with a guidewire?
   A. Origin of the posterior descending artery
   B. Distal left anterior descending
   C. Proximal retroflexed circumflex
   D. Internal mammary-left anterior descending anastomosis

4. The best way to determine if guidewire “kinking” is responsible for apparent coronary narrowing is to:
A. Inflate a balloon in area of narrowing and look for balloon compression.
B. Perform fractional flow reserve measurement.
C. Withdraw floppy segment of wire into area of narrowing.
D. Administer intravenous nitroglycerine.

5. Which of the following are true about guidewire perforation?
   A. Less frequent with polymer coated wires.
   B. More common with subtotal than totally occluded lesions.
   C. More common during wire exchanges.
   D. Are usually obvious.

ANSWERS

5. C
Percutaneous transluminal coronary angioplasty (PTCA) was first described by Andreas Gruentzig in 1976, when he reported the successful application of the new technique in canine coronary experiments. Dr. Gruentzig designed and assembled balloon dilation catheters in his own kitchen. He performed the first coronary angioplasty in a conscious human patient in September 1977 in Zurich, Switzerland. The dilation catheter consisted of a balloon attached to a long shaft and a short wire attached to its tip. Soon after, balloon catheters were designed with a central guidewire lumen. Since the introduction of balloon angioplasty, major advancements have taken place in the field of percutaneous coronary interventions, but the majority of cases still require dilatation of the lesion with a balloon catheter even when a stent or other devices are used. In many instances, lesion preparation is crucial prior to stent deployment.

**BALLOON CHARACTERISTICS**

**Coronary Balloon Material**

Challenging lesions require a balloon with optimal performance in terms of:

- Catheter *pushability* in order to transmit the force applied by the interventionalist’s hand to the distal end of the catheter, especially when guiding support is not adequate;
• Catheter trackability over the guidewire through tortuous segments; and
• Lesion crossability, especially in cases of calcified lesions with severe stenosis.

Therefore, despite the fact that standalone “plain old balloon angioplasty” (POBA) is mostly a thing of the past, there is an ongoing effort to manufacture more user-friendly balloon catheters that can address preparation of complex lesions to complement newer percutaneous technology. Several balloon catheter characteristics are considered in the manufacturing process.

Over-the-Wire and Rapid Exchange Systems

In an over-the-wire (OTW) system, the balloon catheter has a central lumen permitting free guidewire movement. This system is helpful when crossing difficult anatomy such as a chronic total occlusion, where balloon support is helpful and wire exchange is anticipated. On the other hand, the rapid exchange (RX) balloon catheter system is preferred by most single operators. The lesion is crossed with a standard-length guidewire. The wire is then fixed with one hand while the balloon catheter is advanced with the other. The wire exits a few centimeters from the distal end of the balloon catheter rather than its proximal end. The main disadvantage is that the wire cannot be pulled out for reshaping and cannot be exchanged for another wire without taking the entire system out. Balloon support may not be as good as with a full-length OTW system, since the balloon catheter is tracking over a relatively short distance of the wire. Therefore, the shaft design plays a fundamental role in balancing several characteristics for optimal catheter performance. These include pushability of the proximal shaft and flexibility as well as trackability of the distal shaft. Other important characteristics are lubricity, torque transmission and kink resistance. Factors that improve crossability include a smooth transition from the distal shaft to the balloon and a low profile of the very distal catheter tip.

Balloon Material

The first balloon catheter used by Andreas Gruentzig was made of polyvinylchloride, a low compliance plastic polymer. Most balloon catheters available on the market today are derived from 1 of 4 families of balloon
materials: polyolefin, nylon, polyester, and urethane. It is the type of balloon material derived from these categories of plastic that largely determine the characteristics that differentiate dilatation catheters. Noncompliant balloons are usually made of polyethylene terephthalate, a widely used resin in plastic soda bottles. The strength of the material allows the balloon to be used in calcified lesions at high pressures. The maximum recommended pressure is provided by the manufacturer. Relatively high-pressure balloons can be made out of nylon, although the strength of the material is somewhat less than that of polyethylene terephthalate; therefore, nylon balloons are characterized as semicompliant. Compliant balloons are made out of polyethylene or polyolefin copolymer, allowing for lower profile, more flexibility, and a lower tendency to “wing” after deflation. This allows for more effective rewrapping of semicompliant as compared to noncompliant balloons. The disadvantage of a compliant balloon is the reduced ability to dilate hard lesions with a greater tendency to “dog-bone” since the distending force may stretch the balloon longitudinally rather than concentrating the force circumferentially on the atherosclerotic plaque. Manufacturers also use hydrophilic surface coating for better crossability, however this is balanced against creating slippage during balloon inflation especially in hard lesions.

Each balloon comes with a compliance chart that correlates the balloon diameter to the inflation pressure. The nominal pressure is the atmospheric pressure at which the balloon reaches its nominal preset diameter as tested in vitro. Because of their stretching properties, compliant balloons attain a larger diameter with higher pressures compared to non-compliant balloons. The rated burst pressure is the maximum allowed pressure below which there is a high confidence that 99.9% of balloons will not rupture. Balloon rupture can be caused by specific lesion morphology\(^1,2\) such as the sharp edge of a calcium spicule. Most commonly, however, a rupture takes place at pressures exceeding the burst pressure in the form of a pinhole or a longitudinal tear in the balloon. Balloon rupture can cause dye staining which is usually benign or can cause an intramural hematoma and, very rarely, vessel perforation.

**Cutting Balloons**

The cutting balloon was first described by Barath in 1991\(^3\). It consists of a balloon catheter with 3 or 4 microtomes—sharp metal blades mounted longitudinally on the surface of the balloon. The balloon is inflated slowly,
allowing the blades to “cut” into the lesion before actual balloon dilation (Fig. 28-1). It is felt that these controlled microsurgical incisions may limit overall vessel stretch and vascular injury,\(^4\) therefore reducing the balloon dissection rate and possibly also the elastic recoil. The balloon uses lower inflation pressure than conventional balloons and achieves a trend toward larger lumen gain with increased plaque reduction.\(^5\) The cutting balloon has gained popularity for angioplasty of in-stent restenosis. In these situations, it has the advantage of preventing “watermelon seeding” of the balloon and may result in better dilatation.\(^6\) It is not felt to reduce the rate of angiographic restenosis compared to conventional balloons.\(^6-8\) It is important to keep in mind that the device is stiff and has a high crossing profile. Some anatomic situations, such as lesions in very tortuous segments, may be out of reach with the cutting balloon.

![FIGURE 28-1](image) Normal peripheral artery of a pig 4 hours after using the cutting balloon at low pressure without effective balloon dilatation. The arrows point to 2 incisions that extend to the media. (Reproduced from Barath, P., M.C. Fishbein, S. Vari, and J.S. Forrester, Cutting balloon: a novel approach to percutaneous angioplasty. Am J Cardiol. 1991. 68(11): 1249-1252, copyright © 1991, with permission from Elsevier.)
Scoring Balloons

The AngioSculpt Scoring Balloon Catheter (Angio-Score, Inc., Fremont, CA) consists of a minimally compliant balloon housed in 3 low-profile spirally arranged nitinol wires (Fig. 28-2). In theory, during balloon expansion, the dilating force is concentrated focally in the wires resulting in the scoring effect on the vessel lumen surface. This mechanism can result in a controlled expansion of the lumen with reduced barotrauma and lower dissection rates. As with cutting balloon angioplasty, device slippage is reduced, especially in in-stent restenosis. Optical coherence tomography (OCT) images show lumen expansion and imprints caused by the scoring elements of the nitinol wire cage (Fig. 28-3). The scoring balloon is lower in profile and more deliverable than the cutting balloon. It has been proposed for lesion preparation prior to stent delivery. In an observational study, predilation with the AngioSculpt balloon, compared with either direct stenting or conventional balloon predilation, resulted in better stent expansion by intravascular ultrasound (IVUS) measurements, irrespective of plaque morphology. This technology has also been proposed in complex bifurcation lesions with dilatation of the side branch with the scoring balloon prior to implantation of a drug-eluting stent in the main vessel. In a prospective clinical trial that enrolled 93 patients, this strategy was associated with a favorable procedure success rate of 91.4%. Dissections were observed in 8.2% of cases in the main branch and 6% in the side branch post scoring balloon angioplasty. Bailout stenting in the side branch was required in 10.8% of cases. At 9 months, the composite major adverse cardiac events (MACE) rate was 5.4%. A similar “simple provisional” strategy in true bifurcation lesions was tested in a pooled analysis of the Nordic Bifurcation and the British Bifurcation Coronary randomized trials. Both trials compared provisional T-stenting versus a complex strategy of bifurcating drug-eluting stents. In the simple strategy group (n = 457), stenting the main vessel was performed first, followed by provisional dilatation of the side branch with a conventional balloon, then stenting if necessary. This strategy resulted in 128 patients (28%) undergoing ballooning of the side branch, and 16 patients (3.5%) requiring a T-stent. At 9 months—the composite endpoint of all-cause death—myocardial infarction and target vessel revascularization occurred in 10.1% of the simple strategy group versus 17.3% of the complex group (P = 0.001). While most evidence
supports the simple strategy approach in bifurcating lesions, it is difficult to properly evaluate the place of the scoring balloon compared to the conventional balloon in the absence of a randomized clinical trial.

**FIGURE 28-3** Angiographic and optical coherence tomographic findings before and
after scoring balloon angioplasty. A–C. Before the procedure, an angiogram shows 2 severe stenoses in the right coronary artery (A). Optical coherence tomography (OCT) shows that the proximal lesion is composed mainly of fibrous tissue. No stent struts are seen at this de novo lesion (B). Thick neointimal proliferation inside the stent struts (black arrowheads) is revealed via OCT (C). D–F. After scoring balloon angioplasty, an angiogram shows the disappearance of both stenoses. There are no major dissections or visible recoil (D). In OCT analyses, the minimum lumen areas of the de novo lesion and in-stent restenosis increase from 1.18 to 2.75 mm$^2$, and from 1.51 to 4.09 mm$^2$, respectively. Marks caused by the scoring elements (white arrowheads) are clearly visible via OCT (E and F). (Reproduced from Takano, M., M. Yamamoto, D. Murakami, et al., Optical coherence tomography after new scoring balloon angioplasty for in-stent restenosis and de novo coronary lesions. *Int J Cardiol*. 2010. 141(3): e51-e53. Copyright © 2013 with permission from Elsevier.)

Drug-coated scoring balloon catheters are discussed in Chapter 32.

**MECHANISM OF CORONARY BALLOON ANGIOPLASTY**

The mechanism of coronary angioplasty is intriguing. In the original 1964 publication describing the transluminal treatment of arteriosclerotic peripheral artery obstructions with serial dilating catheters, Charles Dotter and Melvin Judkins speculated the following mechanism: “relatively non-traumatic remodeling and lateral displacement of the encircling atheromatous material.” However, soon after the inception of coronary balloon angioplasty, the theory of vessel injury gained momentum. In one of his publications, Andreas Gruentzig wrote: “the atherosclerotic material is compressed and pressed into the vessel wall, thereby partly disrupting and dissecting the intima and overstretching the media.” Gruentzig refers to this as “controlled injury.” The notion of plaque compression has since been largely refuted for lack of experimental evidence. Human coronary arteries studied postmortem after successful angioplasty demonstrated splitting of the atheromatous plaque at the point of least resistance. Morphologic studies are never conclusive, primarily because atherosclerotic plaques differ in their composition. In acute coronary syndrome for example, the plaque may have already ruptured and may have varying degrees of superimposed thrombotic material. These types of plaques may respond differently to balloon
angioplasty than those in stable coronary artery disease situations where fibrosis and calcifications usually prevail. Nevertheless, the body of evidence, especially from IVUS data, supports the mechanism of lumen enlargement with balloon angioplasty to be largely the result of endothelial desquamation, plaque fissuring and arterial wall dissection, stretching of the vessel wall through the elasticity of both the media and adventitia, and axial plaque redistribution. Recent work addressed the dissection mechanisms triggered during the early stages of angioplasty in an atherosclerotic coronary artery 2-dimensional geometric-based computational model. The study showed that the onset of dissection damage occurs very early. Plaque detachment at the shoulder region results in an intimal flap or partial dissection of the plaque from the media, but what is interesting is the occurrence, very early on during balloon inflation, of damage within the wall of the media layer itself. This again stresses the probability of several injury mechanisms at different locations. The degree to which each of these various mechanisms play a role varies with each lesion morphology and atherosclerotic plaque composition as well as with balloon pressure and sizing.

COMPLICATIONS OF BALLOON ANGIOPLASTY

Procedural Complications

Intimal tears and arterial wall dissections are commonly identified by IVUS following balloon angioplasty. Some form of plaque disruption is seen in 50% to 75% of cases. Intramural hematomas have also been described by IVUS. These can result from a medial dissection with blood accumulating in the medial space and extending into the contiguous normal arterial wall, especially in the absence of a clear re-entry point. Coronary dissections pose a risk for acute or subacute vessel closure, one of the most dreaded complications of balloon angioplasty. In particular, intramural hematomas predict a high rate of non–Q-wave myocardial infarction, need for repeat revascularization, and sudden death. By providing scaffolding to “tack up” dissections, coronary stents have largely resolved the problem of acute vessel
closure that is caused by a coronary dissection with or without intramural hematoma. However, before the stent era, PTCA resulted in a significant complication rate. In the first 1500 patients enrolled in the National Heart, Lung, and Blood Institute Percutaneous Transluminal Coronary Angioplasty Registry (1977-1981), major complications occurred in 9.2% of patients and were in the form of myocardial infarction, urgent revascularization, or in-hospital death. Emergency surgery was required in 6.8%. It is interesting to note that in this very early experience, success rate was reported in only 63% of cases. Despite refinement in balloon technology, the incidence of periprocedural vessel occlusion after angioplasty remained relatively high at 6.8% through 1985 to 1986, with roughly two-thirds of the vessel occlusions occurring in the cardiac catheterization laboratory. Acute vessel closure was associated with a high risk of major complications, including bypass surgery in 35% and mortality in 5%, which was substantially higher than the 1% mortality reported in PTCA patients without vessel closure.

Acute vessel closure with balloon angioplasty is primarily caused by severe coronary dissections. Less common reasons include thrombus formation and coronary spasm. Acute closure occurring in a proximal location of a large vessel can result in ST-segment elevation and significant hemodynamic compromise, especially if the area of myocardium supplied by the vessel is substantial and/or collaterals are absent. If the wire is still across the lesion, redilatation with a properly sized balloon was the only thing that could be tried in the vessel before the availability of stents. In the early era of coronary angioplasty, heparin was administered generously (10,000 units at the beginning of the procedure and 5000 units every hour). Automatic coagulation timer (ACT) machines were not widely available in cardiac catheterization laboratories, and a weight-based heparin approach was not routine. Prolonged balloon inflations were the norm as long as the hemodynamic situation allowed. Intra-aortic balloon pumps were frequently used. A fully staffed operating room was kept on standby and the surgery and anesthesia teams were alerted as soon as a major complication took place. Even now, recrossing a lesion during acute vessel closure when the wire is no longer across the lesion remains potentially very challenging, as the wire may inadvertently advance through the false lumen, resulting in propagation of the dissection. In the very early period of balloon angioplasty, the rate of emergency bypass surgery was high, either as a result of procedure failure or due to acute vessel closure.
In 1988, Stack RS et al described the coronary perfusion balloon that allows passive myocardial perfusion during balloon inflation. Perfusion holes are distributed on the catheter shaft proximal to the balloon. Blood enters through the holes and exits distally from the wire lumen, perfusing the distal artery bed beyond the inflated balloon. Early results were encouraging in terms of improving the hemodynamic condition of the patient or reducing the angiographic severity of the dissection.

The laser balloon was another modality that was proposed for sealing severe coronary dissections and reversing abrupt closure. It works by heating tissues with an Nd:YAG laser during balloon inflation and welding plaque-arterial wall separation. However, restenosis following successful treatment with the laser balloon was relatively high. The experimental device was discontinued before entering the clinical market.

Significant improvement in clinical outcome and reduction in major complications were not seen until coronary stents were introduced to clinical practice. This was shown when 1559 consecutive patients in the 1997-1998 Dynamic Registry who were having percutaneous interventions including use of stents in de novo lesions were compared to 2431 patients in the 1985-1986 National Heart, Lung, and Blood Institute (NHLBI) Registry of patients undergoing PTCA in the prestent era. Patients in the Dynamic Registry were on average older, clinical presentation was more unstable and lesions were more complex than patients in the NHLBI PTCA registry. Coronary stents were used in 70.5% of patients in this early era. Procedural success was higher in the Dynamic Registry (92.0% vs 81.8%; \( P < 0.001 \)) and the rate of major in-hospital complications was lower (4.9% vs 7.9%; \( P = 0.001 \)) compared to the NHLBI registry. Similarly, the 1-year rate for coronary artery bypass grafting (CABG) was nearly cut in half in the early stent era (6.9% vs 12.6%; \( P = < 0.001 \)) compared to the prestent era.

In contemporary percutaneous coronary interventions, the in-hospital major cardiac event rate is very low compared to that of the balloon angioplasty era.

**Predictors of Procedural Complications With Balloon Angioplasty**

Several angiographic and clinical predictors have been found to be associated
with balloon angioplasty procedural complications. In 1988, new American College of Cardiology/American Heart Association guidelines on PTCA emerged. The guidelines described lesion morphologies that can affect both the success and complication rates with PTCA. These angiographic characteristics were grouped into three types: A, B, and C reflecting an anticipated low, moderate, or high procedural risk (Table 28-1). Ellis et al assessed the procedural outcome in patients with multivessel disease undergoing PTCA. Three hundred and fifty consecutive patients (1100 stenoses) from 4 clinical sites were analyzed. A modified ACC/AHA score was applied whereby type B lesions were sub-grouped into type B₁ (having 1 type B characteristic) and type B₂ (having ≥2 type B characteristics). The distribution was as follows: type A, 28.7%; type B₁, 34.1%; type B₂, 26.6%; and type C, 10.6%. The influence of lesion characteristics according to the modified score on the procedural success and complication rates are shown in Figures 28-4 and 28-5.

In-hospital mortality was 1.1% in this study. Major ischemic complications (death, myocardial infarction, or emergency bypass surgery) occurred in 30 patients (8.6%). The only variables that were independently predictive of procedural outcome were the modified scoring system and the presence of diabetes mellitus. Consequently, this modified ACC/AHA score
became widely applicable. However, as experience matured, there was practically less reliance on a scoring system and more on lesion-specific morphologic characteristics to predict clinical outcome with angioplasty.\textsuperscript{42}

In a review of databases of patients undergoing PTCA, Kleiman et al\textsuperscript{43} reported the multivariate predictors of complications. It was evident that clinical factors such as acute coronary syndrome presentation played an important role in increasing the complication risk by creating a thrombogenic milieu. Other clinical factors included female gender, age, diabetes, chronic renal failure, low ejection fraction, and jeopardy score.

\section*{Restenosis}

\subsection*{Occurrence of Restenosis With Balloon Angioplasty}

Since the early days of PTCA, it became readily apparent that longterm efficacy after a successful procedure was primarily limited by recurrence of the original lesion. The definition of angiographic restenosis evolved over time. In one of the early reports of the PTCA registry,\textsuperscript{44} Holmes et al applied the definition of an increase of at least 30\% from the immediate post-PTCA stenosis to the follow-up stenosis or a loss of at least 50\% of the gain achieved at PTCA. In 557 patients with successful PTCA and follow-up angiography in 84\%, the restenosis rate was reported as 33.6\% of patients. In another study of patients who underwent elective PTCA to native coronary arteries between July 1980 and July 1984\textsuperscript{45} and angiographic follow-up in 57\%, angiographic restenosis was seen in 302 patients (30.3\%), according to the more traditional definition of luminal narrowing greater than 50\% at the time of follow-up angiography. A more complete angiographic follow-up rate of 90\% was achieved in the CAVEAT trial that randomized 1012 patients to directional coronary atherectomy versus percutaneous balloon angioplasty.\textsuperscript{46} Based on the classic definition of greater than 50\% diameter stenosis 6 months after an initially successful procedure, the restenosis rate was 57\% in the balloon angioplasty group. This rate was viewed as surprisingly high at the time of study publication, but it was probably more reflective of the true incidence of angiographic restenosis with balloon angioplasty.

The clinical relevance of angiographic restenosis is measured in terms of associated anginal symptoms, demonstration of ischemia and/or the need for
target lesion revascularization (TLR). Binary restenosis according to the classic definition of lesion recurrence ≥50% in diameter stenosis does not always result in TLR. Hemodynamically significant lesions usually correlate with a diameter stenosis ≥70%. We analyzed 3363 patients who had a successful elective balloon angioplasty procedure at Emory University Hospitals between 1980 and 1990 and who had a repeat angiographic evaluation for different indications at 4 to 12 months. Angiographic restenosis was seen in 1570 patients (47%). In patients with restenosis, 71% had angina versus 39% in patients without restenosis ($P < 0.0001$). At 6 years, the survival in patients with and without restenosis was not statistically different (93% vs 95% respectively $P = 0.16$). These data support the well-accepted notion that restenosis after PTCA does not increase short- or long-term mortality.

**Pathophysiology of Restenosis**

Our understanding of restenosis following coronary interventions continues to evolve. Indeed, despite the fact that many mechanisms have been elucidated, many others remain obscure or incompletely understood. The most accepted theory is that coronary arteries dilated with a balloon are prone to restenosis through acute lumen loss from elastic recoil and through late loss from intimal hyperplasia and negative vessel remodeling. IVUS technology has also helped shed some light on the different patterns of remodeling that can occur after angioplasty and the complex nature of the restenotic process.

Restenosis occurs in response to deep arterial wall injury to the intima and media which often creates a strong thrombogenic response. Lesion-specific characteristics as well as regional flow dynamics and wall shear stress contribute to the extent of injury. Longitudinal plaque fissures that commonly occur with balloon angioplasty expose the subendothelial and medial components including collagen, elastin, and smooth muscle cells to the circulating blood. Platelets deposit and aggregate at the site of balloon injury and release various cytokines, chemokines, and growth factors. Thromboxane A2, a very powerful platelet aggregator and vasoconstrictor, is released. Platelets also release platelet-derived growth factor, transforming growth factor-β1, and insulin-like growth factor 1. Inflammatory cells also
release a wide variety of mitogens. Thrombin, which is the most potent known platelet activator, plays a key role following balloon injury and endothelial denudation. Thrombin activity and thrombin receptor expression are upregulated. Thrombin facilitates several biologic responses that can induce vascular lesion formation, including being a direct smooth muscle mitogenesis. Growth factors and mitogens, in turn, will stimulate cell migration and proliferation. Vascular smooth muscle cells will migrate from the media to the intima and deposit extracellular connective tissue matrix proteins. This results in what is referred to as intimal hyperplasia.

Geometric remodeling occurs after balloon expansion, as the area circumscribed by the internal elastic lamina increases. Beyond acute lumen loss, however, the mechanism that leads to chronic remodeling after balloon injury is not very well understood. In de novo atherosclerosis, compensatory vessel enlargement occurs in the early stages in response to progressive plaque expansion. Following balloon angioplasty, the same mechanism of chronic positive arterial remodeling can be instigated by the release of proteolytic enzymes as part of the inflammatory process caused by the balloon injury. But arterial remodeling following balloon angioplasty can also consist of chronic arterial constriction. It is the magnitude of neointimal proliferation and hyperplasia, as well as the degree and direction of geometric remodeling that will determine which lesions will progress to clinically important restenosis following balloon angioplasty. Elastic recoil and geometric remodeling are thought to be virtually eliminated by coronary stenting.

**Temporal Features of Restenosis**

Restenosis following coronary balloon angioplasty usually occurs within the first few months, most commonly between 6 and 12 weeks. Noboyushi et al studied 229 patients with coronary angiography on day 1 and again at 1-, 3-, and 6-month intervals, and at 1 year after successful PTCA. The authors concluded that restenosis is most prevalent between 1 and 3 months and rarely occurs beyond 3 months. We have shown that if a lesion treated with balloon angioplasty does not recur within the first few months, the chance of restenosis thereafter is dramatically reduced to less than 3%. It is very unusual for restenosis to present as an acute myocardial infarction. Rather,
the recurrence of a lesion treated with angioplasty is often uncovered by the reappearance of symptoms or by functional testing.

**Predictors of Restenosis**

The risk factors that could potentially play a role in restenosis are many and range from clinical, angiographic, morphologic and procedural variables to biologic and geometric variables. The mechanism of restenosis following balloon angioplasty is so complex that to this date many of these factors remain poorly defined or totally unknown. It is likely that a confluence of factors has a synergetic effect in causing restenosis. Previous studies that have attempted to identify the importance of clinical variables have found some that correlated with restenosis, such as unstable angina, insulin-dependent diabetes, chronic hemodialysis, hyperlipidemia, hypertension, and prior restenosis. Angiographic variables that seem to increase the risk of restenosis following balloon angioplasty include long lesions, ostial and bifurcating lesions, small vessels with diffuse disease, total occlusions, and degenerate saphenous vein grafts. The predictive power of many of these variables is poor and derived from small studies. The one concept that is probably most accepted is that achieving a larger lumen after angioplasty favors a lower restenosis rate. This may be explained by the fact that for the same degree of intimal hyperplasia, a larger residual lumen will less likely cause significant luminal renarrowing. The theory of “bigger is better” is probably unrelated to the type of device used in a percutaneous coronary intervention.

**Prevention of Restenosis**

During the PTCA days, numerous studies were conducted in an effort to find a pharmacologic solution to restenosis following balloon angioplasty. These studies tested agents that could alter 1 or more of the multiple pathways that are believed to play a role in the restenotic process. Although many animal studies showed promising results, human studies were largely disappointing. Probulcol, an agent with antioxidant and lipid-lowering properties, and AGI-1067, a metabolically stable modification of probucol, may reduce restenosis if administered a few weeks prior to balloon angioplasty. Cilostazol, an antiplatelet agent and an inhibitor of intracellular
phosphodiesterase activity, has been shown to reduce restenosis following balloon angioplasty.\textsuperscript{78} In addition, in the randomized Cilostazol for R\textsc{E}STenosis (CREST) trial,\textsuperscript{79-81} cilostazol was shown to reduce restenosis when used as adjunct therapy with bare-metal stenting.

**PERCUTANEOUS BALLOON ANGIOPLASTY IN THE DRUG-ELUTING STENT ERA**

Since Andreas Gruentzig performed the first coronary balloon angioplasty on a living human in September of 1977, a balloon remains a fundamental tool in almost any percutaneous revascularization procedure.

As previously mentioned, stents have significantly reduced the problem of acute closure or threatened vessel closure. Incrementally, bare-metal and subsequently drug-eluting stents have reduced the problem of restenosis. However, in some situations, percutaneous coronary interventions still rely on POBA. Some examples include:

- The use of a plain balloon or a cutting balloon in a bifurcation lesion with disease in the ostium of the side branch without main branch stenosis, particularly if the strategy is to avoid stenting the side branch and encroachment on the main branch.
- Treatment of in-stent restenosis.
- Small vessel lesions.
- Distal lesions in which severe proximal tortuosities, especially with calcifications, prohibit the advancement of a stent.
- Poorly dilatable lesions in which placing a stent is felt to be inadvisable because of the risk of poor stent expansion.
- Some bifurcating lesions, when a balloon result is adequate and a stent is avoided to prevent jailing of the side branch.
- Treatment of lesions at the anastomosis of the left internal mammary artery (LIMA) or more distally in the native artery. In such instances, advancing a stent in a tortuous LIMA may be difficult. Moreover, data suggest that the longterm result with stenting is not favorable over
ballooning in LIMA anastomosis lesions.
• Rare situations in which prolonged antiplatelet therapy is contraindicated, such as in the presence of severe thrombocytopenia, the potential for active bleeding, or the anticipation of certain types of nonelective surgeries post angioplasty.

These examples, as well as others, lead to the performance of percutaneous coronary angioplasty without placing a stent. With that in mind, the interventionalist needs to be familiar with what to expect from a balloon result both in the short and long term.

SPECIAL LESION SUBSETS

Ostial Lesions and Bifurcating Lesions

The current era of stent and new technology has considerably limited the use of balloon angioplasty in aorto-ostial lesions. This stems from the fact that aorto-ostial lesions in locations such as the right coronary artery posed a big challenge for balloon technology. In one study from the pre-stent era involving 53 patients who underwent percutaneous transluminal angioplasty of a right coronary artery ostial stenosis, the procedure success rate was only 79%. Emergency coronary artery bypass grafting was needed in 5 patients because of abrupt closure. One-year follow-up revealed clinical recurrence of angina in 20 patients (48%) and restenosis in 16 (38%). A non-randomized study that compared different strategies, including balloon angioplasty in right coronary artery ostial lesions, reported that stenting provided the best short- and long-term outcomes. However, even with the current use of drug-eluting stents, aorto-ostial lesions are still associated with poorer long-term outcomes than ostial LAD and nonostial coronary lesions, as evidenced by a significantly higher restenosis and lower cardiovascular event-free survival rates.

For non–aorto-ostial lesions located at bifurcation points, such as the ostium of the left anterior descending or circumflex arteries, stenting poses a particular challenge. Possibilities of an untoward outcome in such situations include a proximal stent edge tear that could propagate into the left main artery, plaque shift into the adjacent large vessel, and complete or partial
jailing of the bifurcating artery. Carina shift is another potential problem that seems to be more important than once thought. In a volumetric IVUS analysis of bifurcating lesions, carina shift was found to be the major mechanism of side branch ostial compromise after main vessel stent implantation. There was no clear correlation with plaque shift in this study.

These problems can at times be circumvented by avoiding use of a stent altogether. For example, one way to approach an ostial left anterior descending artery would be to debulk the lesion with rotational atherectomy prior to balloon angioplasty. Use of a stent would follow only if a suboptimal result was obtained post balloon angioplasty. Another approach would be to use cutting balloon angioplasty with provisional stenting. No randomized trials have been performed to test these different strategies. But in current practice, the vast majority of cases are performed using coronary stenting in order to reduce the chance of future revascularization procedures. Exceptions include cases of isolated branch ostial lesions such as in diagonal or obtuse marginal arteries where placing a stent to cover the ostium fully may result in stent protrusion into a non-diseased main vessel. A stent that is positioned slightly more distally in the side branch artery will miss the ostium. In such instances, stenting could be avoided and conservative medical management or provisional cutting balloon angioplasty could be considered.

Ostial lesions have been excluded from the landmark randomized trials of drug-eluting stents. The efficacy of such stents in challenging anatomic subsets is being studied from large post-market registry data.

**Long Lesions**

A long lesion with diffuse disease is one of the most powerful predictors of a reduced procedural success rate, increased risk of hemodynamically important dissections, and acute closure as well as increased risk of restenosis with balloon angioplasty. Treatment of long lesions with long balloons and prolonged balloon inflations may be correlated with improved success rate without influencing the restenosis rate. Until the emergence of coronary stents, adjunctive debulking devices such as the excimer laser and rotational atherectomy have been applied to long lesions but without achieving significant gains in procedural success or restenosis. It was not until the introduction of coronary stents that the chance of dissections in long
lesions was dramatically reduced and the restenosis rate significantly dropped, especially with drug-eluting stents which seem for now to be the treatment of choice in long coronary artery obstructions.

**Diffuse Small Vessel Coronary Artery Disease**

Small vessel disease and diffuse coronary atherosclerosis can be seen in a number of clinical situations, but most importantly in patients with diabetes mellitus. Chronic hyperglycemia sets the stage for a proinflammatory and prothrombotic state and increases the risk of exaggerated neointimal hyperplasia and diffuse coronary artery disease and a potential for inferior clinical outcome with revascularization.

Optimal medical therapy may be the ideal approach in patients with stable small vessel coronary artery disease when considering the limitation of the invasive percutaneous approach. But in acute coronary syndrome or when symptomatic patients fail medical therapy, small vessels, especially with coexisting diffuse disease, pose a genuine challenge. In general, percutaneous revascularization of small coronary vessels carries a lower chance of success and a relatively higher risk of major adverse cardiac events compared with revascularization of large vessels, specifically when located in proximal coronary segments. Consequently, a distinction must be made between a small vessel supplying a small amount of myocardium and a proximal lesion in a small artery that supplies a large amount of myocardium, either because it travels a considerable length or it supplies important collaterals. In the first case, where the amount of myocardium in jeopardy is small, the benefit from an angioplasty may not outweigh the risks, and medical therapy is most often the first choice. The second case, in which a large amount of myocardium is at risk, presents a challenging problem for the interventionalist. When performing percutaneous revascularization to a small vessel, especially in association with diffuse disease, options are limited because of the risk of dissection, acute closure, and restenosis with balloon angioplasty, as well as debulking techniques. Furthermore, deployment of stents in this situation is fraught with the risk of underexpansion and the possibility of subacute thrombosis. Another concern is the risk of perforation when stents are oversized and overexpanded in small vessels. In the early stent era, the French multicenter registry reported a subacute stent thrombosis rate of 10% in vessels with diameters less than 2.5 mm. Comparison of balloon
angioplasty of small coronary vessels with bare-metal stenting can be derived from sub-analysis of randomized trials such as BENESTENT, which showed that decreasing vessel size was associated with an increasing risk of cardiac events for both the stent and balloon angioplasty groups. A more contemporary analysis of bare-metal stents versus drug-eluting stents in vessels ≤2.25 mm demonstrated the mid-term advantage of drug-eluting stents over bare-metal stents; however the benefit was not sustained at 5 years. In particular, diffuse atherosclerosis in patients with diabetes mellitus is a strong risk factor for restenosis following coronary stenting, despite the recent advances in drug-eluting stent technology.

Coronary artery bypass surgery is also inadequate, especially in terms of longterm graft patency when the target arteries are complex and diffusely diseased. A recent meta-analysis of observational studies reporting on the combination of coronary endarterectomy with bypass surgery in patients with extensive diffuse coronary atheroma reported an increased 30-day mortality and postoperative MI compared with coronary artery bypass surgery alone. Furthermore, angiographic patency at follow-up was reduced in the adjunctive coronary endarterectomy group. All these limitations stress the need to properly evaluate the clinical indication while considering any of the available revascularization strategies.

**Saphenous Vein Grafts**

One of the main limitations of coronary artery bypass surgery is the lifespan of the saphenous vein graft. At 10 years post-surgery, more than half of these bypass grafts are severely diseased or completely closed. Since the early days of percutaneous transluminal revascularization, balloon angioplasty of saphenous vein grafts was viewed as a logical approach in selected cases compared with the less-attractive alternative of repeat bypass surgery. However, the procedure was associated with more significant risks than balloon angioplasty of native coronary vessels. The short-term risks included distal embolization, no-reflow phenomenon, and myocardial infarction. Angiographic predictors of procedural complications included a diffusely diseased vein graft, presence of thrombus, irregular or ulcerated lesion surface, large plaque burden and marked lesion eccentricity. Older saphenous vein bypass grafts were prone to more complications. In the long term, there was a significant occurrence of late cardiac events and a
restenosis rate that could exceed 50%. It became clear that balloon angioplasty treatment of saphenous vein grafts was a suboptimal solution that had significant limitations.

With the advent of stents, the SAphenous VEin De Novo (SAVED) randomized trial compared the safety and efficacy of the Palmaz-Schatz stent with balloon angioplasty in 220 venous bypasses. There was no significant improvement in angiographic restenosis, which was the primary endpoint of the study. However, stenting was associated with more favorable procedural outcomes, a larger gain in luminal diameter, and a reduction in major cardiac events. This advantage, seen with stenting, led to the widespread use of stents in saphenous vein grafts. The emergence of distal embolic protection technology has allowed the treatment of more complex saphenous vein graft disease with safer procedural outcome.

The comparison of bare-metal stents to drug-eluting stents in the treatment of saphenous vein bypass lesions has yielded conflicting results. In the absence of large randomized trials, one can derive some limited conclusions from the existing studies. A report from a US multicenter registry suggests that the short-term benefit of drug-eluting stents in SVG may be limited to SVGs < 3.5 mm in diameter with loss of target vessel revascularization benefit after 9 months. The long-term results of percutaneous intervention in saphenous vein grafts have remained suboptimal compared to the outcome in native vessels. One important reason is that the long-term failure of saphenous vein grafts post intervention correlates not only with restenosis, but also with the natural course that these bypasses follow in the years following surgery.

**Balloon Angioplasty Through a LIMA Bypass**

The challenge posed by performing percutaneous angioplasty to a native artery via an internal mammary artery bypass is primarily correlated with the tortuosities of the conduit. Severe bends may be prohibitive and bear the increased risk of acute closure of the bypass during angioplasty. Moderate tortuosities may allow advancement of a low-profile balloon without permitting advancement of a stent, therefore limiting the chance of a bailout for acute vessel closure during angioplasty. Relatively straight internal mammary conduits are usually approachable with stents. A good balloon result at the anastomosis with the native vessel does not necessarily need to
be followed by stenting.

A retrospective analysis\textsuperscript{108} of 50 patients who underwent percutaneous revascularization of the LAD artery via a LIMA bypass (16 patients) or at the anastomosis site (34 patients), reported a success rate of 88%. The main reasons for failure were lack of adequate guide catheter support and excessive tortuosities of the LIMA. Thirty-four of the successfully treated patients were restudied with angiography. Restenosis was documented in 14 patients (41%). The restenosis rate was significantly higher if stenting was performed (65% vs 18%; $P = 0.005$). In particular, lesions at the anastomosis did better with balloon angioplasty compared to stenting (restenosis rate 14% vs 80%; $P = 0.001$). Other studies have also reported good short- and long-term outcomes with balloon angioplasty.\textsuperscript{109} A study specifically addressed the LIMA to LAD anastomotic site in 56 consecutive patients.\textsuperscript{110} Balloon angioplasty alone was successful in 15 patients (28.8%), and stenting was required in 37 patients (71.2%). Procedural results were similar in the 17 patients where bare-metal stents were used and in the 20 who received drug-eluting stents. At 1 year, there was no significant difference in target lesion revascularization with BMS and DES (26.6% vs 25% respectively; $P = 0.99$). Two late stent thrombosis were reported after placement of drug-eluting stents. Target lesion failure was lower with plain balloon angioplasty (6.7%) although this was not statistically significant. Therefore, a good acute result following plain balloon angioplasty of a LIMA to LAD anastomotic lesion without stenting may be considered an acceptable strategy.

**CONCLUSION**

Ever since the birth of transluminal coronary angioplasty, a balloon remains a fundamental tool in almost any percutaneous revascularization procedure. This is true even in the event of primary stenting, because most stents are balloon expandable. It is also true when adjunctive methods such as rotational atherectomy are used, because these rarely consist of standalone devices. A balloon is used to predilate a lesion or postdilate a stent. The evolving technology has resulted in newer modalities of treatment. Stents have significantly reduced the problem of acute closure or threatened vessel closure. Drug-eluting stents, in particular, have dramatically improved the problem of restenosis. Significant advances have also been witnessed in
adjunctive pharmacotherapy. Bypass surgery techniques are going through continuous refinement and the approach to secondary prevention has become more aggressive. Despite the fact that the bearing of the balloon has diminished with time, in some situations, percutaneous coronary revascularizations still rely on “plain old balloon angioplasty.”

**MULTIPLE CHOICE QUESTIONS**

1. A 62-year-old woman taking oral hypoglycemic agents for known diabetes presents with a 2-h history of retrosternal chest pain and nausea to an emergency department without a cardiac catheterization laboratory. On presentation, she did not appear to be in any distress. Her vital signs: BP 135/88 mm Hg, HR 90/mn regular, respiratory rate 18/minute, and she was afebrile. Her ECG is shown in **Figure 1**. She was started on anti-platelets and anti-thrombotic agents and was transferred to the cardiac
catheterization laboratory where angiographic images showed a small area of inferior akinesis and a non-dominant right coronary artery. The left system is shown in Figure 2. The totally occluded second obtuse marginal was pre-dilated then stented with a 2.75 × 23 mm drug-eluting stent. The angiogram taken after stent deployment is shown in Figure 3. The interventional cardiologist administers intracoronary nitroglycerin without appreciable improvement in the lesion distal to the stent. At this point the most appropriate next step is to:

A. Dilate the lesion distal to the stent with a 2.0 mm non-compliant balloon.
B. Directly stent the lesion distal to the stent with a 2.25 mm × 12 mm drug-eluting stent.
C. Withdraw the wire and obtain a coronary angiogram.
D. Use a thrombus aspiration catheter.

2. A 57-year-old man presented with unstable angina. He receives treatment for chronic hypertension and dyslipidemia. He has a strong family history of coronary artery disease. At coronary angiography he was found to have a bifurcating lesion in the left anterior descending artery (LAD)/diagonal distribution (Figure 4). The rest of his coronary arteries are free of hemodynamically significant coronary obstructions. His ejection fraction is 60%. The revascularization options were discussed with the patient who consented to percutaneous coronary intervention. In planning for the procedure, which of the following options would be considered INCORRECT?
FIGURE 2
FIGURE 4

A. Apply the Nordic and BBC trial protocols by stenting the LAD first followed by provisional dilatation of the side branch with a conventional balloon, then T-stenting if necessary.
B. Apply the AGILITY trial methodology by stenting the LAD first followed by provisional dilatation of the side branch with a scoring balloon then stenting if necessary.

C. Plan bifurcating stenting using the mini-crush technique.
D. Plan bifurcating stenting using the TAP technique (T And Protrude).

3. A 73-year-old woman receives treatment for hypertension and dyslipidemia. She presents to her primary care physician for a checkup. She is totally asymptomatic from the cardiac standpoint and has a good exercise tolerance. Her ECG shows minor non-specific ST-T wave
abnormalities. Her physician orders stress echo. Baseline images show a normal left ventricular systolic function with no regional wall motion abnormality and significant anterior wall hypokinesis at peak stress. A cardiac catheter identifies a focal non-calcified 70% proximal LAD lesion. In evaluating the management options, which of the following statements is correct?

A. The COURAGE trial cannot be applied in this situation since proximal LAD disease was excluded.
B. The COURAGE nuclear substudy showed that ischemia reduction ≥5% is associated with lower risk of death/MI.
C. LIMA to the LAD in this patient is preferable to percutaneous coronary intervention because it confers a survival benefit at 1 year.
D. Percutaneous coronary intervention plus optimal medical therapy in this patient is associated with a survival benefit at 1 year compared to optimal medical therapy alone.

ANSWERS

1. C

New unexpected lesions in the course of a coronary intervention should raise the suspicion of a pseudo-lesion. The clue is moderate-to-severe coronary tortuosity at baseline before introducing the guidewire. Pseudo-lesion is the result of straightening of a tortuous coronary artery over the stiff part of the guidewire. It is also referred to as pseudo-narrowing or accordion effect. The differential diagnosis includes spasm, a coronary dissection and thrombus formation/embolization. But if a pseudo-lesion is not suspected or considered in the differential diagnosis, unnecessary interventions may take place, possibly subjecting the patient to inadvertent complications. Pseudo-lesions can be severe and can cause total obstruction of coronary flow with resultant chest pain and electrocardiogram changes. When suspected, the guidewire may be withdrawn while keeping the soft part across the suspected lesion. The soft part of the wire will cause less straightening, therefore improving the angiographic appearance of the pseudo-lesion. In case this is not confirmed, the wire can be safely re-advanced since it is already across the lesion. Figure 5 shows the angiographic appearance of the artery after withdrawing the wire.
2. B

The protocol in the AGILITY trial in complex bifurcation lesions consisted of dilatation of the side branch with the scoring balloon prior to implantation of a drug-eluting stent in the main vessel. Bailout stenting of the side branch was performed after stenting the main branch if the result in the side branch was felt to be suboptimal. Crossing the side branch with a scoring balloon to dilate the struts of a stent is not advisable.

3. B

The COURAGE trial randomized patients with ≥70% stenosis in ≥1 proximal epicardial vessel and objective evidence of ischemia (or ≥80% stenosis + CCS class III angina without provocation testing) to optimal medical therapy (OMT) plus percutaneous coronary intervention (PCI) or medical therapy alone. About a third had proximal LAD disease. The study concluded that PCI added to optimal medical therapy did not reduce risk of death, MI, or other major CV events compared with optimal medical therapy alone (Boden
INTRODUCTION

The technical goal of coronary stenting should be to eliminate or lessen ischemic symptoms in the short/intermediate term and possibly reduce the risk of death or myocardial infarction, while not exposing the patient to excess short- or long-term risk. Yet major adverse cardiac events (MACE) occur in 4% to 20% of stented sites within a year,\(^1,2\) and stent underexpansion\(^3,4\) and axial misalignment (“geographic miss”)\(^5\) account for nearly half of these. Although a discussion of choosing percutaneous intervention instead of bypass surgery or optimal medical therapy alone is beyond the scope of this chapter, we will address various issues to be considered to provide the patient with an optimal technical result.

CHOICE OF VASCULAR ACCESS

Improvements in guide catheter and wire support, as well as balloon and stent deliverability, have facilitated small-caliber device intervention and, in particular, radial access–based intervention. The result has been a dramatic reduction in bleeding complications and red cell transfusion–induced inflammation and perhaps even a reduction in patient mortality under some circumstances (especially primary percutaneous coronary intervention [PCI] for ST-segment elevation myocardial infarction [STEMI]).\(^6\) Except when
anatomy precludes it, radial access should be the preferred route of vascular access. Femoral, brachial, and axillary access can at times be reasonable alternatives.

**ADJUNCT PHARMACOLOGY**

Both antiplatelet and antithrombin therapies are required for safe stent implantation and healing. Aspirin and clopidogrel are usually sufficient antiplatelet therapy for patients with stable ischemic symptoms. Second-generation P2Y\textsubscript{12} inhibitors have been shown to be superior to clopidogrel in unstable angina patients but not, in general, in stable patients.\textsuperscript{7,8}

Although direct thrombin inhibitors have several potential advantages over unfractionated heparin as the requisite antithrombin agent to accompany coronary stenting, with good dual antiplatelet therapy, heparin alone is almost always adequate to prevent complications\textsuperscript{9} and is cost effective.\textsuperscript{10} The situation with STEMI patients is perhaps less clear, with a recent post HEAT-PPCI (Unfractionated Heparin Versus Bivalirudin in Primary Percutaneous Coronary Intervention) meta-analysis showing no difference between bivalirudin and heparin for the end points of death or myocardial infarction, but more stent thrombosis and less bleeding with bivalirudin.\textsuperscript{11} Although disputed by some,\textsuperscript{12} most operators use activated clotting time monitoring to assure satisfactory antithrombin effect (200-250 seconds for the commonly used HemoTec) (Medtronic, Dublin, Ireland system) (the Hemochron [Accriva, Piscataway, NJ] system measures 50 seconds longer),\textsuperscript{13} with higher levels for complex interventions (eg, acute coronary syndrome)\textsuperscript{14} or those requiring multiple guide wires in the same coronary artery.

**SIZING**

**Stent Length**

In general, stents should be chosen to cover the lesion, from (angiographic) “normal to normal” vessel. Assessing where “normal” begins and ends is sometimes challenging, and intravascular imaging can often be helpful. Stent
ends should not be deployed in areas of obvious plaque buildup, in vessel
bends, or ideally in sites compressing thin-capped plaque or areas of necrotic
debris (“lipid-rich plaque”). Subsequent studies have demonstrated that stents should also be deployed to cover the
length of artery traumatized by predilatation ballooning or atherectomy, so as to avoid the “geographic miss” found in the STLLR (Stent Deployment Techniques on Clinical Outcomes of Patients Treated With the Cypher Stent) study that doubled the risk of MACE (Fig. 29-1). For longer lesions, it is often difficult to anticipate the stent length needed. One can use the length of the radiopaque part of the coronary guide wire (30 mm for most) or the known length of the predilation balloon for a “ruler.”

![Figure 29-1](image)

**FIGURE 29-1** A total 1557 patients from 41 US hospitals with protocol-based careful angiographic technique were reviewed to assess the impact of geographic miss on patient outcomes. Longitudinal geographic miss (L-GM) was identified in 47.6% of patients and was associated with more than doubling of risk of target vessel revascularization at 1 year and any GM tripled the risk of MI within that time frame. GM, geographic miss; MI, myocardial infarction; TVR, target vessel revascularization.

**Diameter**
To a large extent, the degree of luminal late loss after stenting is related to biologic processes such as the presence of diabetes and not to the extent of stent expansion (within limits)\(^\text{17}\); hence, the general adage has become “bigger is better.” But how big is big enough? Studies from a decade or more ago reliably found that what appeared angiographically to be a very good stent result (<10% stenosis) not infrequently left the stent undersized, underexpanded, or both when viewed by intravascular ultrasound (IVUS).\(^\text{18}\) In addition, meta-analysis of the 7 moderate-sized randomized controlled trials of IVUS versus angiographic guidance for bare metal stent implantation found that IVUS modestly reduced restenosis\(^\text{19}\); hence, we rely a lot on IVUS findings to answer this question. Importantly, IVUS has shown that balloon postdilation at 14 to 16 atm for a nominally sized stent delivery balloon typically results in the stent achieving only about 75% of predicted (out of the body) diameter (Fig. 29-2).\(^\text{20}\) In the drug-eluting stent era, Hong et al\(^\text{21}\) found that the best IVUS cross-sectional area (CSA) cutoff value discriminating risk of restenosis or no restenosis was \(5.5 \text{ mm}^2\) (length also was a risk factor). However, the implications of achieving that value are not the same for a patient with a 2.25- or 3.5-mm diameter vessel and further leave the patient with an average rather than ideal risk of restenosis. Other criteria have been proposed, ranging from the classic but difficult to achieve MUSIC (Multicenter Ultrasound Stenting in Coronaries) criteria (complete stent apposition and CSA \(\geq 80\%\) of the average of proximal and distal “normal” reference areas\(^\text{22}\)), achieved in only about 60% of cases,\(^\text{23}\) and the easier to achieve \(\geq 55\%\) CSA of the reference segment proposed by Moussa et al.\(^\text{24}\)
FIGURE 29-2 Intravascular ultrasound (IVUS) data from comparing final stent diameter with manufacturer’s predicted stent diameter in patients with direct stenting, balloon predilation, and AngioSculpt predilation in whom Taxus (Boston Scientific, Marlborough, MA) or Cypher (Cordis, Hialeah, FL) stents were implanted. IVUS-based diameters are approximately 75% of “nominal.” Consider also that IVUS overestimates stent size by 10% to 15%. Very similar data can be found for most other coronary stents. (Reproduced with permission from Costa JR, Mintz GS, Carlier SG, et al. Nonrandomized comparison of coronary stenting under intravascular ultrasound guidance of direct stenting without predilation versus conventional predilation with a semi-compliant balloon versus predilation with a new scoring balloon. Am J Cardiol. 2007;100:812-817.)

IVUS studies have also linked poor stent expansion to risk of early stent thrombosis, finding, for instance, increased risk with failure to achieve 80% reference CSA or CSA <5 mm.25-27 Dimensions obtained via optical coherence tomography (OCT) are likely helpful in this regard, because they more closely reflect actual dimension compared with IVUS, which overestimates vessel diameter by 10% to 15%.

However, in the current era of cost containment, IVUS or OCT cannot be
justifiably used in all cases, so many advocate their use principally to clarify angiographic ambiguities, and evaluate pre- or poststent anatomy, and treated lesions that are at high risk of restenosis (diabetes, long lesions) or are anatomically high risk (left main stenosis).

Although perhaps not as well validated as one might like, we favor using angiographic step-up and step-down as a surrogate for adequate stent expansion, as initially put forward by Antonio Colombo’s group\textsuperscript{18} and, more recently, supported by work of Haldis et al.\textsuperscript{28} This approach has led to a 90\% likelihood of successful implant by MUSIC criteria, albeit with an increased risk of OCT-detected small edge dissections.\textsuperscript{29}

**PRETREATMENT: LESION MODIFICATION/DEBULKING**

The role of predilatation/pretreatment before stenting should be to both allow stent delivery and also full expansion, without extending the treatment area via dissection or slippage. Balloon inflation, sized at 0.25 to 0.50 mm less than vessel diameter, usually suffices. Several devices other than plain old balloon angioplasty (POBA) have been proposed to improve the likelihood of achieving this goal, but all come with increased cost and hence should be used judiciously. Of these, perhaps the easiest to use is the AngioSculpt (Angioscore, Fremont, CA). Studies have shown greater stent expansion with pretreatment using this device compared with POBA (eg, 88\% vs 77\% of expected CSA in moderately complex lesions, irrespective of lesion morphology\textsuperscript{20}; Fig. 29-3). It should be noted that there were few heavily calcified lesions in this study, and we and others have encountered difficulties with the device in heavily calcified lesions, including device entrapment.\textsuperscript{30} The Cutting Balloon (Boston Scientific, Marlborough, MA) cuts more deeply and is less deliverable than the AngioSculpt, but in general, it has the same benefits and limitations. Both devices are particularly useful to prevent device slippage in the setting of in-stent restenosis (ISR) and for side branch treatment in conjunction with provisional stenting of bifurcation lesions.
FIGURE 29-3 Intravascular ultrasound (IVUS) data depicting percent nominal minimum stent diameter (MSD) achieved for Taxus or Cypher stents according to predilation strategy and IVUS morphology. (Reproduced with permission from Costa JR, Mintz GS, Carlier SG, et al. Nonrandomized comparison of coronary stenting under intravascular ultrasound guidance of direct stenting without predilation versus conventional predilation with a semi-compliant balloon versus predilation with a new scoring balloon. *Am J Cardiol.* 2007;100:812-817.)

More heavily calcified or difficult to cross lesions often require rotational atherectomy with the Rotablator (Boston Scientific) or Orbital Atherectomy Device (Cardiovascular Systems Inc [CSI], Saint Paul, MN) before stenting. An arc of calcium >180° by IVUS has been associated with poor stent expansion, but this may be hard to predict with angiography alone (suggested with somewhat limited sensitivity and specificity by angiographic calcium visible across the diameter using still frame imaging) and is more common in patients with renal insufficiency and in the elderly. A randomized trial comparing Rotablator (mean burr size, 1.5 mm) versus POBA in calcified lesions before drug-eluting stent implantation showed an increase in acute gain that was largely offset by more late loss and no difference in restenosis or stent thrombosis. However, because poor stent expansion is a risk factor for stent thrombosis and restenosis, atherectomy for lesions at risk
for poor stent expansion may be beneficial.

The CSI speed-expansive rotational atherectomy device competes with the older device, being simpler to set up and use and providing for generally more ablation, but with greater risk of vessel perforation (1.8% in the ORBIT-2 [Evaluate the Safety and Efficacy of OAS in Treating Severely Calcified Coronary Lesions] study).\textsuperscript{34}

We will often resort to a trial of balloon inflation to 6 to 10 atm to see if the vessel “yields” if we are uncertain about the need for atherectomy. Although there is a small risk of creating a dissection without adequate vessel enlargement with this maneuver, atherectomy with the Rotablator seems to be safe in this setting.

A more complete discussion of the role of rotational atherectomy is provided in Chapter 34.

**ROLE OF DIRECT STENTING**

For moderately stenotic noncalcified lesions, direct stenting without predilatation or atherectomy has been advocated, largely as a time- and cost-saving approach (generally about 20% for both).\textsuperscript{35} A recent meta-analysis of randomized controlled trials evaluating this approach found a significant 20% to 25% reduction in periprocedural myocardial infarction or death, but no difference in late target vessel revascularization.\textsuperscript{36} The downsides to this approach are occasionally being unable to deliver the stent, potentially misjudging the length of the stent due to lack of the balloon marker “ruler,” and rarely, discovering a difficult-to-dilate lesion after the stent has been placed. Used judiciously, this approach appears to have merit.

**PROPER MANAGEMENT OF STENT EDGES**

Both failing to fully dilate the edges of a stent and dilating beyond the edges (“geographic miss”) are fairly common.\textsuperscript{5} To minimize risk of edge trauma, the delivery balloon should generally be inflated to only 10 to 14 atm (the low end for somewhat oversized stents). Higher pressure inflation risks “dog-
boning” and edge dissection, because the balloons on which contemporary stents are mounted are semi-compliant. Postdilatation is generally required unless angiographic step-up/step-down has already been achieved. Noncompliant balloons with a diameter approximately 0.25 mm larger than apparent vessel diameter should be used, inflated to nearly maximal pressure, for postdilatation. High-quality angiographic imaging (Stent Boost [Philips, Amsterdam, the Netherlands], or equivalent) should be used to assure that dilatation (outside edge of balloon marker) has extended to, but not beyond, the stent edge.

ROLES OF FRACTIONAL FLOW RESERVE, IVUS, OCT, AND INFRARED SPECTROSCOPY

The role of adjunctive imaging techniques is addressed in Chapter 26. Fractional flow reserve (FFR) has been shown in several setting to be highly useful in discerning which lesions require revascularization, but the optimal role of the 3 imaging modalities remains uncertain for routine and uncomplicated situations. We favor the use of IVUS for high-risk anatomic situations (eg, left main stenoses), for use in settings at high risk for restenosis (eg, long lesions, small but important vessels, diabetics), evaluation of the etiology of ISR, and in situations of ambiguous anatomy before or after PCI by angiography alone. OCT yields much better near-field resolution, often finds poststent luminal disruptions, and may be helpful in assessing which persistent dissections need further stents (Fig. 29-4). Infrared spectroscopy allows for identification of lipid-rich plaque, the placement of a stent into which leads to an increased risk of debris embolization.
FIGURE 29-4 A. Optical coherence tomography (OCT) image depicting measurement technique for dissection width. B. Relationship of risk of major adverse cardiac events (MACE) with dissection width as assessed by OCT.39

INFLOW AND OUTFLOW

Both inflow and outflow narrowing, variably defined, have been found to be associated with heightened risk of stent thrombosis, although they are generally less powerfully predictive than poor stent expansion, residual dissections, and slow flow.38 For example, using a definition of >40% plaque burden by IVUS, Alfonso and colleagues found inflow and or outflow narrowing in most of their stent thrombosis patients.40,41 Similarly, Fujii et al42 found reference vessel CSA <4 mm² by IVUS to be an independent measure of risk (67% of stent thrombosis cases vs 9% of controls).42 Some have also advocated poststent FFR <0.90 as an overall (stent plus adjacent vessel) correlate of MACE.43 Taken together and admitting the limitations of angiography, one should generally attempt to treat all “significant” narrowing
that might potentially impact stent-related blood flow.

**EMBOLIC PROTECTION**

Embolic protection is discussed in Chapter 62.

**PRIORITIZING AND ORDERING LESION TREATMENT**

The issue of optimally sequencing lesion treatment often arises when treating patients with multivessel disease. Generally, it is best to treat the most severe lesion in a major vessel first, so if the procedure has to be halted at that point, at least the worst of the ischemia should have been eliminated. There are at least 2 exceptions, however. First, if the most severe lesion is such that if it were to close for more than a short while hemodynamic instability would likely result and one could lessen that risk by treating another lesion, then the latter lesion should be treated first. Second (and this is less common with improving chronic total occlusion [CTO] results), if there is a CTO that, if unsuccessfully treated, would prompt referral for coronary artery bypass grafting, then the CTO should be attempted first. In general, the overall revascularization goal should be a physiologic SYNTAX (Synergy Between Percutaneous Coronary Intervention With Taxus and Cardiac Surgery) score of <8.44

**DELIVERY ISSUES**

*Guide Catheters and Adjuncts*

A key to stent delivery is adequate guide catheter support. Various diameters (generally 5-8 Fr) and shapes are available for radial and femoral approaches, and detailed selection is somewhat beyond the scope of this chapter. Active (deep seating as necessary) support with 5- to 6-Fr catheters has generally superseded passive (catheter placed at or outside the coronary ostium only)
support as a means to decrease access site complications. Without deep seating, support is largely dependent on 3 factors: guide catheter diameter, coaxiality and fit into the coronary ostium, and support off the contralateral aortic wall as reflected by contact length and the cosine of the angle of engagement. We generally use 6-Fr catheters unless the lesion requires bulky equipment (eg, a 1.75-mm Rotablator burr or 2 stents are a very tight fit in a 0.71-inch 6-Fr guide catheter [any bending or kinking of the guide catheter may make device advancement impossible]). From the radial approach, we generally favor extra support/extra backup (XB/EBU) catheters for the left coronary artery (LCA). Right coronary access requires a greater variety of catheters to provide support for downward, horizontal, and upward takeoffs. Specialty radial catheters such as the Tiger and Ikari series are also often very useful. From the femoral approach, XB/EBU catheters generally supply adequate support for the LCA, but AL 1.5-2 catheters are sometimes required. JR4-5 or Amplatz AR1-2, ALR, or AL1 catheters are useful for right coronary artery lesions. A summary of radial guide catheter use from a relatively recent international registry is provided in Table 29-1. A useful tip when a right coronary guide catheter appears to be engaged and coaxial in the left anterior oblique view but is not providing adequate support is to check in the 30° right anterior oblique view to be sure it is “pointed at” the operator (unless the right coronary originates anteriorly). The availability of several “mother and child” devices such as the Guideliner catheter (Vascular Solutions, Minneapolis, MN) has greatly enhanced device delivery (Fig. 29-5). These can be placed over the coronary guide wire or drawn in over a (previously inflated) coronary balloon, fairly deeply into the coronary as long as proximal stenosis is absent. In challenging cases where the stent “hangs up” on rough/calcific plaque proximal to the target, often the Guideliner can be advanced across the lesion, with the stent brought forward and then “unsheathed” and deployed after the Guideliner is withdrawn proximally. It is important to remember, however, that use of this device reduces the internal diameter of the guide catheter by about 0.012 inch. An alternative approach that is less expensive but generally provides less support is to use a buddy wire in the target or adjacent coronary artery.

Guide Wires

Guide wire use is reviewed in detail in Chapter 27. Specific to stent delivery, however, “workhorse” wires such as the Prowater (Abbott Vascular, Santa Clara, CA), Runthrough (Terumo, Somerset, NJ), BMW (Abbott), or Sion Blue (Abbott) generally provide sufficient support. Stiffer wires (eg, Grand Slam [Abbott], others) are sometimes needed to deliver stents distally or through areas of tortuosity, but it must be recalled that they also may cause “wire bias,” forcing the stent into the inner curvature of the artery. When that aspect of the vessel is roughened or calcified, this may actually impair stent delivery.

Completion Angiography

After stent implantation and postdilatation, angiography should be performed in 2 (nearly) orthogonal views, specifically looking for guide catheter trauma (common if the guide catheter jumped forward when initially engaging the coronary or was pulled forward during the removal of stiff or partially engaged equipment), stent expansion and edge trauma, and guide wire trauma (eg, perforation, particularly with hydrophilic guide wires). The guide wire should have been removed at least prior to the last injection so as not to be fooled by missing a dissection that had been “propped open” by the guide wire. Angiography should also be somewhat prolonged so as to allow inspection of sites where the guide wire tip might have caused an occult...
perforation. Management of complications occurring before or noted with completion of angiography is covered elsewhere in this text. However, it is important to note that the operator must remain vigilant and the catheter lab must be equipped with covered stents, coils, injectable thrombin, and pericardiocentesis equipment to manage the occasional tamponade, with intra-aortic balloon pump and Impella (Abiomed, Danvers, MA) support devices for hemodynamic compromise, as well as a wide variety of coronary stents, fibrinolytics, and intravenous antiplatelet agents to manage more common dissection- and thrombus-related complications. Finally, plans to rapidly activate the surgical team must always be in place.

OTHER IMPORTANT ISSUES

Prevention of radiation-related complications is dealt with in Chapter 11, and prevention of contrast-induced nephropathy is discussed in Chapter 19. Treatment of especially complex anatomy and management of PCI-related complications are discussed in Chapters 37 to 42.

**MULTIPLE CHOICE QUESTIONS**

1. When used for pretreatment before stenting, how does use of the AngioSculpt compare to balloon angioplasty?
   A. With comparable-sized devices, resultant cross-sectional areas (CSAs) are similar.
   B. With comparable-sized devices, cross-sectional area is greater with AngioSculpt regardless of lesion complexity.
   C. With comparable-sized devices, results with AngioSculpt are better in calcified or long lesions, but not other lesions.
   D. When used with comparable-sized devices, high-pressure balloon angioplasty generally results in larger CSA than AngioSculpt.

2. After inflation to 16 atm with typical balloons, what is the average ratio of in vivo versus ex vivo minimum lumen diameter?
   A. 0.75
   B. 0.85
   C. 0.95
   D. 1.00

3. To minimize the risk of DES restenosis using IVUS, what is the best approach to follow?
   A. Attempt to achieve minimal in-stent cross sectional area of >5.5 mm² for all stents.
   B. Attempt to achieve minimal in-stent cross sectional area of >5.5 in vessels with reference diameters 2.25-3.00 mm.
   C. Attempt to achieve in-stent cross sectional area of >80% of adjacent normal reference segments.

4. Which of the following imaging modalities most closely approximates in-vivo vessel dimensions?
   A. QCA
B. IVUS
C. OCT
D. CTA

5. Which of the following is least closely related to the risk of stent thrombosis?
   A. Outflow narrowing.
   B. Poor stent expansion.
   C. Residual dissection.
   D. Slow flow.

Drug-Eluting Coronary Stents

Arie Steinvil
Ron Waksman

INTRODUCTION

Several major leaps in technology and immense research and development have led to the current wide use of drug-eluting stents (DES). Stents were initially developed to reduce the high rates of restenosis and acute vessel closure following balloon angioplasty–induced endothelial cell denudation and coronary artery medial layer tearing. The first bare metal stent (BMS) implantation in a coronary artery was reported by Sigwart et al in 1987, and the first randomized trial comparing balloon angioplasty and BMS was reported by Fischman et al in 1994. As compared to balloon angioplasty, BMS implantation was associated with an improved rate of procedural success, a lower rate of angiographically detected restenosis, similar rates of clinical events after 6 months, and a less frequent need for target vessel revascularization (TVR). These results eventually led to the use of BMS as the standard of care for the treatment of de novo coronary stenosis. The use of BMS, however, was associated with a high incidence of in-stent restenosis (ISR) mainly due to intimal hyperplasia. The high ISR rates in BMS eventually led to the idea of coating the BMS with antiproliferative agents. Therefore, the primary purpose of DES has been the prevention of vessel recoil, negative remodeling, and ISR. First introduced in 2002, first-generation DES have been shown to be superior to BMS with respect to lower rates of clinical and angiographic restenosis and target lesion
revascularizations (TLR) as compared to BMS.\textsuperscript{5,6} However, following real-world experience, concerns regarding high rates of late stent thrombosis (ST) have emerged,\textsuperscript{7} leading to a change in the recommendations for dual antiplatelet therapy following DES implantation.\textsuperscript{8} The vast research and development leading to a newer generations of DES, better understanding of the mechanisms of ST, and advances in technology, technique, adjunctive pharmacology, and operator experience have resulted in improved outcomes and the widespread use of DES. This eventually lead to the fact that the vast majority of stents being implanted during percutaneous coronary intervention (PCI) in the United States are DES\textsuperscript{9} as well as to the wide endorsement for the use of these stents in US and European clinical guidelines.\textsuperscript{10,11}

**DRUG-ELUTING STENT STRUCTURE**

The basic structure of DES includes a metallic strut platform, a polymer, and the drug. Due to the concept of persistent arterial wall inflammation attributed to the polymer and the risk for ST, novel DES designs have been introduced and include the biodegradable polymer and polymer-free DES,\textsuperscript{12} discussed later, and the bioresorbable vascular scaffold systems.\textsuperscript{13} A design summary for the first- and second-generation DES available in the United States for clinical use as well as newer platforms with bioresorbable polymer and polymer-free DES are presented in Table 30-1 and Figures 30-1 and 30-2.

**Stent Platform**

Drug-eluting stents were initially constructed on a stainless steel platform due to their mechanical radial force properties and corrosion resistance. However, these stainless steel stents contained and released nickel, chromate, or molybdenum ions, causing a local inflammatory response leading to ISR. Currently, most second-generation DES are built on a cobalt-chromium platform, which exhibits superior radial strength with remarkably thinner struts (~80 μm) and improves deliverability. Some novel DES are constructed on a platinum-chromium platform. A meta-analysis has shown that compared with BMS, the use of cobalt-chromium everolimus-eluting stents (EES) improves global cardiovascular outcomes, including cardiac survival, myocardial infarction, and overall ST. Novel structural designs feature thinner struts and less metal, offering increased flexibility and deliverability, and thus, they are both more efficacious and safer.

Currently, all available DESs are balloon expandable. Symmetric expansion of stents with homogeneous distribution of struts is required for optimal drug delivery. Stent design can be either a closed- or open-cell configuration. A closed-cell stent design has a uniform cell expansion and constant cell spacing when deployed in a curved vessel, which gives uniform drug distribution. An open-cell design has variation in the surface coverage between inner and outer curvatures in the curved vessel but has better conformability to a curved surface at the expense of less uniform distribution. Current second-generation DESs are based on an open-cell design to minimize strut deformation after deployment while maintaining conformability, radial support, and flexibility.

**Stent Polymers**

Stent polymers are large compounds that carry the drug and control the kinetics of its elution. Both first- and second-generation DESs use durable polymers (see Table 30-1). First-generation DESs, compared to second-generation DESs, have thicker and more durable polymers that control the
release of sirolimus and paclitaxel. The durable polymers used in first-generation DESs have been associated with nonuniform coating, resulting in erratic drug distribution. In addition, they have been associated with perpetuating local vascular inflammatory reaction and potentially inducing the occurrence of late and very late ST.\textsuperscript{18} Therefore, the ideal DES would entirely inhibit restenosis while at the same time promote vascular healing with minimal risk of thrombus formation. DESs have evolved on this premise, initially with thinner polymers to enhance biocompatibility to fully bioabsorbable polymers and scaffolds to eliminate hypersensitivity reactions and local inflammatory response.

**Drug Coating of DES**

The antiproliferative agents that are used for the platforms of DESs are molecules that are distributed into the arterial wall and exert either immunosuppressive effects (inhibitors of mammalian target of rapamycin [mTOR]) or antiproliferative effects (paclitaxel) on smooth muscle cells. Paclitaxel and the “limus” drugs (eg, sirolimus, everolimus, zotarolimus, umirolimus) are lipophilic agents. In general, the degree of lipophilicity is higher with newer generations of DES. Eventually these substances inhibit migration and proliferation of vascular smooth muscle cells (VSMC). However, their mode of action is different.\textsuperscript{19} The limus drugs intracellularly bind to the FK-binding protein 12 (FKBP12) prior to blocking the mTOR pathway and ultimately interrupting the cell cycle. The inhibition of mTOR prevents the degradation of p27kip1, a cyclin-dependent kinase inhibitor that plays an important role in regulating VSMC migration and proliferation. More pertinent to the process of arterial healing, sirolimus is also a potent inhibitor of endothelial cell proliferation by deactivating the p70 S6 kinase pathway, an essential step for cell cycle progression in response to growth factors. Paclitaxel binds to microtubules and stabilizes their structure by shifting the dynamic equilibrium between soluble and insoluble tubulin, thereby enhancing microtubule assembly, resulting in inhibition of cellular replication. Most antimitotic agents used in DES are bonded to a matrix polymer, which acts as a reservoir to ensure drug retention during deployment and uniform distribution on the stent. The type of polymer will determine the drug-eluting kinetics.
CELLULAR RESPONSE TO DRUG-ELUTING STENT DEPLOYMENT

The cellular and molecular response to vascular injury is direct repair and vascular healing. However, dysregulation of these responses can result in adverse arterial remodeling, neointimal proliferation, and restenosis. The cellular cascade response to mechanical vascular injury initiated immediately after PCI can be divided into 3 different time phases: (1) an early phase consisting of platelet activation and inflammation, (2) an intermediate phase of granulation tissue corresponding to smooth muscle cell migration and proliferation, and (3) a late phase of tissue remodeling. During the early phase, the endothelium undergoes denudation, reendothelialization, and the formation of neoendothelium. After this early phase, endothelial cells proliferate and migrate over the injured areas, while smooth muscle cells and macrophages replace the fibrin clot with granulation tissue. The smooth muscle cells secrete proteoglycans that interact and stabilize the fibrin-rich extracellular matrix. This allows more smooth muscle cells to bind and proliferate while trapping inflammatory cells, which release matrix metalloproteinases that digest proteoglycans and hyaluronan. Ultimately, a more permanent matrix from collagen type I and III production occurs, allowing the wound to completely heal with eventual fibrosis.

The inhibition of intimal hyperplasia of the DES disrupts the physiologic arterial healing of the vessel wall, limiting endothelial coverage of all stent struts (Fig. 30-3). Their antiproliferative effect and the persistence of stent components have been shown to lead to chronic inflammation and impaired arterial healing, with the attendant risk of thrombotic events. The understanding of the pathophysiology of late ST of the first-generation polymer-based sirolimus-eluting stent (SES) and the paclitaxel-eluting stent (PES) has been derived from animal and human pathologic samples taken after implantation of these devices. The data indicate that both of these first-generation DESs cause substantial impairment in arterial healing characterized by lack of complete reendothelialization and persistence of fibrin when compared with BMS. This delayed healing was the primary substrate underlying all cases of late DES thrombosis at autopsy. However, additional barriers to physiologic healing and late ST have been described, such as penetration of necrotic core, stent malapposition, overlapping stent
placement, excessive stent length, and bifurcation lesions. Second-generation DESs covered with everolimus (EES) and zotarolimus (zotarolimus-eluting stent [ZES]) have shown improved endothelial coverage following implantation with the use of sequential optical coherence tomography (OCT). With OCT, both ZES and EES showed comparable neointimal thickness and low rates of uncovered stent struts (3%) at 9 months after stent implantation.

![Imagery of vascular response to durable stent polymers]

**FIGURE 30-3** Vascular response to durable stent polymers. The images show (*from left to right*) focal inflammation with eosinophils at 4 months after drug-eluting stent (DES) implantation; chronic inflammation with giant cells secondary to polymer delamination at 3 months after implantation; foamy macrophage accumulation indicating neoatherosclerosis at 6 months after implantation; and antemortem slide demonstrating a 6-month late stent thrombosis event in an everolimus-eluting stent implanted within a paclitaxel-eluting DES. (Slides used with permission from Renu Virmani, MD.)

**FIRST-GENERATION DRUG-ELUTING STENTS**

The Cypher SES (Cordis Medical, Fremont, CA) and the TAXUS PES (Boston Scientific, Marlborough, MA) were the first US Food and Drug Administration (FDA)-approved DESs. Their major pivotal trials are summarized in **Table 30-2**.

**Table 30-2  Selected First-Generation Drug-Eluting Stent Trials**
The Cypher (Cordis) SES uses a stainless steel platform and poly(ethylene-covinyl acetate) (PEVA) and poly(n-butyl methacrylate) (PBMA) as the polymer that carries the drug. The SES was the first FDA-approved DES in the United States. The RAVEL (Randomized Comparison of a Sirolimus-Eluting Stent With a Standard Stent for Coronary Revascularization) trial was the first randomized comparison of an SES with a standard BMS. At 6 months, the degree of neointimal proliferation, manifested as the mean (± standard deviation [SD]) late luminal loss, was significantly lower in the SES group (–0.01 ± 0.33 mm) than in the BMS group (0.80 ± 0.53 mm; \( P < .001 \)). None of the patients in the SES group, as compared with 26.6% of the BMS group, had restenosis of 50% of the luminal diameter (\( P < .001 \)). There were no episodes of ST. The overall rate of major adverse cardiac events (MACE) was substantially reduced in the SES group versus the BMS group (5.8% vs 28.8%; \( P < .001 \)). This difference was driven by a higher rate of TVR in the BMS group. Five-year follow-up of the RAVEL cohort showed 1-, 3-, and 5-year rates of survival free from TLR of 99.2%, 93.8%, and 89.7% in the SES group versus 75.9%, 75.0%, and 74.0% in the BMS group, respectively (log-rank \( P < .001 \)). Rates of all MACE at 5 years were 25.8% in patients treated with SES versus 35.2% in patients assigned to BMS (log-rank \( P = .03 \)).

### Sirolimus-Eluting Stent

The Cypher (Cordis) SES uses a stainless steel platform and poly(ethylene-covinyl acetate) (PEVA) and poly(n-butyl methacrylate) (PBMA) as the polymer that carries the drug. The SES was the first FDA-approved DES in the United States. The RAVEL (Randomized Comparison of a Sirolimus-Eluting Stent With a Standard Stent for Coronary Revascularization) trial was the first randomized comparison of an SES with a standard BMS. At 6 months, the degree of neointimal proliferation, manifested as the mean (± standard deviation [SD]) late luminal loss, was significantly lower in the SES group (–0.01 ± 0.33 mm) than in the BMS group (0.80 ± 0.53 mm; \( P < .001 \)). None of the patients in the SES group, as compared with 26.6% of the BMS group, had restenosis of 50% of the luminal diameter (\( P < .001 \)). There were no episodes of ST. The overall rate of major adverse cardiac events (MACE) was substantially reduced in the SES group versus the BMS group (5.8% vs 28.8%; \( P < .001 \)). This difference was driven by a higher rate of TVR in the BMS group. Five-year follow-up of the RAVEL cohort showed 1-, 3-, and 5-year rates of survival free from TLR of 99.2%, 93.8%, and 89.7% in the SES group versus 75.9%, 75.0%, and 74.0% in the BMS group, respectively (log-rank \( P < .001 \)). Rates of all MACE at 5 years were 25.8% in patients treated with SES versus 35.2% in patients assigned to BMS (log-rank \( P = .03 \)).
Additional long-term data were provided by the SIRIUS (Sirolimus-Eluting Stent In Coronary Lesions) family of trials (see Table 30-2) and the SIRIUS extension data\(^{25}\) showing that at 5 years TLR rates were 9.4% versus 24% for SES versus BMS (\(P < .001\)) and target vessel failure (TVF) rates were 22.5% versus 33.5% (\(P < .001\)).

Increased interest in SES and BMS comparisons led to the evaluation and safety of SES in subgroups of patients at higher risk of restenosis. The C-SIRUS trial\(^{26}\) described that in patients with long lesions in small vessels at higher risk of restenosis the SES significantly reduces angiographic restenosis (2.3% vs 52.3%; \(P < .001\)) and TLR (4% vs 18%; \(P = .05\)). The Italian DESSERT study\(^{27}\) and the German SCORPIUS study\(^{28}\) showed that SES significantly decreases restenosis rates in diabetic patients compared to BMS. However, use of the SES in the setting of ST-segment elevation myocardial infarction examined in the MISSION trial\(^{29}\) failed to demonstrate superiority of SES as compared to BMS. In that trial, survival rates were comparable between SES and BMS groups (94.3% vs 92.8%, respectively; \(P = .57\)), as were the rates of repeat myocardial infarction (10.6% vs 13.7%; \(P = .40\)), freedom from death or myocardial infarction (84.4% vs 79.8%, \(P = .29\)), and TVF (14.9% vs 21.7%; \(P = .11\)). Likewise, rates of overall ST (5.4% vs 2.7%; \(P = .28\)) and very late ST (4.1% vs 0.7%; \(P = .07\)) did not significantly differ between the SES and BMS groups.

**Paclitaxel-Eluting Stent**

The TAXUS Liberté (Boston Scientific) PES was approved a few months after the Cypher SES. The family group of trials comparing this PES to BMS were the TAXUS I through TAXUS VI trials.\(^{6,30,31}\) The TAXUS IV trial\(^{32}\) led to the final FDA approval of the DES. In the TAXUS IV trial, 1314 patients were prospectively randomized to PES or BMS. The PES reduced the 12-month rates of TLR by 73% (4.4% vs 15.1%; \(P < .0001\)), TVR by 62% (7.1% vs 17.1%; \(P < .0001\)), TVF by 52% (10.0% vs 19.4%; \(P < .0001\)), and composite MACE by 49% (10.8% vs 20.0%; \(P < .0001\)). The 1-year rates of cardiac death (1.4% vs 1.3%), myocardial infarction (3.5% vs 4.7%), and ST (0.6% vs 0.8%) were similar between the PES and BMS groups. Long-term follow-up data from the TAXUS IV trial\(^{31}\) also showed that compared with BMS, the significant reduction of TVR with PES was maintained.
through 5 years (27.4% vs 16.9%; \( P < .0001 \)). Similar patterns were observed for the composite MACE (32.8% BMS vs 24.0% PES; \( P = .0001 \) at 5 years). ST was comparable as well at 5 years (2.1% BMS vs 2.2% PES; \( P = .87 \)). The overall revascularization benefits of PES were consistent across multiple subgroups, including gender, diabetes, left anterior descending artery lesion location, reference vessel diameter, lesion length, and multiple stents.

**Safety Concerns of First-Generation DES**

A concern that first-generation DESs may cause pronounced endothelial dysfunction because of delayed endothelialization has been raised.\(^{33}\) Comparisons between SES and BMS suggest that endothelial function is significantly impaired with SES, especially distal to the stent.\(^{34,35}\) In addition, first-generation DESs historically had slight increased risk of ST. Many large meta-analyses have addressed the differences in the rates of ST and clinical outcomes between SES and PES versus BMS. The largest one to date was published in 2007 by Stettler and colleagues\(^{36}\) and included 38 trials (18,023 patients) with a follow-up of up to 4 years. That analysis reported no mortality or ST differences between the 3 groups and that SES was associated with the lowest risk of myocardial infarction. However, the risk of late definite ST (>30 days) was increased with PES. The reduction in TLR was more pronounced with the SES than with the PES. Similarly another meta-analysis on 33 randomized controlled trials involving 31,379 patients compared first-generation to second-generation DESs.\(^{37}\) In that report, similar to the comparison with BMS, no differences in mortality among devices were found. In the overall class comparison, second-generation DESs were associated with a 22% reduction of odds of myocardial infarction; EES reduced the odds of definite/probable ST compared with PES; and first-generation SES along with second-generation EES and ZES showed similar efficacy in decreasing the odds of repeat revascularization. Overall, therefore, it seems that second-generation DESs offer similar levels of efficacy compared with first-generation DESs; however, second-generation DESs may be much safer than the first-generation DESs.

**SECOND-GENERATION DRUG-**
ELUTING STENTS

Zotarolimus-Eluting Stent

Zotarolimus is a derivative of sirolimus with a similar mechanism of action. The Endeavor ZES (E-ZES; Medtronic Cardiovascular, Santa Rosa, CA) was evaluated in the ENDEAVOR trials and was compared to BMS and first-generation DES. In the ENDEAVOR II trial, 1197 patients treated for single coronary artery stenosis were randomized to E-ZES versus BMS. As compared to BMS, almost all outcomes measures were reduced by the E-ZES, including the primary end point of TVF at 9 months (15.1% vs 7.9%; \( P = .0001 \)), MACE (14.4% vs 7.3%; \( P = .0001 \)), and TLR (11.8% vs 4.6%; \( P = .0001 \)). The rate of ST was 0.5% with the E-ZES, which was not significantly different from the rate of 1.2% with the BMS. In 531 patients submitted to angiographic follow-up, late loss was reduced from 1.03 ± 0.58 to 0.61 ± 0.46 (\( P < .001 \)) in stent and from 0.72 ± 0.61 to 0.36 ± 0.46 (\( P < .001 \)) in segment. The rate of in-segment restenosis was reduced from 35.0% to 13.2% with the E-ZES. Differences in clinical outcome were maintained at 12 and 24 months (\( P < .0001 \)).

The E-ZES was compared to SES in the ENDEAVOR III and SORT-OUT III trials. The ENDEAVOR III was a multicenter 3:1 randomized trial conducted to evaluate the safety and efficacy of E-ZES (n = 323) relative to SES (n = 113) in 436 patients undergoing elective PCI. The primary end point of 8-month angiographic in-segment late lumen loss was significantly higher among patients treated with E-ZES compared with SES (0.34 ± 0.44 mm vs 0.13 ± 0.32 mm, respectively; \( P < .001 \)). In-hospital MACE was significantly lower among patients treated with E-ZES (0.6% vs 3.5%; \( P = .04 \)). TLR rates at 9 months were 9.8% and 3.5% for the E-ZES and SES groups, respectively (\( P = .04 \)). However, the results for clinically driven TLR (6.3% vs 3.5%; \( P = .34 \)) and TVF (12.0% vs 11.5%; \( P = 1.0 \)) did not differ significantly for E-ZES and SES, respectively. Similarly, the SORT-OUT III trial randomized 2332 patients to E-ZES (n = 1162) or SES (n = 1170). In that trial, the E-ZES underperformed when compared to SES. At 3-year follow-up, the MACE rate was higher in patients treated with the E-ZES than in patients treated with SES (12.9% vs 10.1%; \( P = .022 \)). TVR was more frequent in the E-ZES group compared with the SES group (9.1% vs 6.7%; \( P = .0001 \)).
= .025), whereas the occurrence of myocardial infarction (3.8% vs 3.3%) and cardiac death (2.8% vs 2.8%) did not differ significantly. Although the rate of definite ST was similar at 3-year follow-up (1.1% vs 1.4%), very late (12 to 36 months) definite ST occurred in no patients (0%) in the E-ZES group versus 12 patients (1.1%) in the SES group ($P = .0005$). In addition, 5-year long-term follow-up registry data have shown significant differences in cardiac death, myocardial infarction, and composite end points favoring treatment with E-ZES over the comparators BMS and DES.\(^{41}\) In that report, the rates of clinical restenosis and safety events, including ST beyond the first year of revascularization, remained stable with E-ZES, leading to significant differences compared with first-generation DES.

The discouraging clinical results from previous trials as compared to first-generation SESs have led to the development of a newer zotarolimus-coated DES, the Resolute ZES (R-ZES; Medtronic Cardiovascular). Tada et al\(^ {42}\) have compared the R-ZES versus the E-ZES in 1000 patients who were enrolled in the ISAR-TEST 2 and ISAR-TEST 5 trials. His results have suggested that the R-ZES as compared to the E-ZES displayed overall superior antirestenotic efficacy with TLR rates of 12% versus 16% at 2 years ($P = .052$). Both devices were associated with a similar low risk of adverse safety events through 2 years. In a randomized trial including 2292 patients,\(^ {43}\) the R-ZES was compared with the Xience EES (X-EES; Abbott Vascular, Santa Clara, CA). The R-ZES was found to be noninferior to X-EES for the primary outcome of cardiac death, myocardial infarction, or TLR (8.2% vs 8.3%; $P$ for noninferiority = .001) or the rate of ISR (21.65% vs 19.76%; $P$ for noninferiority = .04). The R-ZES had a similar ST rate as the X-EES (2.3% vs 1.5%; $P = .17$). In longer follow-up experience from the RESOLUTE All-Comers trial,\(^ {44}\) R-ZES ($n = 1140$) and X-EES ($n = 1152$) demonstrated similar safety and efficacy throughout 4 years. At 4 years, the rates of target lesion failure (TLF; 15.2% vs 14.6%; $P = .68$), cardiac death (5.4% vs 4.7%; $P = .44$), target vessel myocardial infarction (5.3% vs 5.4%; $P = 1.00$), clinically indicated TLR (7.0% vs 6.5%; $P = .62$), and definite/probable ST (2.3% vs 1.6%; $P = .23$) were similar in the R-ZES and X-EES arms. Table 30-3 shows a comparison of the outcomes of the key trials examining the safety and efficacy of the E-ZES and R-ZES as well as EES.

Table 30-3 Selected Second-Generation Drug-Eluting Stent Trials

---

\(^{41}\) A. Ahmad, F. Steinhubl, L. Wang, et al. 2015. \(^{42}\) Tada et al. 2015. \(^{43}\) Tada et al. 2015. \(^{44}\) Tada et al. 2017.
The new-generation Resolute Onyx (RO-ZES; Medtronic Cardiovascular) DES was built on the clinical performance and deliverability of the R-ZES and features CoreWire Technology that allows it to have a denser core metal surrounded by a cobalt alloy outer layer. The CoreWire Technology builds on the R-ZES’ continuous sinusoid technology (CST), a method of stent manufacturing first introduced with the R-ZES, which molds one single strand of wire into a sinusoidal wave enabling a continuous range of motion. This technology enables the stent to have better radiopacity during the procedure and have thinner struts and improves deliverability without compromising radial and longitudinal strength. Safety and efficacy studies of the RO-ZES for lesions under 2.0 mm and between 2.25 and 4.0 mm have been launched in 2015 (ClinicalTrials.gov identifiers: NCT02412501, NCT02419521).

### Everolimus-Eluting Stent

The X-EES is built on a cobalt-chromium platform, whereas the PROMUS Element and the PROMUS Premier EES (P-EES; Boston Scientific) are novel EESs built on a platinum-chromium platform.

**Abbreviations:** BMS, bare metal stent; EES, everolimus-eluting stent; E-ZES, Endeavor zotarolimus-eluting stent; MACE, major adverse cardiac events; NS, not significant; P-EES, PROMUS Premier everolimus-eluting stent; PES, paclitaxel-eluting stent; R-ZES, Resolute zotarolimus-eluting stent; SES, sirolimus-eluting stent; ST, stent thrombosis; TLR, target lesion revascularization; X-EES, Xience everolimus-eluting stent.
The X-EES was studied in the SPIRIT family of trials. In SPIRIT IV, 3687 patients were randomized to X-EES versus PES. X-EES was superior to PES in the primary end point of TLF (4.2% vs 6.8%; \( P = .001 \)), as well as in the major secondary end point of the 1-year rate of ischemia-driven TLR (\( P = .001 \)), and was noninferior with respect to the major secondary end point of the 1-year composite rate of cardiac death or target vessel myocardial infarction. The 1-year rates of myocardial infarction and ST were also lower with X-EES than with PES (1.9% vs 3.1%, \( P = .02 \) for myocardial infarction; 0.17% vs 0.85%, \( P = .004 \) for ST). Similar results were seen in the meta-analysis of the final 3-year results from the SPIRIT II, III, and IV clinical trials. In that report, patient data from 4989 patients who were prospectively randomized to treatment with X-EES (n = 3350) or PES (n = 1639) were pooled for analysis. In this large data set with 3-year follow-up, coronary implantation of X-EES compared with PES resulted in reduced rates of all-cause mortality, myocardial infarction, ischemia-driven TLR, ST, and TLF. Real-world registry data have similarly shown the safety and efficacy of the X-EES over previous stent design.

The platinum-chromium–based P-EES was compared with a cobalt-chromium strut design in the PLATINUM trial (vs X-EES) as well as against another cobalt-chromium second-generation stent in the DUTCH-PEERS and HOST-ASSURE trials (vs R-ZES). In the PLATINUM trial, a total of 1530 patients were randomized to the cobalt-chromium X-EES (n = 762) or the platinum-chromium P-EES (n = 768). The platinum-chromium P-EES was found to be noninferior to the cobalt-chromium X-EES for the primary end point of 12-month TLF (3.4% vs 2.9%; \( P \) for noninferiority = .001, \( P \) for superiority = .60) or for any other outcome measures of safety and efficacy through 12-month follow-up after PCI. A 3-year follow-up of that trial showed comparable safety and efficacy outcomes for both EESs. In the DUTCH-PEERS trial, 1811 eligible all-comer patients were randomized to P-EES versus R-ZES. The primary end point of TVF occurred in 5% and 6% of patients, respectively (\( P \) for noninferiority = .006), with no significant differences in individual components of the primary end point. Definite ST occurred in 0.7% and 0.3% of P-EES and R-ZES patients, respectively (\( P = .34 \)). Similarly, in the HOST ASSURE trial, 3755 all-comer patients were randomized to P-EES versus R-ZES. At 1 year, TLF occurred in 2.9% of each group, meeting the noninferiority margin, with
no significant differences in the individual components of TLF noted.

THIRD-GENERATION DRUG-ELUTING STENTS

The biodegradable polymer DES, the polymer-free DES, and drug-coated stents represent a true leap in stent technology and are commonly referred to as the third generation of DESs (Table 30-4).

Biodegradable Polymer Stents

The Biomatrix DES is a Biolimus-eluting stent (B-BES; Biosensors, San Diego, CA) with a biodegradable polymer. The B-BES was evaluated versus SES in 1707 patients in the LEADERS trial. The primary end point of a composite of cardiac death, myocardial infarction, or TLR at 9 months occurred in 9% versus 11% of patients in the B-BES and SES arms, respectively (P for noninferiority = .003, P for superiority = .39). Components of the primary outcome did not differ between groups as well. Similarly, in the SORT OUT IV trial, the Biomatrix was also found to be noninferior to R-ZES for the primary composite end point of cardiac death, myocardial infarction, and TLR at 12 months in an unselected population of 1502 patients randomized to both stents (5.3% vs 5.0%; P for noninferiority = .004 for the B-BES vs the R-ZES, respectively). Compared with a BMS, the use of B-BES also resulted in a lower rate of the composite of MACE at 1
year among patients with ST-segment elevation myocardial infarction undergoing primary PCI in the COMFORTABLE AMI randomized trial. The SYNERGY DES is a thin-strut, platinum-chromium metal alloy platform with an ultrathin bioabsorbable poly(D,L-lactide-co-glycolide) abluminal everolimus-eluting polymer (S-EES; Boston Scientific). The EVOLVE II trial randomized 1684 patients to the S-EES stent versus the platinum-chromium P-EES. The primary end point of 12-month TLF was observed in 6.7% of the S-EES patients and 6.5% of the P-EES patients (P for noninferiority = .0005). Both TLR and ST rates were similar as well (2.6% vs 1.7%, P = .21; 0.4% vs 0.6%, P = .5 for the S-EES vs P-EES, respectively).

The Orsiro stent is a newly developed, ultrathin strut, cobalt-chromium stent releasing sirolimus (O-SES; Biotronik, Bulach, Switzerland) and featuring a unique dual-polymer matrix. An active bioabsorbable polymer delivers the antiproliferative drug via controlled release, while a passive biocompatible polymeric coating shields the metallic strut from surrounding tissue, preventing interaction. The O-SES has been found to be noninferior to the durable polymer X-EES in the BIOSCIENCE trial, as well as in the BIO-FLOW II trial. The ongoing BIO-FLOW V trial is a prospective, randomized, investigational device exemption trial that will study the O-SES versus X-EES. Finally, the SORT OUT VII trial will study the O-SES versus the N-BES biodegradable polymer stent.

Additional biodegradable polymer stents have been reported as well. The Nobori Biolimus-eluting biodegradable polymer stent (N-BES; Terumo, Tokyo, Japan) did not improve clinical results compared to the durable polymer first-generation SES in the SORT-OUT V trial. However, the N-BES was further evaluated versus X-EES in the COMPARE II trial, which randomized 2707 patients to either the N-BES or X-EES. The primary end point occurred in 5.2% and 4.8% of stents, respectively (P for noninferiority <.0001). The ISAR-TEST 4 trial compared the efficacy and safety of the biodegradable polymer SES Yukon Choice PC (YC-SES; Translumina, Hechingen, Germany) versus X-EES and SES. At 5-year follow-up, the YC-SES and permanent polymer X-EES stents showed comparable clinical outcomes, whereas the SES showed numerically higher rates of device-related adverse events. The Excel stent, a biodegradable polymer sirolimus-coated DES (E-SES; JW Medical Systems, Weihai, China) was evaluated in
the CREATE registry enrolling 2070 patients. The rates of cardiac death, myocardial infarction, TLR, and overall MACE at 5-year follow-up were 3.0%, 1.5%, 3.7%, and 7.4%, respectively. Five-year definite and probable ST rates were 1.1% and 0.3%, respectively. Finally, the Combo Stent Platform (OrbusNeich, Fort Lauderdale, FL) is a 100-μg-thick strut stainless steel stent covered abluminally with a biodegradable polymer that releases sirolimus. An additional circumferential layer of anti-D34 antibodies is applied on the stent strut on top of the polymer aiming to accelerate endothelialization. This stent was tested in the REMEDEE trial randomizing 100 patients in a 2:1 ratio to the Combo versus PES. The Combo stent was found to be noninferior to the PES regarding 9-month angiographic in-stent late lumen loss (0.39 ± 0.45 mm vs 0.44 ± 0.56 mm; \( P \) for noninferiority = .0012). At 12 months, the occurrence of MACE was 8.9% versus 10.2% (\( P = .8 \)) in the Combo group versus the PES group, respectively, with no difference in mortality, occurrence of myocardial infarction, or TLR. No ST was reported in either group.

**Polymer-Free Stents and Drug-Coated Stents**

Several technologies have been developed to design polymer-free DESs, such as the use of microporous stents and inorganic coatings that can be drug loaded. Polymer-free systems have included drug coatings with Biolimus, paclitaxel, tacrolimus, sirolimus, and a combination of Sirolimus and Probucol.

The BioFreedom stent (Biosensors) is a polymer-free, Biolimus-coated DES. This stent has been studied in the LEADERS FREE trial. In this randomized, double-blind trial, the stent was compared with a BMS in 2466 patients with a high risk of bleeding who underwent PCI and received 1 month of dual antiplatelet therapy. At 390 days, the primary safety end point (composite of cardiac death, myocardial infarction, or ST) occurred in 9.4% and 12.9% of the DES and BMS patients, respectively (\( P < .001 \) for noninferiority and \( P = .005 \) for superiority). During the same time period, TLR occurred in 5.1% and 9.8% of DES and BMS patients, respectively (\( P < .001 \)).

Other polymer-free stents have reached human testing. The VESTAsync system (MIV Therapeutics, Atlanta, GA) was evaluated in the VESTAsync II
feasibility observational trial,\textsuperscript{66,67} showing the VESTAsync stent to be effective in reducing late lumen loss and neointimal hyperplasia. The polymer-free sirolimus Yukon stent was evaluated in the ISAR-TEST trial versus PES,\textsuperscript{68} showing both systems to be equivalent. In fact, at 5 years, there were no significant differences in clinical outcomes.\textsuperscript{69} Byrne et al\textsuperscript{70} have reported their experience with a polymer-free rapamycin-eluting DES as compared to a durable polymer rapamycin-eluting DES and PES.

Finally, a novel drug-filled stent (DFS) has been presented at the 2015 Transcatheter Cardiovascular Therapeutics (TCT) conference. The new DFS, studied in the RevElution trial (NCT02480348), has a novel trilayer wire design, which allows the inner sacrificial layer to become a lumen continuously coated with drug. The drug (sirolimus) is contained on the inside of the stent and is released from a single continuous inner lumen through multiple laser-drilled holes on the abluminal side (outer surface) of the stent. This allows for a controlled and sustained polymer-free drug elution over a desired period of time directly into the arterial wall, thereby potentially avoiding chronic inflammation and adverse vascular responses. The initial report presented at TCT 2015 showed that the optical coherence tomography data demonstrate an early healing profile with an average of 90% strut coverage at 1 month, with a low rate of malapposed struts (2%) in the 6 patients analyzed.

**SUMMARY**

Considerable progress has been made in the development of new-generation DESs. The initial experience with balloon angioplasty and BMS set the groundwork for the development of metal struts with drug-eluting capability to prevent restenosis. Leaps in technology have brought forward new generations of DES. These leaps gave rise to the novel strut design, allowing greater stent deliverability and use of newer polymers and thereafter biodegradable polymers and polymer-free stents, reducing the local inflammatory effect of these materials, allowing shorter duration of dual antiplatelet therapy, and finally, allowing use of highly lipophilic drugs, which enhances drug absorption capabilities. All of these leaps in technology have been accompanied by extensive research and development that has shown the long-term safety and efficacy of the newer generation of DESs.
Available data suggest that DESs can be used safely and effectively in a wide array of patient and lesion subsets. The advances in the field have also led to the endorsement for the use of these stents in the practice guidelines in the United States and Europe. As continuous advances in technology change clinical practice, it remains to be seen whether older technologies, such as the BMS, will eventually become obsolete and whether novel technologies, such as the bioresorbable vascular scaffold systems, will eventually replace the durable framed DES.

Special Stents: Bioresorbable Coronary Scaffolds

Bill D. Gogas
Habib Samady

INTRODUCTION

Despite innovations in stent design, including reduction in strut thickness, novel antiproliferative agents, and more recently, the development of bioresorbable polymers, permanent metallic stents remain a nidus for sustained vascular inflammation, in-stent neoatherosclerosis, and impaired coronary vasomotor function. Therefore, the concept of a drug-eluting bioresorbable scaffold (BRS) with properties of medium-term temporary vascular scaffolding and long-term vascular reparative properties is appealing.

Several drug-eluting scaffolds, made of either biodegradable polymers or biocorrodible metals, have been developed and tested in first-in-man (FIM) studies showing comparable performance with current-generation drug-eluting stents (DES) in selected clinical subsets. More recently, large-scale randomized trials have demonstrated noninferiority of BRS compared to current-generation DES with respect to safety and efficacy. This cumulative evidence indicates the gradual maturation of the novel field of vascular reparative therapy.
RATIONALE FOR TRANSIENT BIORESORBABLE SCAFFOLDS

The impetus for developing drug-eluting BRS was driven by the need for more elastic and conformable platforms instead of stiff and permanent metallic implants to prevent acute and late recoil, seal post-procedural dissections derived from vascular barotrauma, and inhibit in-segment restenosis using appropriate drug elution.¹ This technologic endeavor would overcome mid- and long-term effects of rigid metal caging over a previously pulsatile vascular tissue.

As early as 1996, van der Giessen et al² reported on deploying synthetic polymer-based scaffolds in porcine coronary arteries. His preliminary observations demonstrated marked inflammatory reactions and subsequent intense neointimal proliferation. Further bench studies indicated that lower molecular weight polymers were an important determinant of these adverse vascular responses.² Current polymeric BRSs are therefore engineered using high-molecular-weight polymers, with poly-L-lactic acid (PLLA) being the most commonly used material. Other polymeric BRSs include tyrosine-derived polycarbonates and poly(anhydride-esters) composed of salicylic acid. Furthermore, an alternative approach to polymeric materials has been the use of magnesium metallic alloys (Table 31-1). Long-term potential advantages of BRS over permanent metal stents have been proposed based on preliminary observations from multicenter registries.

| Table 31-1 | Bioresorbable Coronary Scaffolds in Clinical Development |
Physiologic Restoration of Vascular Function

First- and second-generation metallic DESs have been associated with midterm endothelial dysfunction as well as a blunted vasodilatory response to endothelial-independent vasodilators such as nitroglycerine. Experimental models and clinical studies indicate that both polymeric and magnesium-based BRSs result in improved endothelial function, restoration of non–endothelial-dependent coronary vasoreactivity, and retained vessel pulsatility within and adjacent to the BRS deployed coronary segments. In addition to the pure biomechanical advantages of a more compliant platform, it is postulated that certain endothelial cell signaling and mechanotransduction pathways may be favorably affected by BRS. Finally, compensatory adaptive expansive remodeling with regression of plaque between the struts and the vessel wall resulting in incremental lumen gain has been described in observational studies.

Restoration of Original Vascular Anatomy

Wentzel and colleagues first demonstrated, in a porcine model, that alterations of vessel geometry following stenting resulted in unfavorable rheologic profiles in the treated segments. The authors found that permanent metallic stent implantations changed the 3-dimensional coronary geometry at the proximal edge by 121% and the distal edge by 100%, inducing regions of
low wall shear stress with subsequent development of neointimal hyperplasia and asymmetric patterns of in-stent restenosis. In contrast, both polymeric- and magnesium-based scaffolds were found to result in improved retention of baseline vascular curvature and angulation, with increased gain over 12 months in the ABSORB Cohort B.\textsuperscript{5,7} It is hypothesized that such improvement in vascular conformability will translate into more physiologic vascular flow patterns, which, in turn, can facilitate homogenous long-term scaffold healing patterns. These vessel-level differences in post–device deployment flow patterns, as well as strut-level hemodynamic differences, between BRS and permanent metallic stents are being investigated prospectively in ongoing studies.\textsuperscript{8,9}

\textbf{Reduction of In-Scaffold Neoatherosclerotic Risk}

In-stent neoatherosclerosis has been observed with both metallic DESs and bare metal stents (BMS). The timing of neoatherosclerosis appears to be earlier with DES (6-24 months) compared with BMS (>24 months)\textsuperscript{10} (Fig. 31-1). The mechanism of neoatherosclerosis is not fully elucidated; however, incomplete endothelial coverage and sustained endothelial dysfunction are thought to play important roles. Although selected cases with neoatherosclerosis following BRS deployment have been published,\textsuperscript{11} intravascular imaging data from limited but consecutive patient cohorts treated with BRS do not demonstrate evidence of neoatherosclerosis (ABSORB Cohort B). It is hypothesized that the combination of complete scaffold resorption, regenerated intact endothelium with restored vasomotor function, and plaque passivation has the potential to reduce the risk of neoatherosclerosis.\textsuperscript{12,13}
**FIGURE 31-1** Distal stent edge neoatherosclerosis 6 years after bare metal stent implantation. A. Distal right coronary artery (RCA); the trilaminar vascular structure is preserved between 1 and 5 o’clock. B. The white arrows demonstrate the shadow behind the metallic struts. E-I, K. Metallic struts at different stages of healing. J. Delayed strut healing. AM=acute marginal; GWS=guide wire shadow.

**Pediatric Applications**

Absorbable scaffolds appear as more appropriate technologies for the treatment of pediatric obstructive vascular lesions such as premature coronary atherosclerosis, aortic coarctation, and pulmonary artery stenosis. Permanent metallic implants limit vessel growth and require future surgical removal, in contrast to BRS, which may allow natural vessel growth after the time of radial strength elimination and further resorption.

**Other Potential Advantages of BRS**
There are additional proposed advantages of BRS. First, they provide options for coronary artery bypass surgery in patients with advanced distal disease. This may seem esoteric, but not infrequently patients undergo percutaneous interventions with metallic stents that extend into the distal vessels, limiting targets for future coronary bypass. BRS for treatment of such distal diffuse disease may allow future bypass after resorption of the scaffold. The second advantage is the feasibility of computed tomographic imaging of the coronary arteries. With continued improvements in computed tomography angiography (CTA), including postprocessed computational techniques for hemodynamic lesion assessment, it is anticipated that noninvasive assessment of coronary arteries and bypass grafts will increase.\textsuperscript{14,15} Presently, coronary segments with metallic stents cannot be visualized by CTA, but segments treated with BRS can be adequately visualized, thereby reducing the need for invasive coronary angiography in patients with prior percutaneous coronary intervention (PCI).\textsuperscript{16} The third advantage is percutaneous treatment of large bifurcation lesions. The rationale is that one might achieve adequate revascularization with a 2-scaffold technique, with careful lesion preparation and image-guided postdilatation limiting risk of in-stent restenosis and with bioresorption over time not incurring long-term risk of stent thrombosis or neoatherosclerosis.\textsuperscript{17} The final advantage is a reduction of angina due to the favorable effects of BRS in the microvasculature. The observation that for similar epicardial revascularization, patients treated with BRS had lower rates of angina at follow-up was derived from the 1-year interim analysis of the ABSORB II randomized clinical trial, which compared a BRS with Xience metallic DESs (Abbott Vascular, Santa Clara, CA).\textsuperscript{18} However, this was not confirmed in the larger ABSORB III clinical trial, and ABSORB IV is currently under way to further evaluate this hypothesis.

**MECHANICAL PROPERTIES OF BRS**

Polymers have specific mechanical properties defined by 2 parameters. First is the Young tensile modulus of elasticity, which describes the material’s \textit{transient} deformation in response to an applied force. The Young modulus quantifies the elastic property or measure of stiffness of the material and is highly dependent on temperature. Second is the tensile strength, which quantifies the amount of stress the material will endure before suffering
permanent deformation. The spectrum of the Young tensile modulus of elasticity and tensile strength for polymeric and metallic scaffolds as well as permanent metallic implants is shown in Table 31-2.

CHEMICAL PROPERTIES AND BIODEGRADATION OF BRS

**Polymer-Based BRS**

The chemical properties of scaffolds inform the site where degradation begins as well as the rate of degradation. Hydrolytic degradation favors the amorphous tie chains of the polymer that connect the crystal lamellae (Fig. 31-2). Once these tie chains are hydrolyzed, then bulk degradation of the crystal lamellae takes place starting from the inside core of the strut progressing to the strut surface. The surface polymer in which the antiproliferative agent is blended consists of both $D$ (dextro) and $L$ (levo) isomers of polylactic acid (PDLLA). PDLLA is fully amorphous, lacking crystalline structures, which results in relatively rapid degradation.\(^{19}\)
**FIGURE 31-2** Bench bioresorption of poly-L-lactic acid. A. The pathway of ester bond hydrolysis of poly-L-lactic acid. B. Poly-L-lactic acid is semicrystalline (70% crystallinity) consisting of amorphous tie chains linking the semicrystalline phased polymer. Degradation process starts at the sites of amorphous tie chains. C. Graph showing the change of radial support, molecular weight, and mass loss over time after hydrolysis. The device retains its radial support until 6 months; after this time point, it is transformed to a passive implant with no supportive properties.

**Hydrolytic Degradation of PLLA**

The first stage in the process of polymer bioresorption is hydration. Polylactides are relatively hydrophilic; thus water diffuses into the less dense amorphous regions of the implant and hydrolyzes the ester bonds. Random
chain scissions occur at this stage, leading to reduction of the polymer’s molecular weight. The second stage is characterized by continuous cleavage of the amorphous tie chains reducing the radial strength of the scaffold, leading to structural discontinuities. During the third stage, polymer chains that have been hydrolyzed to short lengths diffuse out of the implant (mass loss) as they are increasingly hydrophilic and soluble in aqueous solution. Following these sequential stages, oligomeric polylactic acid molecules hydrolyze to lactic acid monomers, which deprotonate (release of a proton [\(\text{H}^+\)]) to lactate. Lactate is converted to pyruvate and enters the citric acid cycle (Krebs cycle) and is further metabolized in carbon dioxide and water excreted through the lungs and kidneys, respectively.\(^{20}\)

In vivo polymer bioresorption has been analyzed by histology and visualized with optical coherence tomography (OCT). In the first experimental study that investigated the PLLA-based Absorb\textsuperscript{TM} bioabsorbable vascular scaffold (BVS) biodegradation process, 35 polymeric scaffolds (3.0 × 12 mm) were implanted in the main coronary arteries of 17 healthy Yucatan minipigs. OCT was performed after the procedure (n = 2) and at 28 days (n = 2), 2 years (n = 3), 3 years (n = 5), and 5 years (n = 5).\(^{21}\) Struts imaged with OCT, had a box-shaped appearance after implantation with sharply defined borders. At 28 days, 82% of the struts visualized with OCT remained box-shaped, whereas by histology, all struts appeared intact with no evidence of resorption. At 2 years, 80% of the struts still had a box-shaped appearance; however, polylactide was not able to be detected by gel permeation chromatography. Histology confirmed that PLLA had been replaced by proteoglycan-rich matrix (glycoconjugate) that stained positive with Alcian blue. At 3 years, only 5% of strut voids were box-shaped imaged with OCT, whereas 44% showed dissolved black box, 35% showed dissolved bright box, and 16% displayed an open box appearance.

Pathologic assessment at this time point showed that connective tissue had replaced the resorption sites previously occupied by proteoglycan-rich matrix. At 4 years histology revealed that strut voids are minimally discernible as foci of hypocellular connective tissue. These observations provide evidence of complete polylactide resorption at 2 years, whereas at 4 years, both in vivo OCT and ex vivo histology confirmed complete integration of the strut voids into the arterial wall.\(^{22,23}\)
**Igaki-Tamai Scaffold**

The Igaki-Tamai (Kyoto Medical Planning Co, Kyoto, Japan) scaffold was the first polymer-based device that underwent FIM evaluation. The material of the scaffold was PLLA, had a helical zig-zag design with sinusoidal hoops linked by 3 connectors, and carried 2 radiopaque cylindrical gold markers at the proximal and distal ends (Fig. 31-3A). The device was mounted over a conventional angioplasty balloon and was self-expanding following heated contrast injections (up to 70°C or 158°F) to inflate the delivery balloon. Importantly, this first BRS was not a drug-eluting device.

**FIGURE 31-3** Ten-year follow-up of the Igaki-Tamai scaffold. A. Macroscopic view of the polymeric scaffold demonstrating a helical zig-zag design interconnected with straight bridges. B. Angiographic view of the right coronary artery (RCA) demonstrating a significant mid-RCA lesion before procedure and the excellent angiographic result after implantation of the 2 Igaki-Tamai scaffolds. B’ and B”. Angiographic views 10 years after implantation of the Igaki-Tamai scaffolds without evidence of in-scaffold restenosis. Yellow asterisks demonstrate the gold markers at each proximal and distal scaffold end. Red asterisk demonstrates the outgrowth of a side branch. I-VI. Optical coherence tomographic views of the RCA after 10 years of
The FIM study was performed in 15 patients (19 lesions, 25 scaffolds implanted) demonstrating absence of major adverse cardiac events (MACE) or scaffold thrombosis defined by angiographic follow-up at 30 days. Longitudinal evaluation at 6 months demonstrated an acceptable angiographic loss index (late loss/acute gain) of $0.48 \pm 0.32$, which was comparable to BMS. Interestingly, intravascular ultrasound (IVUS) demonstrated scaffold expansion from post-deployment to 6-month follow-up ($7.42 \pm 1.51 \text{ mm}^2$ to $8.13 \pm 2.52 \text{ mm}^2$), a finding observed for the first time with coronary implantable devices. Target lesion revascularization (TLR) rates reached 6.7%, and 4-year MACE-free survival rates were 82%. The long-term clinical follow-up (>10 years) of 84 Igaki-Tamai scaffolds implanted in 63 lesions was recently reported showing a 10-year MACE rate of 50%, with a TLR rate of 38% and 2 cases of scaffold thrombosis (Fig. 31-3B).

Although the technology did obtain the Conformité Européenne (CE) mark for peripheral interventions, it failed to do so for coronary revascularization largely due to the need for heat to induce scaffold expansion and the requirement for 8-Fr guide catheters for scaffold deployment.

**Absorbable Magnesium-Based Scaffolds**

Magnesium (Mg), the lightest metal, is alloyed with rare earth metals, including aluminum, manganese, lithium, zinc, and zirconium. This class of bioresorbable devices belongs to biocorrodible metals characterized by high corrosion rates (complete biodegradation within 3 months), with end products being elemental Mg and inorganic salts (Fig. 31-4). The earliest proof-of-mechanism that demonstrated the biocompatibility of these materials with vascular tissue was introduced by Heublein et al who employed absorbable Mg devices in porcine coronary arteries and demonstrated rapid endothelialization with low inflammatory response.
FIGURE 31-4 Schematic representation of magnesium (Mg)-based scaffold bioresorption. The end product following magnesium scaffold bioresorption facilitated by hydrolysis is amorphous hydroxyapatite. The whole process takes up to 9 months with the first-generation DREAMS scaffold. Drug elution occurs within 3 months after device implantation.

The PROGRESS AMS (Clinical Performance and Angiographic Results of Coronary Stenting With Absorbable Metal Stents) trial was a nonrandomized, multicenter, prospective FIM trial that assessed the safety, efficacy, and performance of the first absorbable Mg stent (AMS-1; BIOTRONIK, Berlin, Germany). The AMS-1 platform was 93% Mg and 7% rare earth metals, the strut thickness was 165 μm. Sixty-three patients with stable coronary artery disease (CAD) were treated with 71 stents. The angiographic in-stent lumen loss was 1.08 ± 0.49 mm at 4 months, and IVUS imaging suggested that most of the struts were fully resorbed, with only strut remnants being visible and fully embedded into the neointimal layer. TLR rates were rather high (24% at 4 months and 45% at 1 year).
Although this study demonstrated safety of AMS-1, with no reported death, myocardial infarction, or stent thrombosis, imaging and clinical results raised concerns over the further use of this generation in coronary interventions as increased neointimal formation and vessel recoil became evident. Subsequently, AMS-2 and AMS-3 were developed to overcome the aforementioned limitations primarily caused by the lack of drug elution and early loss of radial strength. AMS-2 provided an improved Mg alloy with higher collapse pressure of 1.5 bar (compared to 0.8 bar with AMS-1), a slower degradation rate with expected absorption after 9 to 12 months, and a reduced strut thickness of 125 μm with rectangular shape to enhance stent integrity. The AMS-3 was designed to address the issue of excessive neointimal proliferation; thus, a bioresorbable matrix for controlled release of paclitaxel was added to the previous AMS-2. The new device was named drug-eluting AMS (DREAMS) 1.0. It was evaluated for safety, feasibility, and efficacy in the prospective, multicenter, FIM BIOSOLVE-I trial (Safety and Performance of the Drug-Eluting Absorbable Metal Scaffold [DREAMS] in Patients With De Novo Coronary Lesions). Forty-six patients with stable or unstable CAD or silent ischemia were treated with 47 stents. The angiographic in-stent lumen loss was 0.64 ± 0.50 mm at 6 months and 0.52 ± 0.49 mm at 1 year, which represents a 61% reduction compared to the 4-month results of AMS-1. Serial IVUS imaging confirmed the angiographic observations showing in-scaffold area obstruction of only 6.2% ($P < .0001$) at 1 year, attributed to neointimal formation with extra-scaffold plaque area increase. The TLR rate reached 7% with no reported episodes of scaffold thrombosis at 3 years of follow-up.

An important part of BIOSOLVE-I trial included the evaluation of anatomic changes induced by the scaffold from before to after the procedure and at follow-up. In particular, vessel curvatures showed a significant change of –32.1% ($P < .0001$) from before to after the procedure and returned to the pre-implantation levels at the 12-month follow-up. Vessel angulation similarly changed significantly by –40.5% ($P < .0001$) from before to after the procedure (vessel straightening) and increased by 33.1% at 12-month follow-up. These findings reflect the restoration of vessel anatomy after DREAMS scaffold bioresorption, which, from a rheologic perspective, potentially translates into improved flow patterns over the scaffolded segments and the transition zones. The beneficial hemodynamic implications
of these conformable materials may minimize the flow-dependent changes of wall shear stress, which precipitate neointimal formation and subsequent silent or clinical restenosis; however, this hypothesis-generating concept remains to be proven by future clinical trials.29

A second-generation DREAMS device has been recently developed that elutes sirolimus, carries 2 tantalum radiopaque markers at both ends, and provides higher bending flexibility and slower resorption rate compared to the previous generation. Preclinical data are encouraging, showing increased endothelialization rates and decreased inflammatory scores, and the BIOSOLVE-II study has been designed to assess the safety, efficacy, and feasibility of this generation in 123 patients, with follow-up investigations scheduled at 1, 6, 12, 24, and 36 months. IVUS, OCT, and vasmotion testing were completed in a subset of patients at 6 months. The primary end point of in-segment late lumen loss at 6 months was 0.27 ± 0.37 mm. The 2nd generation DREAMS scaffold aka Magmaris received CE mark regulatory approval in 2016.

Current evidence suggests that biocorrodible metallic scaffolds can be safely implanted in patients with favorable clinical outcomes. Despite the encouraging preliminary observations, further randomized clinical trials with head-to-head comparisons with newer generation DESs will define whether these technologies will be adopted over contemporary metallic stents.30

Absorb™ Bioresorbable Vascular Scaffold

The first-generation Absorb BVS (Abbott Vascular) was Absorb BVS 1.0 (Fig. 31-5). The device had circumferential out-of-phase sinusoidal hoops linked either directly or by straight polymeric bridges. The strut thickness including the polymer drug coating was 156 μm, and the crossing profile of 1.4 mm (crimped stage) was slightly larger compared to that of contemporary metallic stents. The device had to be kept refrigerated at −20°C to prevent early aging because room temperature is a precipitating factor for polymer cracking during scaffold deployment.20 The Absorb BVS 1.0 was evaluated in 30 patients with simple de novo native coronary artery stenosis for safety, feasibility, and efficacy in the ABSORB Cohort A. Follow-up included invasive angiography, IVUS, virtual histology IVUS (VH-IVUS), and OCT at 6 months and 2 years, and clinical end points were assessed at 6 months
and 1 and 2 years. Noninvasive coronary angiography with multislice computed tomography was also performed at 18 months and 5 years.

**FIGURE 31-5** Multi-imaging assessment of the Absorb™ bioresorbable vascular scaffold (BVS). The Absorb BVS 1.0 was the first-generation device used in the ABSORB Cohort A trial. The second-generation Absorb BVS 1.1 has been redesigned and is currently under clinical use. Intravascular imaging modalities such as intravascular ultrasound (IVUS), virtual histology IVUS (VH-IVUS), and optical coherence tomography (OCT) have provided important insights in the evaluation of bioresorbable scaffolds. The top panel of cross-sections shows IVUS, VH-IVUS, and OCT following Absorb BVS implantation, whereas the bottom panel shows 6-month follow-up. Polymeric materials, as opposed to metal materials, do not reflect sound or light; thus, shadow behind the struts is not visible. Guide wires and platinum markers are the only components that generate shadow over the circumference of the cross-section. VH-IVUS detects polymeric struts as a dense calcium tissue component similar to metal stents; in contrast to metal stents, this unique property is a surrogate marker of bioresorption with biodegradable scaffolds.

The angiographic in-scaffold lumen loss with Absorb BVS 1.0 was $0.44 \pm 0.35$ mm at 6 months, which was significantly greater than that observed with metallic everolimus-eluting stents (0.11 mm) but less than late loss with BMS (0.85 mm).\(^{31}\) IVUS imaging demonstrated both reduction of scaffold shrinkage by 12% and neointimal proliferation, which combined resulted in a 24% reduction in minimal luminal area.\(^{32}\) At 2 years, the in-scaffold angiographic late loss remained $0.48 \pm 0.28$ mm, which was not significantly
worse than at 6 months. Additional important findings from this FIM registry showed the following: (1) restoration of vasomotor function of the scaffolded segment in response to methergine or acetylcholine; (2) plaque area regression behind the struts between 6 months and 2 years; (3) a low MACE rate of 3.4% at 4 years without any scaffold thrombosis; and (4) feasibility of noninvasive imaging with CTA. Despite the favorable clinical performance of Absorb BVS 1.0, early scaffold shrinkage, premature loss of radial support, and robust neointimal growth raised the need for development of a second-generation Absorb BVS to overcome these shortcomings.

The second-generation Absorb™ BVS 1.1 device was constructed from the same polymer (PLLA) as the previous generation but with a different processing that delayed the rate of ester bond hydrolysis, increasing the duration of mechanical support and scaffold resorption. Although strut thickness remained at 156 μm, the backbone of the second-generation device was redesigned to reduce the circular unsupported surface area (area between 2 sequential rings) and be replaced by in-phase zig-zag hoops linked by 3 longitudinal bridges that allowed more uniform vessel support. Although the implant remained radiolucent, 2 platinum markers at each end of the scaffold were added for visualization during angiography.

The ABSORB Cohort B trial tested the Absorb™ BVS 1.1 in 101 patients. This cohort was split into 2 subgroups: cohort B₁ (n = 45), which underwent imaging with angiography, IVUS, VH-IVUS, and OCT after the procedure and at 6 months and 2 years, and cohort B₂ (n = 56), which underwent the same imaging after the procedure and at 1 year and 3 years. Additionally, CTA was performed in both groups at 18 months of follow-up. Angiographic in-scaffold lumen loss was 0.19 ± 0.18 mm at 6 months and 0.27 ± 0.20 mm at 2 years, and remained relatively unchanged at 3 years at 0.29 ± 0.43 mm. IVUS imaging revealed an increase of neointimal generation at 3 years from 0.08 ± 0.13 to 0.28 ± 0.41 mm² (Δ = 0.20 ± 0.41 mm²; P < .002), which was compensated by an increase in the scaffold area by 0.80 ± 1.26 mm² (from 6.29 ± 0.91 to 7.08 ± 1.55 mm²; P < .001), allowing lumen dimensions to remain preserved. The angiographic in-segment restenosis rate in the entire cohort B at 3 years was 6%, and the 3-year MACE rate was 10% without any events of scaffold thrombosis. The results of the ABSORB Cohort B trial indicated the dynamic nature of vessel wall changes following implantation of a fully
bioresorbable device showing low restenosis rates and low clinical adverse events up to 3 years.\textsuperscript{35}

**Randomized Clinical Trials with the First-Generation Absorb\textsuperscript{TM} Bioresorbable Vascular Scaffold**

Despite CE mark approval of the Absorb\textsuperscript{TM} BVS 1.1 in 2012 for revascularization of noncomplex lesions, the paucity of randomized comparisons of BRS with metallic DES in “low-risk” patients and early concerns for higher very late scaffold thrombosis rates resulted in questions regarding the merit of this technology.\textsuperscript{36} It was not until 2015 that the results from international large-scale randomized trials from the United States, China, and Japan were published.

**ABSORB III**

The ABSORB III was the first large-scale, multicenter, randomized trial designed to support the Absorb\textsuperscript{TM} BVS transition from the stage of premarket approval, to complete US FDA clearance for clinical use in the United States. Two thousand and eight patients with stable or unstable angina were randomly assigned to receive in a 2:1 ratio an everolimus-eluting metallic stent (Xience) or the Absorb\textsuperscript{TM} BVS 1.1. The primary end point was target lesion failure (TLF), a composite of cardiac death, target vessel myocardial infarction (TV-MI), or ischemia-driven TLR, tested for both noninferiority and superiority at 1 year. The treated lesions were relatively complex, with the majority being type B2. Only very complex lesion subsets, such as very long or heavily calcified lesions, chronic total occlusions, left main disease, and large bifurcations, were excluded.\textsuperscript{37}

The Absorb\textsuperscript{TM} BVS was found to be noninferior to Xience at 1 year, meeting the primary end point of noninferiority albeit with a generous noninferiority margin of 4.5%. TLF occurred in 7.8% versus 6.1% of patients in the Absorb BVS arm versus the Xience arm, respectively (difference, 1.7%; 95% confidence interval [CI], –0.5% to 3.9%; \(P = .007\) for noninferiority and \(P = .16\) for superiority). Individual components of TLF were not significantly different among both arms at 1 year. More specifically, rates of cardiac death in the Absorb BVS arm versus Xience arm were 0.6%
versus 0.1% (P = .29), respectively. TV-MI event rates in the Absorb BVS arm versus the Xience arm were 6.0% versus 4.6% (P = .18), respectively, and TLR rates were 3.0% versus 2.5% (P = .50), respectively. Device thrombosis among the groups reached 1.5% in the Absorb BVS arm versus 0.7% in the Xience arm (P = .13). Interestingly, 25% (n = 375) of the vessels treated in the ABSORB III trial had a reference diameter of <2.25 mm. Device thrombosis rates in these smaller vessels were significantly different, reaching 4.65% in the Absorb BVS arm versus 1.55% in the Xience V arm. This subanalysis demonstrates the importance of vessel sizing, suggesting avoidance of vessels <2.5 mm for BRS deployment.

In summary, the ABSORB III trial demonstrated the clinical safety and efficacy of Absorb™ BVS implanted in moderately complex lesions at 1 year. Although device thrombosis rates were numerically larger than the best-in-class metallic stent, there was no statistically significant difference among the treated groups. Obviously, long-term evaluation of both cohorts will determine whether the rates of late clinical events will decline in the Absorb BVS arm, an expectation based on the encouraging observations from FIM registries related to the reparative properties of the Absorb BVS.

**ABSORB China**

ABSORB China enrolled 480 patients randomized for elective PCI to receive in a 1:1 ratio an Absorb™ BVS or an Xience V stent. The trial was designed to assess in a noninferior fashion the angiographic efficacy and clinical safety of Absorb BVS compared with the Xience V stent in order to receive regulatory approval in China. The primary end point was angiographic in-segment late lumen loss powered for noninferiority with a margin of 0.15 mm. The Absorb™ BVS was noninferior to the Xience V stent at 1 year, meeting the primary end point of noninferiority. In-segment late lumen loss (in device + 5-mm proximal and distal edge vascular responses) was 0.19 ± 0.38 mm versus 0.13 ± 0.38 mm in the Absorb BVS versus the Xience V stent, respectively (P for noninferiority = .01). There were no definite scaffold or stent thromboses during the 1-year follow-up period. TLF rates and individual components of cardiac death, TV-MI, and TLR were similar among the groups at 1 year.38,39
**ABSORB Japan**

ABSORB Japan enrolled 400 patients randomized for elective PCI to receive in a 2:1 ratio an Absorb™ BVS or an Xience V stent. The trial was designed to assess in a noninferior fashion the clinical safety and angiographic efficacy of Absorb BVS compared with the Xience V stent in order to receive regulatory approval in Japan. The primary clinical end point was TLF at 1 year, whereas the secondary efficacy end point was angiographic in-segment late lumen loss at 13 months. The Absorb BVS was noninferior to the Xience V stent at 1 year, meeting the primary end point of noninferiority. The secondary end point of in-segment late lumen loss (in device +5-mm proximal and distal edge vascular responses) did not differ among the groups and was 0.13 ± 0.30 mm versus 0.12 ± 0.32 mm in the Absorb BVS versus Xience V stent groups, respectively ($P = .74$). Similarly, in-device late lumen loss (excluding the 5-mm proximal and distal edge vascular responses) was not significantly different among the Absorb BVS versus Xience V stent groups ($0.19 ± 0.31$ mm vs $0.16 ± 0.33$ mm, respectively; $P = .35$). There were no differences in the rates of stent or scaffold thrombosis among the arms.

**ABSORB Clinical Trial Data in Aggregate**

In a recent meta-analysis including the ABSORB II and III, ABSORB China, ABSORB Japan, EVERBIO II, and TROFI II randomized trials, the Absorb™ BVS was compared with a best-in-class cobalt-chromium DES in 3738 patients. The average follow-up was 1 year. Both devices had similar efficacy outcomes. However, the primary safety outcome of early (<30 days) definite/probable thrombosis was higher with the Absorb™ BVS compared with DES (1.3% vs 0.5%; odds ratio, 1.99; 95% CI, 1.00-3.98; $P = .05$).

**DESolve Scaffold**

The DESolve bioresorbable coronary scaffolds (Elixir Medical Corporation, Sunnyvale, CA) include the first-generation device made of PLLA eluting the antiproliferative agent Myolimus (Novartis, Basel, Switzerland) and the second-generation which elutes a novel macrocyclic lactone Novolimus (Elixir Medical) at a dose of 5 μg/mm. The scaffold design incorporates...
sinusoidal in-phase hoops with straight connectors, the strut thickness is 150 μm, and the expected strut resorption is 1 year, as indicated in porcine models. Despite the radiolucency of the device, it has 2 radiopaque platinum markers at the proximal and distal edges for appropriate visualization.

Both systems have a crossing profile of 1.47 mm and are 6-Fr compatible. The degradation process resembles that of the Absorb BVS undergoing polymer hydrolysis, and further metabolism occurs in the Krebs cycle to end products of carbon dioxide and water. The DESolve Myolimus-eluting scaffold was tested for efficacy, feasibility, and safety in the DESolve FIM trial (A Nonrandomized, Consecutive Enrollment Evaluation of the DESolve Myolimus-Eluting Bioresorbable Coronary Stent in the Treatment of Patients With De Novo Native Coronary Artery Lesions), which enrolled 16 patients with a single de novo coronary lesion. Multi-imaging assessment with IVUS, VH-IVUS, and OCT was serially performed at the 6-month follow-up. Multislice computed tomography (MSCT) was performed at 12 months and will be repeated at 24 months, whereas clinical end points were assessed at 30 days and 6 months and will be assessed annually for up to 5 years. The angiographic late lumen loss at 6-month follow-up was 0.19 ± 0.19 mm, similar to that of contemporary DES (Xience V everolimus-eluting stent) and far less than that of paclitaxel-eluting stents, which is in the range of 0.35 to 0.40 mm, with no evidence of scaffold shrinkage as indicated by serial IVUS assessment. MSCT at 12 months demonstrated comparable in-scaffold lumen diameters with the angiographically derived 6-month results (2.40 ± 0.28 mm vs 2.41 ± 0.28 mm, respectively).

In view of these encouraging results, the second generation Novolimus-eluting scaffold was developed and further evaluated in the DESolveNx study, which recruited 126 patients with single de novo coronary artery lesions. The primary end point of in-scaffold late lumen loss was 0.21 ± 0.34 mm at 6 months, and IVUS-based assessment in a subset of 40 patients indicated significant increases in scaffold and lumen areas of 16% and 9%, respectively. DESolve has recently received CE mark approval for coronary interventions in Europe.

Poly(Anhydride-Esters) Composed of Salicylic Acid for Engineering BRS
Poly(anhydride-esters) are biodegradable polymeric compounds composed of a trimer of 2 salicylic acid molecules joined by a linker molecule. The Bioabsorbable Therapeutic Inc. (BTI) scaffold (Bioabsorbable Therapeutic Inc., Menlo Park, CA) consists of 2 components: (1) the core composed of salicylic acid bridged with sebacic acid and (2) the coating composed of salicylic acid linked with adipic acid and 1:1 ratio of sirolimus in a total dose density of 8.3 μg/mm of scaffold length (Fig. 31-6). The bioresorbable coating, which is salicylate based, has previously proved its compatibility and efficacy in bench studies showing reduced inflammatory responses compared to BMSs (Multi-Link Vision stent; Abbott Vascular) attributed to the salicylic acid compound, which is an anti-inflammatory agent.

FIGURE 31-6 Poly(anhydride-ester) salicylic acid for engineering bioresorbable scaffolds. The first-generation BTI scaffold and the second-generation Ideal BioStent are shown. The scaffolds are composed of a top layer, which is a blend of polymer (salicylic acid linked with adipic acid) and sirolimus, and another layer, which is the scaffold backbone made of salicylic acid linked with sebacic acid. The chemical structures of poly(anhydride-esters) made of salicylic acid are illustrated.
The scaffold has a strut thickness of 200 μm, a crossing profile of 1.83 mm (3.0-mm scaffold) or 1.98 mm (3.5-mm scaffold), and is compatible with 8-Fr guiding catheters. The WHISPER FIM trial conducted in 2008 included 11 patients and confirmed the safety and efficacy of the device. However, high restenosis rates attributed to exaggerated neointimal proliferation subsequent to lower concentrations of sirolimus (25% less than the dose of the Cypher stent) drove the development of the second-generation scaffold.43

The Ideal BioStent (Xenogenics Corporation, Canton, MA) is thinner, with a thickness of 175 μm; has a smaller crossing profile (1.52 mm for 3.0-mm scaffold), which makes it compatible with 6-Fr guiding catheters; and has a higher drug dose of sirolimus and longer scaffold length, which are associated with slower release rates. Preclinical evaluation of the device is currently under way, with plans for clinical assessment in 2016. The poly(anhydride-ester) comprised of salicylic acid has not received either CE mark or US FDA regulatory approval.

Tyrosine-Derived Polymers for Engineering Polymeric Scaffolds

Tyrosine-derived polycarbonates are a group of homologous carbonate-amid copolymers differing in the length of their respective alkyl ester pendent chains. The REVA scaffold (REVA Medical, San Diego, CA) is made of tyrosine-derived polycarbonate polymer and designed with slide-and-lock expansion technology. The polymer undergoes hydrolysis, which produces iodinated desaminotyrosyl-tyrosine ethyl ester (I$_2$DTE) and carbon dioxide. The esters in the presence of water are further hydrolyzed to iodinated desaminotyrosyl-tyrosine (I$_2$DT), which is gradually converted to tyrosine and iodinated desaminotyrosine (I$_2$DAT). I$_2$DAT enters the Krebs cycle, with final products of carbon dioxide and water. The resorption pathway is similar to that of poly-lactic acid–based scaffolds, with early loss of the polymer’s molecular weight mediated by hydrolysis, followed by reduction of radial strength and gradual mass loss.

Resorption time may take up to 18 months. Bench studies in large animal models have demonstrated low inflammatory rates and complete endothelialization at 30 days, whereas serial IVUS imaging confirmed lumen gain from after implantation to 12 months. Another appealing property of the
REVA scaffold is its radiopacity (Fig. 31-7).

**FIGURE 31-7** Tyrosine-derived polymers for engineering bioresorbable scaffolds. A. The ReZolve (second-generation) tyrosine-derived polycarbonate scaffold showing the “slide and spiral lock” design. B. The chemical structure of the amino acid tyrosine, carbonate, and phenyl group, which provides the backbone for the tyrosine-derived polycarbonate polymer. C. The ReZolve scaffold is radiopaque, attributed to the iodination of tyrosine. The metabolic pathway of tyrosine-derived polycarbonates undergoes hydrolysis with end products of carbon dioxide and water. The resorption pathway is similar to polylactide-based scaffolds, with initial loss of molecular weight followed by mass loss and excretion by the lungs and kidneys.

These encouraging observations drove the technology in the clinical setting, with the FIM RESORB (REVA Endovascular Study of a Bioresorbable Coronary Stent) study being performed in 30 patients with de novo CAD. Focal mechanical failure of the technology due to polymer embrittlement led to high TLR rates of 66.7%, which drove the development of the second-generation device ReZolve (REVA Medical) scaffold. ReZolve provided a more robust polymer, acquired a “slide and spiral lock” mechanism, eluted the antiproliferative agent sirolimus, and was compatible with 6-Fr guiding catheters. The safety of this scaffold was evaluated in the FIM RESTORE (ReZolve Sirolimus-Eluting Bioresorbable Coronary
Scaffold) pilot study, which included 22 patients. The primary end point was freedom from ischemia-driven TLR at 6 months and angiographic late lumen loss at 12 months, which was $0.29 \pm 0.33$ mm with minimal acute recoil of 3.79%. The second-generation sirolimus-eluting FANTOM scaffold is undergoing safety and efficacy evaluation in the FANTOM II registry intending to enroll 240 patients from 28 clinical centers. The primary endpoint of MACE at 6 months was 2.1% and late lumen loss was $0.25 \pm 0.40$ mm. The 9-month secondary endpoints of MACE and late lumen loss are anticipated after completion of the follow-up. Following these encouraging observations, the technology received recently CE mark approval.

**PDLLA ART Scaffold**

The ART scaffold (Arterial Remodeling Technologies, Paris, France) is a polymer-based, non–drug-eluting device made of amorphous PDLLA. The scaffold has a strut thickness of 170 μm, consists of out-of-phase zig-zag hoops, and is compatible with 6-Fr guiding catheters. Preclinical assessment has shown early endothelialization, low inflammatory rates, and complete scaffold resorption at 18 months. The second-generation ART18Z is currently undergoing FIM evaluation in the ARTDIVA (Arterial Remodeling Transient Dismantling Vascular Angioplasty; ClinicalTrials.gov identifier: NCT01761578) trial, which intends to recruit 30 patients with de novo CAD.44

**NOVEL ASSESSMENT OF CORONARY BRS**

Both blood fluid dynamics and plaque/vessel solid mechanics adjacent to an implantable vascular device affect vascular healing around the device. Therefore, an important design element of BRS is platform flexibility, which induces alterations in angulation, curvature, and vessel compliance to a lesser degree compared to metal stents. Scaffold material properties, strut thickness, design, and resorption are properties that regulate the scaffold’s flexibility, further influencing vascular responses and healing.

The impact of stiffer metallic materials on vessel anatomy and the local
hemodynamic implications of these stiffer metalloids were first described by Wentzel and colleagues, who showed alterations of vessel geometry following stenting with subsequent unfavorable rheologic profiles at the stented segments. Polymer and Mg-based BRSs are made of elastic materials, providing a more conformable platform compared to metal stents. For example, Absorb BVS has shown a significantly lower modification of vessel angulation and numerically lesser change in curvature from before to after procedure compared to metal stents.

Strut thickness is an important determinant of scaffold flexibility; thus, current-generation DESs are manufactured with thinner struts in the range of 75 to 90 μm. BRSs were first introduced in the interventional market with strut thickness in the range of 140 to 150 μm to provide additional radial strength because these materials have inferior tensile strength compared to cobalt-chromium or stainless steel alloys.

Despite the larger struts resulting in more disturbed strut level flow after implantation, gradual scaffold resorption and neointima in between the struts result in more laminar flow patterns over time, which promote homogenous vascular healing. Indeed, we have recently described and quantified, using finite element methods and advanced computational fluid dynamic simulations, the device-flow interaction over time in a virtual model. Additionally, we have demonstrated the feasibility of assessing these rheologic patterns by fusing angiographic with optical-based imaging (Fig. 31-8).
FIGURE 31-8 Wall shear stress (WSS) derived from angiographic and optical coherence tomography (OCT) imaging data using computational fluid dynamics modeling techniques following implantation of the Absorb bioresorbable vascular scaffold (BVS). A, A’. Two-dimensional (2-D) angiographic views of the significant proximal left circumflex (LCx) lesion (A) and the scaffolded segment following implantation of the 3.0 × 18 mm Absorb BVS (A’). B, B’. Three-dimensional (3-D) angiographic views before (B) and after (B’) scaffold implantation. C. The Absorb BVS. D, D’. Time-averaged WSS (TAWSS) magnitude distribution from angiographically derived 3-D geometries before (D) and after (D’) scaffold deployment. Velocity profiles before and after implantation of the Absorb BVS are superimposed. E. 2-D OCT cross-section with embedded polymeric struts demonstrating in a 3-D pattern the distribution of TAWSS between the polymeric struts. The quantified color coding demonstrates low WSS regions (blue color). The matched OCT cross-section is superimposed. E’. Reconstructed stream lines of the velocity field demonstrating altered flow patterns in the proximity of the arterial wall induced by the polymeric struts. The RESTORATION (Evaluation and Comparison of Three-Dimensional Wall Shear Stress Patterns and Neointimal Healing Following Percutaneous Coronary Intervention With Absorb Everolimus-Eluting Bioresorbable Vascular Scaffold Compared to Xience V or XiencePrime Everolimus-Eluting Metallic Stent) study was designed to address the changes induced by BRS versus a permanent metallic stent in local hemodynamic conditions, vessel compliance, and angulation form after the procedure to 3 years of follow-up in selected patients enrolled in the ABSORB III randomized controlled trial. This head-to-head comparison will precisely describe the association of poststent wall shear stress with vessel healing using a combination of angiography and IVUS or high-resolution optical imaging and will add further insights in the field of vascular reparative therapy.

COST EFFECTIVENESS OF EVOLVING STENT TECHNOLOGIES

The reduction in the economic burden of restenosis with DES compared with BMS has been shown to compensate for the higher upfront cost of DES. Market competition has resulted in further reduction in costs of newer generation DESs. BRS technologies in clinical use within the European market are more expensive than current-generation DESs. Given that there is no expectation for BRS to clinically outperform current-generation DESs within the first year, one would not expect a compensation for the greater upfront cost, as was seen with DES compared with BMS in the early time period. However, if in the long-term BRSs reduce the ongoing 2% per year event rate related to DES technology, one might expect downstream cost savings that might offset the upfront additional cost. Long-term outcomes and cost-effectiveness analyses will shed light on this prospect.

SUMMARY

Interventional cardiovascular medicine has witnessed tremendous progress over the past 20 years. Undoubtedly, metal stents have revolutionized the practice of interventional cardiology over the past decade. However, concerns
of late stent thrombosis, neoatherosclerosis, metallic caging of long segments of vessels, lack of physiologic vasomotion, and ongoing endothelial dysfunction remain. The premise for BRS is to address these long-term concerns with metallic stents. However, ongoing refinement and research should address the following 2 major remaining issues: (1) strut thickness—efforts are under way to reduce strut thickness while maintaining mechanical properties to prevent acute scaffold recoil; and (2) strut integrity—polymer-based scaffolds have limited expansion properties, and therefore, overdilatation entails the risk of strut fracture or discontinuity. Aggressive lesion preparation and close attention to accurate BRS sizing with use of intravascular imaging will optimize strut integrity and scaffold expansion, likely improving outcomes.

CONCLUSION

BRSs have been heralded as the fourth revolution in interventional cardiovascular medicine following DES, BMS, and balloon angioplasty. Although BRS technologies are in their early stages, further developments will mature this novel field of vascular reparation therapy with scaffolds that are intended to “do their job and disappear.”

MULTIPLE CHOICE QUESTIONS

1. Which of the following statements regarding polymer-based scaffold bioresorption is true?
   A. Polymer-based scaffolds undergo bulk degradation following polymer hydrolysis.
   B. The end products of polymer-based degradation are elemental magnesium and inorganic salts.
   C. The average resorption time of poly-l-lactic acid is 1 year, as indicated by gel permeation chromatography. Regions previously occupied by polymeric struts are replaced by functional connective tissue at 2 years.
   D. Continuous cleavage of polymer’s amorphous tie chains leads to oligomeric molecules that enter the Cori cycle with end products carbon dioxide and water.
   E. Continuous cleavage of polymer’s amorphous tie chains increases the scaffold’s radial strength, enabling sufficient vessel support.

2. The ABSORB III trial randomized 2008 patients with stable or unstable angina to receive in a 2:1 ratio the everolimus-eluting bioresorbable vascular scaffold (BVS; Absorb) or the metallic Xience V stent. The findings of this trial include all of the following except:
   A. The primary end point was target-lesion failure (TLF), a composite of cardiac death, target vessel myocardial infarction (TV-MI), or ischemia-driven target lesion revascularization (TLR).
   B. TLF occurred in 7.8% of patients in the Absorb BVS arm versus 6.1%
of patients in the Xience arm (difference, 1.7 percentage points; 95% confidence interval, −0.5 to 3.9; \(P = .007\) for noninferiority and \(P = .16\) for superiority).

C. Device thrombosis among the groups reached 1.5% in the Absorb BVS arm versus 0.7% in the Xience arm (\(P = .13\)).

D. Device thrombosis rates in vessels with a reference vessel diameter (RVD) of \(<2.25\) mm did not differ among the groups, and the Absorb BVS is indicated in small vessels as well as in vessels with RVD \(>2.5\) mm.

E. The Absorb BVS was found to be noninferior to Xience at 1 year, meeting the primary end point of noninferiority, albeit with a generous noninferiority margin of 4.5%.

3. The ABSORB China trial randomized 480 patients to receive in a 1:1 ratio an Absorb BVS or an Xience V stent. Which of the following was the primary end point?
   A. The efficacy end point of in-stent late lumen loss at 1 year
   B. The safety end point of in-segment late lumen loss at 2 years
   C. The efficacy end point of in-segment late lumen loss at 1 year
   D. The safety end point of in-stent late lumen loss at 2 years
   E. The efficacy end point of scaffold thrombosis at 2 years

4. Which of the following statements regarding the DESolve scaffold is false?
   A. The DESolve scaffold has 2 radiopaque platinum markers at the proximal and distal edges for appropriate visualization.
   B. The DESolve scaffold incorporates sinusoidal in-phase hoops with straight connectors, and the strut thickness is 150 \(\mu\)m.
   C. The DESolve first-in-man trial enrolled 16 patients, and the angiographic late lumen loss at 6 months was similar to that of contemporary drug-eluting stents (DES).
   D. The DESolve scaffold is made of tyrosine-derived polycarbonate. The first-generation device eluted everolimus, whereas the second-generation scaffold elutes Myolimus.
   E. The DESolve Myolimus-eluting scaffold has acquired the CE mark for clinical use in Europe.
5. The second-generation DREAMS device is a:
   A. Tyrosine polycarbonate scaffold that elutes paclitaxel and provides similar bending flexibility and slower resorption rate compared with the DREAMS I device.
   B. Hybrid of three lactide polymers that elutes sirolimus.
   C. Magnesium-based scaffold that elutes Myolimus with higher resorption rate compared with the DREAMS I device.
   D. Magnesium-based scaffold that has been studied in the BIOSOLVE-I trial.
   E. Magnesium-based scaffold that elutes sirolimus and provides higher bending flexibility and slower resorption rate compared with the DREAMS I device.
   F. Polymer-based scaffold that elutes everolimus and has a slower resorption rate compared with the DREAMS I device.

ANSWERS

1. A

Polymer-based scaffolds undergo bulk degradation after polymer hydration. The first stage in the process of polymer bioresorption is hydration. Polylactides are relatively hydrophilic; thus water diffuses into the less dense amorphous regions of the implant and hydrolyzes the ester bonds. Random chain scissions occur at this stage, leading to reduction of the polymer’s molecular weight. The second stage is characterized by continuous cleavage of the amorphous tie chains, reducing the radial strength of the scaffold and leading to structural discontinuities. During the third stage, polymer chains that have been hydrolyzed to short lengths diffuse out of the implant (mass loss) as they are increasingly hydrophilic and soluble in aqueous solution. Following these sequential stages, oligomeric polylactic acid molecules hydrolyze to lactic acid monomers, which deprotonate (release of a proton [H⁺]) to lactate. Lactate is converted to pyruvate and enters the citric acid cycle (Krebs cycle), which is further metabolized in CO₂ and H₂O excreted through lungs and kidneys. The end products of magnesium-based scaffolds are elemental magnesium and inorganic salts.
Device thrombosis rates in vessels with an RVD of <2.25 mm did not differ among the groups, and the Absorb BVS is indicated in small vessels as well as in vessels with RVD >2.5 mm. The ABSORB III was the first large-scale, multicenter, randomized trial designed to support the Absorb BVS transition from the stage of premarket approval, which allows the execution of phase III clinical trials, to complete Food and Drug Administration (FDA) clearance for clinical use in the United States. Two thousand eight patients with stable or unstable angina were randomly assigned to receive in a 2:1 ratio an everolimus-eluting metallic stent (Xience) or the Absorb BVS 1.1. The primary end point was target lesion failure (TLF), a composite of cardiac death, target vessel myocardial infarction (TV-MI), or ischemia-driven target lesion revascularization (TLR), tested for both noninferiority and superiority at 1 year. The treated lesions were relatively complex, with the majority being type B2. Only very complex lesion subsets, such as very long or heavily calcified lesions, chronic total occlusions, left main disease, and large bifurcations, were excluded. The Absorb BVS was found to be noninferior to Xience at 1 year, meeting the primary end point of noninferiority, albeit with a generous noninferiority margin of 4.5%. TLF occurred in 7.8% of patients in the Absorb BVS arm versus 6.1% of patients in the Xience arm (difference, 1.7 percentage points; 95% confidence interval, −0.5 to 3.9; \( P = .007 \) for noninferiority and \( P = .16 \) for superiority). Individual components of TLF were not significantly different among both arms at 1 year. More specifically, rates of cardiac death in the Absorb BVS arm versus Xience arm were 0.6% versus 0.1% (\( P = .29 \)), respectively. TV-MI event rates in the Absorb BVS arm versus the Xience arm were 6.0% versus 4.6%, respectively (\( P = .18 \)), with TLR rates reaching 3.0% versus 2.5%, respectively (\( P = .50 \)). Device thrombosis among the groups reached 1.5% in the Absorb BVS arm versus 0.7% in the Xience arm (\( P = .13 \)). Interestingly, 25% (\( n = 375 \)) of the vessels treated in the ABSORB III trial had a reference diameter of <2.25 mm. Device thrombosis rates in these smaller vessels were significantly different, reaching 4.65% in the Absorb BVS arm versus 1.55% in the Xience V arm. This subanalysis demonstrates the importance of vessel sizing, suggesting avoidance of vessels >2.5 mm for bioresorbable stent deployment.
In-segment late lumen loss at 1 year was the efficacy end point and the primary end point. The ABSORB China trial was designed to assess in a noninferior fashion the angiographic efficacy of Absorb BVS compared to the Xience V stent in order to receive regulatory approval in China. The primary end point was angiographic in-segment late lumen loss powered for noninferiority with a margin of 0.15 mm. The Absorb BVS was noninferior to the Xience V stent at 1 year, meeting the primary end point of noninferiority. In-segment late lumen loss (in-device + 5-mm proximal and distal edge vascular responses) was 0.19 ± 0.38 mm versus 0.13 ± 0.38 mm (P noninferiority = .01) in the Absorb BVS versus the Xience V stent arms, respectively.

4. D

The DESolve scaffold is made of poly-l-lacatic acid (PLLA). The first-generation device eluted everolimus, whereas the second-generation scaffold elutes Myolimus. The DESolve bioresorbable coronary scaffolds (Elixir Medical Corporation, Sunnyvale, CA) include the first-generation device made of PLLA eluting the antiproliferative agent Myolimus (Novartis, Basel, Switzerland) and the second-generation device, which has the same platform but elutes a novel macrocyclic lactone Novolimus (Elixir Medical Corporation, Sunnyvale, CA) at a dose of 5 μg/mm. The scaffold design incorporates sinusoidal in-phase hoops with straight connectors and a strut thickness of 150 μm, and the expected strut resorption is 1 year, as indicated in porcine models. Despite the radiolucency of the device, it has 2 radiopaque platinum markers at the proximal and distal edges for appropriate visualization. Both systems have a crossing profile of 1.47 mm and are 6-Fr compatible. Degradation process resembles that of Absorb BVS undergoing polymer hydrolysis and further metabolism in the Krebs cycle to end products of carbon dioxide and water. The DESolve Myolimus-eluting scaffold was tested for efficacy, feasibility, and safety in the DESolve FIM trial (A Nonrandomized, Consecutive Enrollment Evaluation of the DESolve Myolimus Eluting Bioresorbable Coronary Stent in the Treatment of Patients With De Novo Native Coronary Artery Lesions), which enrolled 16 patients with a single de novo coronary lesion. Multi-imaging assessment with intravascular ultrasound (IVUS), virtual histology IVUS, and optical coherence tomography was serially performed at 6-month follow-up. Multislice computed tomography was performed at 12 months and repeated
at 24 months, whereas clinical end points were assessed at 30 days, 6 months, and annually for up to 5 years.

5. E

The second-generation DREAMS device elutes sirolimus, carries two tantalum radiopaque markers at both ends, and provides higher bending flexibility and slower resorption rate compared with the previous generation DREAMS device. Preclinical data are encouraging and show increased endothelialization rates and decreased inflammatory scores, and the BIOSOLVE-II study has been designed to assess the safety, efficacy, and feasibility of this second-generation device in 120 patients. The primary end point of this trial is in-segment late lumen loss.
Drug-Coated Balloon Technologies: Technical Features and Clinical Applications

Juan F. Granada
Yanping Cheng
Bruno Scheller

HISTORICAL BACKGROUND

The concept of delivering antiproliferative drugs via balloon angioplasty has been around for several decades. However, the specific idea of developing a drug-coated balloon (DCB) system originated from the seminal work of professor Ulrich Speck in the use of contrast agents as carriers of antiproliferative drugs.\textsuperscript{1} At the early stages of his research, it was found that paclitaxel solubility was significantly increased when mixed when contrast agents. Experimental data showed that a repeated intracoronary bolus injection of a taxane-iopromide formulation resulted in significant reduction of neointimal proliferation in the porcine model of restenosis.\textsuperscript{2,3} In 2001, the concept of mixing iopromide with paclitaxel in a form of a balloon coating was reduced to practice and validated at the experimental level.\textsuperscript{4} This original DCB formulation was then clinically validated in small randomized controlled studies in the coronary in-stent restenosis\textsuperscript{5} and de novo superficial femoral artery stenosis settings.\textsuperscript{6,7} Stimulated by these early clinical results, several DCB programs were started following a similar technologic approach
of using hydrophilic carriers as a method to transport paclitaxel into the vessel wall after balloon dilatation.

**TECHNOLOGIC APPROACH**

The development of drug-eluting stents (DESs) dramatically reduced the long-term rate of reintervention and improved clinical outcomes among patients undergoing percutaneous coronary interventions. However, despite their continuous technologic evolution and well-validated clinical efficacy, long-term complications (eg, target lesion revascularization) continue to occur. Several autopsy and in vivo imaging studies suggest delayed healing of the permanently implanted stent as the most important biologic mechanism responsible for these events. As a result, stent-based drug delivery technologies continue to evolve aiming to minimize the amount of permanent implantable components (ie, polymer) left behind following DES implantation.

The concept of developing a balloon-based drug delivery system to prevent arterial restenosis was based on the hypothesis that a durable effect on neointimal proliferation could be achieved following single-drug delivery and potentially minimizing the impact of the chronically implantable components. This technologic approach appeared to contradict historical experimental and clinical data suggesting that sustained tissue exposure to therapeutic levels of drug was necessary to effectively inhibit neointimal proliferation. Due to its particular delivery mechanism and resulting pharmacokinetic profile, the promising results shown by the early DCB trials were originally challenged under the premise that sustained drug release was needed to attain long-term clinical efficacy.

**COATING FEATURES AND MECHANISM OF ACTION**

All DCBs developed to date use paclitaxel due to its high lipophilic profile, potent antiproliferative effect, and chemical stability following tissue delivery. Paclitaxel has shown to inhibit cell proliferation and migration
due to an irreversible stabilization of intracellular microtubules, resulting in inhibition of cell replication during metaphase and anaphase of mitosis.\textsuperscript{15} Early experimental data showed that drug carriers are needed to transfer and maintain paclitaxel tissue levels over time.\textsuperscript{16} Thus, the pharmacokinetic characteristics of each DCB largely depend on the carrier and manufacturing process used to develop the coating. DCBs achieve the short-term transfer and long-term retention of paclitaxel to the arterial wall by different biologic mechanisms.\textsuperscript{17} Experimental data have shown that paclitaxel transfer and retention are not necessarily interrelated phenomena and largely depend on drug morphology and resulting solubility attained during the coating process (Fig. 32-1).\textsuperscript{18,19} At present, although a potential mechanism of action explaining long-term drug retention yielding sustained biologic efficacy following DCB drug delivery is still a matter of debate, important lessons have been learned regarding the pharmacokinetic behavior of some of these technologies. Early experimental data confirmed that paclitaxel transfer into the vessel wall occurs rapidly following balloon inflation.\textsuperscript{4} In addition, several tissue pharmacokinetic studies showed that the short-term tissue levels of paclitaxel following balloon delivery were several-fold higher compared with DES.\textsuperscript{20} Finally, most of the pharmacokinetic studies using clinically available DCB technologies have confirmed that paclitaxel tissue levels are successfully maintained over time (Fig. 32-2).\textsuperscript{17}

Several experimental studies suggest that the presence of paclitaxel deposits on the surface of the vessel wall contribute to the biologic process of sustained local drug delivery. A recent study suggested that following DCB dilatation, a large proportion of the paclitaxel coating is retained on the vessel surface and is not actually dissolved into the tissue (Fig. 32-3). In this study, it seemed apparent that arterial tissue levels were directly related to the sustained retention of drug on the surface of the vessel wall, thereby providing a constant concentration gradient from the vessel surface into the arterial wall over time. Interestingly, at 7 days, vessel wall concentrations began to equalize to the vessel surface levels, providing an explanation regarding the lack of tissue toxic effects despite the apparent supratherapeutic tissue levels found in pharmacokinetic studies. These results largely depended on the degree of paclitaxel crystallinity and seemed to be consistent with previous reports showing that specific binding to intracellular proteins occurs primarily in the subintimal space and determines arterial transport properties and microtubule binding of paclitaxel. As a consequence, the observed tissue half-life of paclitaxel delivered by DCB relates to the slow dissolution of paclitaxel deposits from the vessel surface into arterial tissue in a time-dependent fashion. Thus, the proposed mechanism of action reconciles the apparent contradiction between the observed short term
supratherapeutic tissue levels seen right after balloon delivery and the resulting vessel healing profiles seen at the experimental level. However, the mechanism of action of DCB is likely technology dependent and likely will unveil several mechanistic pathways that will help the future development of DCB technologies.

FIGURE 32-3 Impact of crystallinity on paclitaxel (PTX) deposition on the vessel surface: vessel wall (A) versus vessel surface (B) on 2 different coatings.

VESSEL HEALING AND DISTAL
TISSUE EFFECTS

Vessel healing largely depends on the pharmacokinetic features of each DCB technology. Bench data suggest that during balloon transit to the target lesion, approximately 10% to 15% of the drug is lost into the bloodstream. Also, at the time of balloon inflation, coating fragmentation occurs and paclitaxel particles are either transferred to the vessel wall or lost into the distal bloodstream (Fig. 32-4).\textsuperscript{16} Despite the high paclitaxel tissue levels achieved immediately after DCB delivery, tissue levels rapidly decline in 72 hours, and most of the paclitaxel remains attached to the surface of the vessel wall.\textsuperscript{4} After 7 days, paclitaxel tissue levels are comparable (although slightly higher) to the ones reported for DES.\textsuperscript{20}

\textbf{FIGURE 32-4} Proposed mechanism of drug loss and particulate production in drug-coated balloon technologies. PCB, paclitaxel-coated balloon.

The vessel healing characteristics of arteries treated with DCB vary according to the presence or absence of stents. In the absence of the stent, the vessel healing profile is characterized by neointimal inhibition, presence of fibrin, and smooth muscle cell loss persistent over 90 days and resolving at 180 days.\textsuperscript{16} In contrast, the vascular healing profile of bare metal stents...
(BMSs) followed by DCB dilatation is similar to the one reported for paclitaxel-eluting stents (Fig. 32-5). Finally, a significant amount of emphasis has been put on the phenomenon of particulate embolization into the distal bloodstream. In vitro data have shown that the degree of particulate formation is significantly higher compared to DES. However, it has also been described that these particles are usually small and unlikely to be trapped into the distal microcirculation. Experimental data also suggest that microembolization is a rare finding and perhaps clinically irrelevant. However, due to the potential clinical adverse events derived from this phenomenon, the clinical introduction of these technologies for the treatment of specific critical vascular territories (eg, below the knee) has been slow and limited.

**FIGURE 32-5** Representative histologic pictures and vascular healing response of crystalline and amorphous coatings at 28 days of follow-up. NS, not significant; PCB, paclitaxel-coated balloon; POBA, plain old balloon angioplasty.

**CORONARY DCB APPLICATIONS**
Although current-generation coronary DESs are considered to be standard of care, significant challenges still remain in specific clinical subsets in which DES outcomes are still suboptimal (eg, in-stent restenosis). In addition, DCBs have the potential to improve clinical outcomes in patients in whom the use of long-term dual antiplatelet therapy is limited (eg, bleeding risk). Thus, at present, the use of DCB has been limited to this specific population subset. In addition, although the use of DCB for the treatment of de novo lesions without the use of stents (“leaving nothing behind”) is theoretically appealing, the risk of abrupt vessel closure following balloon angioplasty and the high clinical success of DES have largely limited the introduction of this approach.

**In-Stent Restenosis**

The first publication of DCB use in humans was described for BMS in-stent restenosis (ISR). In this multicenter study, 52 patients with coronary BMS-ISR were randomized to receive angioplasty with either an uncoated balloon or an iopromide-paclitaxel–coated DCB. At 6 months, the DCB group demonstrated a significant benefit in the primary end point of angiographic in-segment late lumen loss (LLL) (0.74 ± 0.86 vs 0.03 ± 0.48 mm; \( P = .002 \)) as well as in the 6-month secondary end points of minimal lumen diameter (MLD) and binary restenosis. An additional 56 patients with coronary ISR were randomized, and the combined cohort of 108 patients was followed for 5 years, confirming the durability of the antiproliferative effect.

The PEPCAD (Paclitaxel-Eluting Percutaneous Transluminal Coronary Angioplasty Catheter in Coronary Disease) trial program investigated the SeQuent Please DCB (B. Braun, Berlin, Germany) using the same iopromide-paclitaxel coating. PEPCAD II was a multicenter, randomized trial of the DCB versus the Taxus DES (Boston Scientific, Marlborough, MA) in 131 patients with coronary BMS-ISR. The primary end point of 6-month in-segment LLL was significantly less with the DCB compared with the DES (0.17 ± 0.42 vs 0.38 ± 0.61 mm; \( P = .03 \)). At 12 months, target lesion revascularization (TLR) trended in favor of the DCB (6% vs 15%; \( P = .15 \)), suggesting that the DCB was at least as effective as the DES for BMS-ISR and avoiding the need of a second DES implantation. Since then, 8 randomized trials have been published studying the SeQuent Please DCB in
BMS-ISR\textsuperscript{25,26,28} and DES-ISR.\textsuperscript{29-34} A meta-analysis\textsuperscript{35,36} to assess the clinical efficacy of DCB for the treatment of DES-ISR from 5 studies\textsuperscript{29-34} including a total of 864 patients showed that DCB was superior to plain old balloon angioplasty (POBA) and comparable to first-generation DES for treatment of DES restenosis. Based on these trials, the 2014 European Society of Cardiology/European Association for Cardiothoracic Surgery guidelines on myocardial revascularization state (Class I, Level of Evidence A) that DCBs are clinically recommended for the treatment of ISR (within BMS or DES).\textsuperscript{24} Almalla et al\textsuperscript{37} reported that treatment of 86 patients with DES-ISR using the SeQuent DCB is associated with lower rates of major adverse cardiac events (MACE) and TLR at 1-year follow-up compared to second-generation DES (Xience V; Abbott Vascular, Santa Clara, CA). However, the latest results of the RIBS IV trial,\textsuperscript{38} which compared SeQuent DCB with the Xience Prime DES in 309 patients with DES-ISR, showed that patients treated with everolimus-eluting stents achieved superior 9-month LLL compared to DCB (everolimus-eluting stent 2.03 vs DCB 1.80; $P = .004$). At 1 year, freedom from TLR was higher in the patients treated with everolimus-eluting stents than in the DCB group (96% vs 87%; $P = .008$; Table 32-1). As a result, the use of DCB for DES-ISR needs to be considered on individual basis and the decision based on specific anatomic and clinical characteristics of each patient.

**Table 32-1** Summary of Major DCB Studies in DES-ISR
De Novo Coronary Lesions

The initial concept for the use of DCB in coronary de novo lesions included the combination with a BMS to create a “polymer-free” DES. However, results from the PEPCAD III trial comparing such a BMS/DCB combination with the Cypher DES (Cordis, Hialeah, FL) showed this concept to be an inferior approach. Other concepts combining BMS and DCB as primary therapies have also shown similar results. These results have been partially explained by suboptimal percutaneous coronary intervention (PCI) technique (ie, geographic miss) and/or inferior DCB coatings. Nevertheless, even with optimized PCI techniques and more advanced coatings, the biologic effect of the DCB/BMS combination has proven to be clinically inferior compared to current-generation DESs. The PEPCAD I study was a nonrandomized study investigating the safety and efficacy of the SeQuent Please DCB with provisional BMS implantation in small vessel (mean reference vessel diameter, 2.36 mm) de novo lesions in 120 patients. At 6 months of follow-up, in-segment LLL was significantly less with DCB alone compared with DCB plus BMS (0.18 and 0.73 mm, respectively), with
the majority of the ISR being noted at the stent edges. In patients with adjunctive BMS implantation, geographical miss was thought to be a strong predictor of the occurrence of future ISR.\textsuperscript{48,49}

As a consequence of these findings, the so-called “DCB-only” strategy has been favored for the coronary use of DCB technologies. This concept includes careful lesion preparation, and depending on the result after predilatation, the operator can decide whether to proceed with DCB only in case of an acceptable angiographic result or use a stent or scaffold in case of major dissection (type C or higher), significant residual stenosis, or reduced flow. This approach aims to avoid the use of unnecessary stents and shorten the duration of dual antiplatelet therapy (~4 weeks in DCB-only procedures).\textsuperscript{50,51} This strategy was successfully investigated in 2 large registries\textsuperscript{52,53} and the randomized BELLO study. In this trial, 182 patients with small coronary vessel disease were treated with either the IN.PACT Falcon balloon (Medtronic, Dublin, Ireland) applying the DCB-only approach or the Taxus stent. The primary end point of LLL at 6 months was significantly lower in the DCB arm (0.08 ± 0.38 vs 0.29 ± 0.44 mm; \(P = .001\)), demonstrating superiority of the DCB-only approach over DES in terms of angiographic end points.\textsuperscript{54} Three-year follow-up (N. Ruparelia, unpublished data, May 2015) has been recently completed in more than 90% of the patients and shows a lower incidence of MACE events in the DCB group compared with the paclitaxel-eluting stent group (14.4% vs 30.4%; \(P = .015\)). However, TLR rates in the DCB group were comparable to those in the paclitaxel-eluting stent group at 6 months, 1 year, and 3 years (4.4% vs 7.6%, \(P = .37\); 4.4% vs 9.8%, \(P = .25\); 6.7% vs 13.0%, \(P = .14\), respectively). An interesting application is in the setting of ST-segment elevation myocardial infarction (STEMI). First results of the DEB-AMI (Drug-Eluting Balloon in Acute ST-Segment Elevation Myocardial Infarction) trial\textsuperscript{55} showed that in STEMI patients, DCB followed by BMS implantation failed to show angiographic superiority to BMS only. Six-month angiographic (LLL: DES 0.21 ± 0.32 mm vs BMS 0.74 ± 0.57 mm and DCB+BMS 0.64 ± 0.56 mm; \(P < .01\)) and clinical results of DES (MACE: DES 4.1% vs BMS 23.5% and DCB+BMS 20.0%; \(P = .02\)) were superior to both BMS and DCB. In a recent report, Camaro and colleagues (unpublished data, May 2015) assessed the angiographic and clinical outcomes of the use of DCB in the STEMI setting. In this study, a total of 130 patients were randomly assigned to predilatation with a paclitaxel-coated balloon (PCB) versus POBA, followed by
implantation of a Genous endothelial progenitor cell capture stent (OrbusNeich, Fort Lauderdale, FL; the DEBORA 2 randomized trial). At 9 months, the mean minimal lumen late loss was 0.18 ± 0.60 mm in the DCB group and 0.55 ± 0.52 mm in the POBA group ($P < .01$). No significant difference with regard to MACE was observed between groups (8.1% vs 9.5%; $P = .773$) at any time interval of clinical follow-up to 12 months. Finally, although the potential favorable vascular effects of the DCB-only strategy (eg, positive remodeling) have been shown in small observational studies, the lack of prospective comparative data has limited DCB use to specific clinical applications at the present time.

PERIPHERAL DCB APPLICATIONS

In contrast to the coronary field, peripheral vascular interventions are less dependent on the use of metallic stents. In long femoropopliteal lesions, the regular use of metallic stents has resulted in high mechanical and clinical failures rates. In addition, the treatment of ISR is a major clinical problem with no clear therapeutic alternatives. Thus, the use of DCB in the peripheral territory has gained more traction compared to the coronary field. However, the most important limitation of DCB use in this vascular territory is the potential for suboptimal angiographic results and dissections, leading to the use of “spot” metallic stenting. Although the use of DCB for de novo lesions has been clinically validated, the combination with BMS for this particular application is less clear. In addition, the use of adjunctive atherectomy and other lesion preparation techniques has also been proposed as a way to reduce the incidence of adjunctive stenting and enable the wider use of DCB in this particular vascular territory.

Femoropopliteal Disease

Several first-in-human randomized trials using different DCB technologies in femoropopliteal lesions have validated the safety and efficacy of this technology compared to POBA (Fig. 32-6). A meta-analysis including 381 patients (DCB, n = 186; POBA, n = 195) and using TLR as the primary end point has been recently published. At a median follow-up of 10.3 months, DCB use versus POBA reduced TLR (12.2% vs 27.7%; odds ratio
[OR], 0.22; 95% confidence interval [CI], 0.13-0.38; \( P < .00001 \)), angiographic restenosis (18.7% vs 45.5%; OR, 0.26; 95% CI, 0.14-0.48; \( P < .00001 \)), and 6-month LLL (–0.05-0.50 mm vs 0.61-1.7 mm; mean difference, –0.75 mm; 95% CI, –1.06 to –0.45; \( P < .00001 \)). In addition, the first DCB study performed in the superficial femoral artery (SFA) territory (THUNDER) has already reached 5-year follow-up demonstrating durability of the drug effect (TLR: DCB 21% vs POBA 56%; \( P = .0005 \)).

FIGURE 32-6 Primary efficacy end points of major drug-coated balloon (DCB) first-in-human clinical studies in the femoropopliteal vascular territory. BTCH, butyryltrin-hexyl citrate; LLL, late lumen loss; POBA, plain old balloon angioplasty; PTX, paclitaxel; TLR, target lesion revascularization.
Two large-scale randomized controlled trials have already completed 12-month clinical follow-up (Table 32-2). The LEVANT II trial\textsuperscript{64} enrolled a total of 476 patients, and the IN.PACT SFA II trial\textsuperscript{65} enrolled a total of 331 patients with a 2:1 randomization. In the LEVANT II trial, the primary vessel patency at 12 months, defined as freedom from both restenosis and TLR, was 65.2\% for DCB and 52.6\% for POBA ($P = .015$). At 12 months, the freedom from clinically driven TLR in the DCB group was attenuated and similar to the control group (87.7\% vs 83.2\%; $P = .208$). In this study, despite that both the safety (freedom from death, amputation, and reintervention) and efficacy primary end points were met, clinical efficacy was not demonstrated. The pooled randomized multicenter IN.PACT SFA I and II trials revealed that clinically driven TLR rates were significantly lower in the DCB group compared to the POBA group (2.4\% vs 20.6\%; $P < .001$). Similarly, the primary patency rate achieved with the IN.PACT Admiral balloon was 82.2\% versus 52.45\% in the POBA group ($P < .001$). In these studies, no safety issues were identified. The safety and efficacy of the use of DCB in long lesions have been recently presented (A. Micari, unpublished data, May 2015). In this study, 105 symptomatic patients with SFA lesions greater than 15 cm were enrolled. Angioplasty success was 84.8\%, the mean total lesion length was 252 mm, and the mean total treated length was 263 mm. The rate of primary patency at 12 months was 83.2\%, with 96\% free of TLR and 84.2\% free of restenosis. The primary patency rate was also reported in the IN.PACT SFA trial (D. Scheinert, unpublished data, May 2015) in 157 patients with long lesions. The 360-day primary patency rate was 91.1\%. Freedom from adverse safety events was 94\%; rates of all-cause death and any TLR were 4.5\% and 6.0\%, respectively. Those results demonstrate remarkable overall effectiveness and safety for patients treated with this technology in this lesion subset.

</table>
One recent publication addressed the issue of dissections following DCB use. In a subgroup analysis of the THUNDER trial, dissections did not negatively impact the efficacy of DCB angioplasty if left alone without stent placement. At 6 months, patients displaying dissections of any grade after treatment with DCB (n = 43) had significantly lower LLL than patients with dissection following POBA (n = 43; 0.4 vs 1.9 mm; \( P = .001 \)). In addition, patients displaying severe dissections (grade C-E) also had lower LLL with DCB compared to POBA (0.4 vs 2.4 mm; \( P = .05 \)). At the 2-year follow-up, TLR rates were 56% in the POBA group versus 10% in the DCB group (\( P = .002 \)). Although intriguing, it is important to note that the lesions included in this study were relatively short and noncalcific and thus not representative of the real-world population.

The efficacy of the adjunctive use of BMS plus DCB has been reported in a prospective, randomized, international trial (J. Tacke, unpublished data, May 2015). A total of 200 patients were enrolled and randomized equally to primary BMS implantation followed by either DCB (Freeway; Eurocor, Bonn, Germany) or POBA after dilatation. The results highly favored the use of DCB over POBA based on clinically driven TLR (5.1% vs 11.0% at 6 months and 9.1% vs 18.0% at 12 months) and primary patency rates (88.3% vs 70.0% at 6 months; \( P = .008 \)).

The efficacy of DCB in ISR lesions has also been recently tested. ISR occurs in up to 40% of femoropopliteal lesions treated with BMS within 1 year. In addition, the risk of ISR increases with lesion complexity and treated length. Parallel to the development of more aggressive recanalization techniques, the use of femoropopliteal stenting continues to increase. Thus, the occurrence of ISR has become a common clinical issue in SFA intervention. The optimal treatment of this condition remains elusive as multiple modalities have failed to provide durable results. Early preliminary
data supported the use of DCB for this clinical indication. A single-center prospective registry, including 39 patients, reported a 1-year primary patency rate of 92.1% and a 2-year primary patency rate of 70.3%. A more recent randomized controlled study (FAIR: DCB vs POBA for Superficial Femoral Artery In-Stent Restenosis) was presented including 119 patients with ISR mean lesion length of 8.2 cm in both study cohorts. The 6-month restenosis rate (primary end point) favored the DCB arm compared to POBA (15.4% vs 44.7%; \( P = .002 \)). At 1 year, restenosis rates were 29.5% and 62.5%, respectively (\( P = .004 \)), and freedom from clinically driven TLR rates at 390 days were 90.8% and 52.6%, respectively (\( P = .0001 \)).

**Ancillary Use of Atherectomy Devices**

The combination of debulking followed by PCB technology to achieve the best outcome for both acute and long-term success seems an attractive approach for these patients. Early, small, single-center reports of the combination of directional atherectomy (DA) and DCB have shown some promise of this approach for patients with lower limb arterial disease. In one study, the combination of DA and DCB (\( n = 60 \)) was compared with DA with non-DCB angioplasty (\( n = 29 \)). The outcomes were primary patency of 84.7% in the DCB group compared with 43.8% in the non-DCB group. In addition, in heavily calcified lesions, the combination of DCB provided a 90% freedom from clinically driven TLR in 30 patients studied from a single center. Thus, the combination of DA with the added technology of DCB seems to be an attractive approach in patients with significant arterial obstructive disease. Clearly, the scientific data are still scarce, and the cost-benefit analysis of this approach deserves further evaluation. The DEFINITIVE AR study (T. Zeller, unpublished data, November 2014) is a prospective, multicenter, pilot feasibility study designed to assess and estimate the effect of treating vessels with DA prior to a DCB. Claudicants with 7- to 15-cm SFA and/or popliteal lesions were randomized 1:1 to either DA+DCB or to DCB alone. Subjects with severely calcified lesions were assigned to a nonrandomized registry arm and were treated with DA+DCB. One hundred twenty-one subjects were enrolled, 48 in the DA+DCB arm, 54 in the DCB arm, and 19 in the severely calcified lesion DA+DCB registry group. Mean lesion length ranged from 9.7 to 11.9 cm. In the randomized groups, the primary end point, percent stenosis at 12 months, was similar in
both cohorts. Angiographic patency (≤50% stenosis and without TLR) was 82.4% in the DA+DCB arm and 71.8% in the DCB arm. The major adverse event rate, defined as a composite of clinically driven TLR, death, and major amputation, was 11.6% for the randomized DA+DCB arm, 9.8% for the randomized DCB arm, and 5.9% for the severely calcified lesion registry arm. This pilot study suggests an added benefit for combination therapy (DA+DCB) in long and calcified lesions that was not observed in the DCB-alone subgroup. Further investigation in larger, prospective, statistically powered randomized trials is warranted.

**Below-the-Knee Disease**

Multiple biologic aspects of below-the-knee (BTK) disease impact the performance of DCB in this vascular territory. The management of long calcified lesions in multiple small-caliber, low-flow arteries with a high-resistance outflow bed influences tissue pharmacokinetics. In addition, BTK arteries represent a tapering system with smaller arteries at the ankle and foot. If the artery significantly tapers in a long diseased segment, drug delivery and distribution may not be uniform. In addition, the presence of multiple lesions throughout the length of an artery and few anatomic landmarks may lead to geographic miss. In addition, medial calcification is a common finding among diabetics with BTK lesions. It is not clear whether these complex biologic components affect drug pharmacokinetics.

The use of DCB in the treatment of BTK occlusive disease and critical limb ischemia syndrome is still under debate. From a technical point of view, particulate formation leading to microvessel embolization may play a more significant role compared to DCB use in other vascular territories. Especially among patients with poor vascular runoff, the dislodgment of a large amount of particles may lead to the mechanical occlusion of microvessels vital for tissue survival. In addition, paclitaxel accumulation in hypoxic tissue may either delay or worsen healing in patients with evidence of tissue loss. Many questions need to be answered before the wide adoption of DCB in BTK intervention.

In BTK intervention, restenosis following POBA ranges from 42% to 69% at 12 months according to the lesion length. A meta-analysis of BTK angioplasty studies indicated that the overall 1-year patency of POBA was 58.1% ± 4.6% and the limb salvage rate was 86.0% ± 2.7%. Despite the
large amount of activity in the DCB field, data in the BTK territory are limited and controversial. Early noncontrolled studies suggested that restenosis following DCB use was lower compared to POBA, and recurrences tended to be more focal. A study including long lesions (mean, 17.3 cm) showed a 3-month angiographic restenosis rate of 27.4%. In this study, most of the restenosis (61%) was focal, and only 8% of the DCB failures presented as total vessel occlusion. In the DEBATE BTK trial, a randomized controlled trial of DCB versus POBA, both restenosis (27% vs 74%; \( P = .001 \)) and TLR (18% vs 43%; \( P = .003 \)) were drastically reduced at 1 year. Moreover, vessel occlusion was 17% versus 55% \(( P < .001 \)) complete wound healing occurred in 86% versus 67% of patients \(( P = .01 \)), and there were no significant differences in terms of major limb amputation.

The IN.PACT DEEP multicenter randomized controlled trial used a similar device and failed to confirm the positive early clinical data. This study compared the performance of the IN.PACT Amphirion DCB with POBA in a 2:1 randomization ratio in 358 patients with prespecified primary end points for efficacy (TLR and LLL) and safety (all-cause death, major amputations, or TLR). All patients were assessed at 1-year follow-up for clinical end points. A subgroup of patients with lesions ≤10 cm in length underwent angiographic follow-up. Significant baseline differences between the DCB and POBA cohorts included mean lesion length (10.2 vs 12.9 cm; \( P = .002 \)), impaired inflow (40.7% vs 28.8%; \( P = .035 \)), and previous target limb revascularization (32.2% vs 21.8%; \( P = .047 \)). Primary efficacy results of DCB versus POBA were clinically driven TLR of 9.2% versus 13.1% \(( P = .291 \)) and LLL of 0.61 ± 0.78 mm versus 0.62 ± 0.78 mm \(( P = .950 \)). The primary composite safety end point was 17.7% versus 15.8% \(( P = .021 \)) and met the noninferiority hypothesis. A safety signal driven by major amputations through 1 year was observed in the DCB versus POBA arm (8.8% vs 3.6%; \( P = .080 \); Table 32-3).

Table 32-3 Summary of Major Randomized Controlled Trials of DCB in the Treatment of Below-The-Knee Disease
DCB use in the most distal arteries (ankle and foot) seems to lead to lower patency rates compared to the most proximal arteries. It has been hypothesized that the small size of the arteries causing increased friction and
higher drug losses may be responsible for these findings. However, the low patency of these very distal arteries may also be due to a mechanical effect (external forces, impingement, and constant movement) that cannot be solved by DCB. In any case, the clinical use of DCB in very distal vessels is still unknown. In conclusion, although there is a widespread opinion that suggests that DCB can substantially improve the success of endovascular procedures for BTK disease, the recent results of the IN.PACT DEEP study, which caused alarme in terms of safety and lack of efficacy, suggest that an abundance of caution is reasonable.

**FUTURE PERSPECTIVES**

To date, the use of DCB in the coronary territory is limited to patients with ISR (Class I, Level A recommendation)\(^24\) and other “niche” clinical subsets. Clinical adoption involving other indication will largely depend on the evolution of these technologies toward safer and more predictable local drug delivery devices. Significant technologic improvements are under development and include low-dose, low-particulate coating technologies and sirolimus-based local drug delivery devices. Regardless, comparative randomized studies against traditional DES therapies will be needed in order to introduce these technologies as workhorse devices. In contrast, in the peripheral field, DCB use is a more widely accepted and clinically validated strategy. As in the coronary territory, DCBs are limited by the potential use of extra stents and the additional cost incurred by this approach. However, DCBs have taken a lead for this particular vascular application in which the use of stents is less desirable. Finally, the DCB field continues to evolve toward the development of more precise delivery methods and alternative drugs that permit the expansion to other vascular territories and clinical applications.

**MULTIPLE CHOICE QUESTIONS**

1. Commercially available DCBs developed to date use the anti-proliferative drug, paclitaxel. Which of the following paclitaxel formulations is more effective in maintaining the drug in the vessel wall for a longer time?
   - A. Solid phase (crystalline) paclitaxel
   - B. Amorphous phase paclitaxel
   - C. High dose of liquid phase paclitaxel
   - D. Crystalline paclitaxel without a carrier

2. Which of the following statements is *true* regarding the application of DCBs in coronary diseases?
   - A. DCB has shown to be superior to EES for the treatment of in-stent restenosis
   - B. DCB and BMS combination is superior to BMS in acute myocardial infarction
   - C. DCB has shown to be superior to standard angioplasty for the treatment of in-stent restenosis
   - D. The DCB-only has no benefit to treat atherosclerotic disease involving small coronary vessels

3. Which of the following statements is *false* regarding the potential advantages of DCB over DES?
   - A. Polymer-free single time drug delivery
   - B. Completely prevents the use of ancillary stents
   - C. Allow the treatment of long segments leaving nothing behind
   - D. Does not preclude re-intervention of the treated segment in case restenosis occurs
4. Which of the following is true in regards to the outcomes from the IN.PACT SFA randomized trial?
   A. DCB was not effective in all important patient subgroups
   B. DCB required extensive use of adjunctive stenting in all participating patients
   C. The outcomes from the 1-year follow-up analysis did not confirm the durable effect of the DCB
   D. DCB was superior to standard angioplasty in terms of primary patency and safety composite end point

5. What was the major outcome from the randomized IN.PACT DEEP trial?
   A. DCB was superior to PTA in terms of primary efficacy and safety composite end point
   B. DCB had comparable efficacy to PTA in terms of primary efficacy and safety composite end point
   C. The outcomes from the subgroup did not meet the primary efficacy endpoint
   D. DCB was inferior to PTA in 12 month efficacy results

**ANSWERS**

1. A

   Solid phase drug provides a reproducible pharmacokinetic profile after balloon delivery and the drug stays in the vessel wall after the balloon inflation for a longer time compared with liquid phase drug that diffuses quickly into tissues. Addition of a carrier to crystalline paclitaxel keeps the drug in the vessel wall for a longer time and enhances drug intake.

2. C

   Randomized clinical trials have demonstrated the safety and efficacy profile of DCB over PTA for the treatment of in-stent restenosis. DCB appear to be as effective as paclitaxel-eluting stents in this particular application, however, re-intervention using EES was shown to be more effective in reducing angiographic restenosis compared to DCB. Small clinical studies support their use in other de novo clinical settings such small vessels, diffuse lesions
and bifurcation lesions, but until further refinements in DCB technology are made and larger randomized clinical trials are performed, the role of this technology remains to be completely understood.

3. B

Potential advantages of DCB include (a) single time drug transfer to the entire vessel wall; (b) rapid release of high concentrations of the drug sustained in the vessel wall; (c) absence of polymer could decrease chronic inflammation and the trigger for late thrombosis; (d) leave no implant; and (e) with local drug delivery.

4. D

Treatment effect of DCB was durable, few patients required adjunctive stenting, and the beneficial effect was observed across important patient groups including females and patients with diabetes. The 12-month follow-up results showed a significant benefit to patients treated with the DCB angioplasty compared with patients treated with the standard balloon angioplasty; higher primary patency ($P < 0.001$) and lower CD-TLR ($P < 0.001$).

5. B

The IN.PACT DEEP multicenter randomized controlled trial compared the performance of the IN.PACT Amphirion DCB with PTA in a 2:1 randomization ratio in 358 patients with pre-specified 2 primary endpoints for efficacy (TLR and LLL) and safety (all-cause death, major amputations or TLR). Primary efficacy results of DCB versus PTA were CD-TLR of 9.2% versus 13.1% ($P = 0.291$) and LLL of 0.61 ± 0.78 mm vs 0.62 ± 0.78 mm ($P = 0.950$). Primary safety endpoints were 17.7% vs 15.8% ($P = 0.021$) and met the noninferiority hypothesis.
In-Stent Restenosis

Gennaro Giustino
Roxana Mehran

INTRODUCTION

The safety and efficacy of percutaneous coronary interventions (PCI) have been drastically improved by the introduction of bare metal stent (BMSs) in clinical practice.\(^1\) However, a new pathologic entity arose with the implantation of BMSs within coronary arteries: in-stent restenosis (ISR).\(^2\) ISR can be defined as the in-stent lumen narrowing that pathobiologically relates to the phenomenon of neointimal hyperplasia (NIH).\(^3\) Biologic, mechanical, procedural, and stent-related factors interplay in determining the incidence, morphology, and clinical implications of ISR. Introduction of drug-eluting stents (DESs) in 2001 in clinical practice represented a technologic breakthrough. DESs critically improved the efficacy of percutaneous revascularization procedures by reducing the need of target lesion revascularization (TLR) and target vessel revascularization (TVR) at follow-up.\(^4\) However, a low rate of ISR after DES implantation still exists. With more than 3 million DESs implanted worldwide each year, DES-ISR represents a major public health issue. In this chapter, we comprehensively review the incidence, mechanisms, diagnosis, and potential treatment strategies of ISR, with a particular focus in the contemporary DES era.

DEFINITION AND CLASSIFICATION
The goal of percutaneous revascularization procedures is the relief of significant coronary artery obstructions. Effectiveness of PCI with stent implantation is expressed in terms of clinically significant restenosis assessed objectively as a requirement for ischemia-driven repeat revascularization either of the stented lesion itself (TLR) or of the stented vessels and its collateral branches (TVR). ISR can be defined as a lumen narrowing within the site of stent implantation induced by local vascular barotrauma with reactive NIH. The clinical consequence of ISR is the development of a new flow-limiting obstructive lesion and subsequent reduction of downstream myocardial perfusion.

ISRd differ in their morphologic pattern, which in turn is associated with important clinical, prognostic, and therapeutic implications. The most accepted morphologic classification of ISR is the one proposed by Mehran et al. Before the introduction of this classification, patterns of ISR were broadly classified as focal (in-stent lesion <10 mm in length) or diffuse (in-stent lesion >10 mm in length). The Mehran classification introduced the description of the topographic relation between NIH and the coronary stent implanted. This classification is as follows (Fig. 33-1):
FIGURE 33-1 Descriptive diagram of in-stent restenosis (ISR) angiographic patterns. Pattern I (focal type) is <10 mm in length and contains 4 subtypes (types IA-ID). Patterns II to IV (diffuse type) are >10 mm in length and are distinguished according to the relation with the stent and the vessel lumen. (Reproduced with permission from Mehran R, Dangas G, Abizaid AS, et al. Angiographic patterns of in-stent restenosis: classification and implications for long-term outcome. Circulation. 1999;100:1872-1878.)

- Class I, focal ISR group: Lesions are ≤10 mm in length and are placed at the unscaffolded segment (articulation or gap) (type IA), the body of the stent (type IB), the proximal or distal margin (type IC), or a combination of these sites (type ID; multifocal ISR).
- Class II, diffuse ISR: Lesions are >10 mm in length and are confined to the stented segment, without extending outside the margin(s).
• Class III, diffuse proliferative ISR: Lesions are >10 mm in length and extend beyond the margin(s) of the stented segment.
• Class IV, ISR with total occlusion: Lesions with a Thrombolysis in Myocardial Infarction (TIMI) flow grade of 0.

In order to quantitatively evaluate the magnitude of ISR, 2 parameters have to be taken into account: (1) binary angiographic restenosis, defined as a luminal narrowing of 50% or more measured by follow-up coronary angiography and (2) late lumen loss (LLL), defined as the difference in millimeters between the diameter of a stented segment immediately after PCI and the diameter measured by a follow-up coronary angiography.

Actually, the most widely used definition and classification of ISR is the one proposed by the Academic Research Consortium. This definition requires either a lumen narrowing of at least 50% of the vessel diameter associated with the evidence of functional significance (recurrent angina pectoris, objective signs of ischemia at rest or during exercise test [electrocardiographic (ECG) changes], abnormal fractional flow reserve [FFR <0.80] or intravascular ultrasound [IVUS]–assessed minimum cross-sectional area <4 mm²) or a luminal narrowing of at least 70% or greater in the absence of ischemic symptoms.

Clinical Significance of Morphologic Classification of In-Stent Restenosis

Morphologic classification of ISR is not exclusively descriptive; it also demonstrates a clinical prognostic value (Fig. 33-2). Diffuse intrastent, proliferative, and total occlusions represent a spectrum of increased ISR severity linked to an exaggerated NIH response. With BMS, a significant stepwise increase in TLR is associated with progressively greater levels of ISR in the Mehran classification (class I, 19%; class II, 35%; class III, 50%; class IV, 83%; \( P = .0001 \)).
FIGURE 33-2 The morphologic pattern of in-stent restenosis (ISR) predicts the outcome. A stepwise increase in the need for revascularization is observed in the transition from focal patterns of ISR to occlusive patterns. 1°G, first generation; 2°G, second generation; TLR, target lesion revascularization. BMS, bare metal stent; DES, drug-eluting stent.

Also in DES, the morphologic pattern of ISR is a significant predictor of outcome. Cosgrave et al demonstrated in first-generation DES a significantly higher ISR rate after treatment (with repeat DES stenting or plain old balloon angioplasty [POBA]) in patients with nonfocal DES-ISR as compared to patients with focal DES-ISR (51.1% vs 17.8%; \( P = .001 \)). In the same study, nonfocal pattern of ISR was a strong and independent predictor of TLR at follow-up, independently of the DES type. Latib et al observed in a large group of consecutive patients with DES-ISR treated with PCI (restenting or POBA) that recurrent ISR occurred in 29.1% of the focal type (class I), 45.8% \( (P = .007) \) of the diffuse type (class II and III), and 65.6% \( (P < .001) \) of the occlusive type (class IV) ISR. Accordingly, diffuse ISR was independently associated with a significant increase in TLR compared to focal ISR. In the same study, the investigators observed that the initial
presentation pattern of ISR also predicted the pattern of recurrent ISR after the initial treatment. Occlusive ISR recurred as a reocclusion in 66.7%, diffuse ISR (class II and III) recurred as diffuse or occlusive in 57.9%, and focal ISR (class I) recurred as recurrent focal ISR in 67.2% of patients.

Besides TLR, other main cardiovascular outcomes, such as death, myocardial infarction, and stent thrombosis (ST), seem to not be significantly different across ISR morphology patterns both in BMS and DES.\textsuperscript{5,7}

**PATHOPHYSIOLOGY OF IN-STENT RESTENOSIS**

NIH is the pathobiologic substrate of ISR. Different types of mechanisms account for the temporal development, severity, and distribution of NIH and subsequent ISR (see Fig. 33-2; Fig. 33-3). Stent implantation with local arterial injury represents the first trigger of NIH with activation of complex local inflammatory pathways (see Fig. 33-3).\textsuperscript{9,10} Neointimal development consists in the activation, proliferation, and migration of smooth muscle cells within the intimal layer. These processes are followed by local extracellular matrix (ECM) deposition and remodeling with subsequent restenotic tissue accumulation within the stent. At least 4 types of factors can be identified in the pathogenesis of reactive NIH and subsequent ISR (Fig. 33-4): (1) biologic factors, (2) vascular factors, (3) procedural factors, and (4) stent factors.
FIGURE 33-3 Pathogenic pathways leading to in-stent restenosis. ECM, extracellular matrix; NIH, neointimal hyperplasia; VSMC, vascular smooth muscle cell.
**Biologic Factors**

Biologic factors for ISR include drug resistance, hypersensitivity, and genetic substrate. An accurate knowledge of the biologic factors underlying ISR might allow a customized coronary revascularization strategy. In fact, patients with an intrinsic high risk of developing ISR might benefit from additional local antiproliferative drug release, particular procedural tricks, or surgical revascularization.

Resistance to antiproliferative drugs shares the same molecular mechanisms observed in chemotherapy resistance in oncologic medicine.\textsuperscript{11,12} Drug resistance can be primary (in genetically predisposed individuals) or secondary, following exposure to the antiproliferative drug. The molecular
pathways involved in drug resistance are complex, involving genes operating in drug absorption and metabolism, apoptosis regulation, DNA repair, and drug inactivation. Polymorphisms involving the genes encoding for mammalian target of rapamycin (mTOR) have been shown to be associated with paclitaxel or sirolimus resistance both in vitro and in vivo. Moreover, complex paracrine mechanisms involving cell survival signaling pathways and growth hormone response regulation influence the antiproliferative effect of the drug released by the stent platform.

Hypersensitivity reactions responsible for subsequent ISR may develop against 2 different targets: the DES polymer and the metallic stent platform. Implantation of a stent within a coronary artery induces a local barotrauma with endothelial denudation and subsequent activation of the inflammatory pathways with the distinctive foreign body reaction pattern with giant cell infiltration and granuloma formation. The inflammatory reaction occurring after arterial injury critically influences the burden of NIH. Persistence of local inflammation after 90 days is associated with a subsequent high risk of delayed endothelialization, ISR, and late or very late ST. First-generation DES polymers are strongly associated with an inflammatory response that persists beyond 180 days and for up to 2 years. This is in contrast to BMSs and second-generation DESs (which have a more biocompatible polymer), which are associated with an inflammatory reaction of 90 days and 12 months, respectively. Persistent inflammatory response represents a common pathways for the so-called “stent failure,” which include both ISR and ST. Hypersensitivity reactions to the metallic platform have also been described. Koster et al reported an association between nickel and molybdenum allergy and the risk of ISR with BMS. The evidence surrounding this issue is controversial and contradictory. With DES, no clear data exist. To date, a small study by Nakazawa et al found no association between the risk of ISR and the metallic platform allergy with sirolimus-eluting stents (SESs), suggesting that DESs prevent restenosis irrespective of metallic allergy.

The association between inflammatory and ECM remodeling biomarkers with ISR has been studied. The systemic inflammatory status assessed by means of C-reactive protein levels has not been consistently associated with ISR. Conversely, circulating matrix metalloproteinases (MMPs) have been shown to be useful in identifying patients at high risk of developing ISR. In
particular, MMP-2 and MMP-9 elevations after PCI have been associated with the risk of ISR after DES implantation. MMPs are expressed and released by vascular smooth muscle cells (VSMCs), endothelial cells, and macrophages in response to local vessel trauma.

**Arterial Factors**

Arterial factors determining ISR include vessel size, lesion type, local shear stress, neoatherosclerosis, vessel remodeling, and edge vascular response.

Vessel size is a critical factor determining the effectiveness of PCI with both BMS and DES (Fig. 33-5). Agostoni et al\(^{26}\) demonstrated that BMSs are superior to POBA in a large meta-analysis of randomized controlled trials. Biondi-Zoccai et al\(^{27}\) in another large meta-analysis of the use of DESs in small vessel disease, found that type of DES used has a substantial impact on PCI effectiveness. Pathologic mechanisms through which small vessel size influences PCI outcomes are small postprocedural minimal lumen area (MLA), higher degree of vessel injury and recoil, and higher metallic density.\(^{28}\) In particular, greater strut thickness has been associated with worse outcomes in small vessels.
Highly thrombotic lesions are associated with higher risk of stent failure with thrombosis or restenosis. High thrombus burden interferes with DES performance in several ways: (1) thrombus reduces the drug penetration and distribution by a magnitude of up to 10-fold; (2) thrombus interferes with stent expansion, potentially leading to stent underexpansion; and (3) stent underexpansion and late thrombus resolution significantly increase the incidence of incomplete stent apposition and the risk of ST and restenosis. Despite this, a significant benefit with DESs, especially new-generation DESs, has been observed in ST-segment elevation myocardial infarction (STEMI) in several studies and meta-analyses. Although high thrombotic burden significantly increases the risk of stent failure and need for revascularization, the factors independently associated with TVR in STEMI do not seem to differ from those observed in other PCI settings. Finally, the
use of thrombus aspiration does not seem to reduce the risk of thrombosis or restenosis after DES implantation.\textsuperscript{32}

Blood hemodynamics in relation to vessel geometry and stent strut design play a role in determining endothelial dysfunction, vessel remodeling, and restenosis (Fig. 33-6). Within the arterial vessel, the fluid velocity is maximal in the middle of the lumen and minimal in proximity to the vessel wall due to viscosity forces. Particular lesion subsets, such as bifurcations or ostial lesions, are associated with a significantly lower fluid velocity and endothelial shear stress (ESS).\textsuperscript{33,34} Reduced blood flow combined with local vessel injury may contribute to accumulation of growth factors, cytokines, and blood cells promoting NIH development and subsequent restenosis. The relationship between everolimus-eluting stents (EESs) and ISR has been demonstrated in several studies. Wentzel et al\textsuperscript{35} showed an inverse relationship between EES magnitude and the extent of ISR with BMS, which has been demonstrated by later investigations. Importantly, although ISR did not develop in sites with low ESS, not all sites of ISR originated from low ESS regions, showing the multifactorial contribution to ISR development. The relationship between low ESS regions and ISR was also demonstrated with SESs and paclitaxel-eluting stents (PESs). Apart from vessel anatomy, stent design critically influences ESS and ISR risk (see later Stent Factors section).
FIGURE 33-6 Effect of nonstreamlined (A) and streamlined (B) strut design on endothelial shear stress and risk of thrombosis and restenosis. EES, everolimus-eluting stent; ESS, endothelial shear stress. (Adapted from Koskinas KC, Chatzizisis YS, Antoniadis AP, Giannoglou GD. Role of endothelial shear stress in stent restenosis and thrombosis: pathophysiologic mechanisms and implications for clinical translation. J Am Coll Cardiol. 2012;59:1337-1349.)

Neoatherosclerosis (NA) emerged recently as a potential cause of late DES failure responsible for both restenosis and thrombosis of the stent platform.\(^{36}\) NA can be defined as the presence of an atherosclerotic lesion within the neointima of a stented vascular segment. NA can assume a pathologic feature ranging from simple intimal thickening with lipid infiltration to ruptured thin-cap fibroatheroma with thrombosis and acute clinical presentation. Pooling the evidences from histopathologic and endovascular imaging studies, NA seems to occur with both BMS and DES in which it can be responsible for lumen occlusion with restenosis and subsequent need for revascularization and plaque rupture with thrombotic occlusion of the stent. NA is carefully reviewed and discussed in the Histopathology of In-Stent Restenosis and Imaging of In-Stent Restenosis sections.

Vascular remodeling influences NIH formation.\(^{37-39}\) Large plaque burden is associated with positive arterial remodeling (PR). Okura et al\(^ {38}\) demonstrated that the presence of PR (defined as vessel area at the target lesion greater than that of average reference segments) is associated with adverse outcomes after IVUS-guided stent implantation. Following multivariable adjustment, remodeling index (defined as vessel area at the target lesion site divided by that of average reference segments) was the only independent predictor of TVR at 9 months. The association between PR and ISR may be explained by several mechanisms. First, PR is more frequent in unstable lesions; therefore, lesions with PR may be more biologically active and more prone to an exaggerated NIH response. Second, several studies demonstrated that the relative plaque burden outside the stent is proportional to the NIH that develops within the stent.

Edge vascular response (EVR) is defined as the pathologic changes occurring in the vascular tissue adjacent to the segment of stent implantation with subsequent focal lumen narrowing and need for revascularization of the target lesion.\(^ {40}\) EVR can occur in the presence or absence of longitudinal geographic miss (LGM) with uncovered plaque, and thus, it is only partially
dependent on the stent landing zone. The pathologic factors related to EVR include procedural factors (axial geographic miss or LGM, vascular injury, and plaque shift), stent factors (stent platform and eluted drug), and lesion factors (plaque burden). The TAXUS-II, -IV, -V, and -VI trials reported similar rates of LLL at both proximal and distal stent edges with BMS and PES. Conversely, the SIRIUS trial reported that ISR with SES had more commonly a focal pattern located at the proximal DES edge. In the ENDEAVOR-IV trial, the zotarolimus-eluting stent (ZES) was associated with comparable rates of LLL at both stent edges. Conversely, with bioresorbable vascular scaffolds (BVSs) in the ABSORB Cohort B1 study, LLL was significantly higher at the proximal edge. Compared to BMS, DES seems to be associated with lower distal LLL, most likely because of downstream drug effects related to drug release by the DES platform.

**Procedural Factors**

Optimal stent implantation is of paramount importance in reducing the risk of both restenosis and ST after PCI, as are directly modifiable factors. Procedural factors influencing the risk for ISR include stent underexpansion, LGM and axial geographic miss, unstented segment barotrauma with EVR, stent gap, and off-label DES implantation.

Stent underexpansion and smaller postprocedural minimal lumen diameter (MLD) are strongly associated with long-term DES patency and risk of ISR and ST.** IVUS use significantly improved stent deployment and achievement of an optimal postprocedural MLD. IVUS analyses from the SIRIUS trial and other studies identified an optimal cutoff of postprocedure minimum stent area to reduce the risk of restenosis of 5.0 to 5.5 mm². In a large meta-analysis comparing IVUS-guided with angiographic-guided BMS implantation, Casella et al demonstrated that IVUS use significantly reduces the risk of TVR, binary restenosis, and major adverse cardiac events (MACE) at 6 months of follow-up. Recently, a substudy from the ADAPT-DES (Assessment of Dual Antiplatelet Therapy With Drug-Eluting Stents) trial, the largest observational study of IVUS to date, reported a significant reduction in 1-year rates of ST, myocardial infarction (MI), MACE, and repeated revascularization with IVUS use. Moreover, a large meta-analysis including 26,503 patients demonstrated a significant benefit with IVUS use during PCI with DES implantation. Conversely, results from randomized
clinical trials in the DES era are controversial. Some of them showed that the benefits of IVUS are observed in complex lesions, while others suggested that IVUS use per operator decision was associated with improved results (in the per-protocol analysis of the RESET [Real Safety and Efficacy of a 3-Month Dual Antiplatelet Therapy Following Zotarolimus-Eluting Stent Implantation] IVUS trial). Until large-scale trials demonstrate a clear advantage of IVUS-guided procedures, its use will be at the discretion of the clinical and anatomic evaluation of the operator.

LGM (Fig. 33-7) is defined as the failure to cover the target lesion with intracoronary stent implantation. Failure to cover the lesion with the implanted stent is associated with a significant portion of the lesion remaining out of the stent margins and barotrauma of nondiseased vessel segments. Conversely, axial geographic miss (AGM; see Fig. 33-7) is defined as a final balloon-artery size ratio mismatch <0.9 or >1.3. In the STLLR study, LGM was observed in two-thirds of the study cohort, with half of the patients having LGM and more than one-third having AGM. Approximately 15% had both LGM and AGM. Patients with geographic miss had higher rates of TVR and MI at 1 year of follow-up. Among patients with geographic miss, most of the cases were observed in patients with LGM. Moreover, an additional subanalysis from the STLLR study showed that diabetic patients with LGM had significantly higher rates of TLR compared with nondiabetics, underscoring the importance of optimal stent implantation in high-risk patient subsets such as those with diabetes.
Stent gap can be defined as a discontinuous coverage between 2 DESs throughout the coronary vessel extension. A gap between 2 DESs leaves a small zone of the coronary vessel not exposed to the antiproliferative effects of the released drug and the mechanical support of the metallic strut. Considering that overlapping DESs have been demonstrated to be safe and effective, a gap between 2 DESs should be avoided.54

Finally, off-label DES use has been consistently associated with worse clinical outcomes after PCI. The STENT (Strategic Transcatheter Evaluation of New Therapies) Group is the largest prospective registry evaluating outcomes in patients undergoing DES implantation in the United States. Brodie et al,55 in an analysis from this registry, compared on-label and off-label (ostial, left main, chronic total occlusion, saphenous vein graft, small vessels, multivessel disease, and ISR lesions) indications for DES implantation and reported a significantly higher TVR rate in the off-label group at 2 years (11.8% vs 6.5%; P < .01).

**Stent Factors**
With DES, stent-related factors influencing ISR include strut thickness; drug release kinetics; drug type; stent fracture; polymer disruption, peeling, and cracking; and stent design.

The type of intracoronary stent influences the burden and temporal evolution of NIH. Angiographic and IVUS studies (Fig. 33-8) demonstrated a different pattern of NIH development with BMS and DES over time. IVUS studies with permanent polymer DES documented an increase in neointimal volume beyond the time point in which NIH is interrupted with BMS. Although with BMS the burden of NIH is significantly higher after the procedure and at long-term follow-up, it tends to reduce over time. Conversely, with early-generation DESs, neointimal volume tends to slowly increase years after the implantation. Finally, with bioresorbable polymer DESs, a stable behavior in neointimal volume has been observed. These differences might reflect the variable vascular response and inflammatory reaction to the DES polymer, which involves chronic inflammation associated with very-late restenosis in DES.

**FIGURE 33-8** Differences in neointimal volume at follow-up between bare metal stents (BMSs), first-generation drug-eluting stents, and new-generation drug-eluting stents (DESs). BES, biolimus-eluting stent; EES, everolimus-eluting stent; IVUS, intravascular ultrasound; NIH, neointimal hyperplasia; MR, moderate release; PES, paclitaxel-eluting stent; SES, sirolimus-eluting stent; SR, slow release.
The fine balance between the drug type, drug release kinetics, and dosage is a critical factor in DES design. Drug release kinetics critically influence the suppression of NIH even more than the total dose of drug released. To ensure an adequate suppression of NIH, a certain dose of drug has to be delivered to the vessel wall during a sufficient time period, during which strut endothelization is ongoing. The in-human PISCES trial tested 6 different polymer-drug release formulations and observed that a greater magnitude in the inhibition of neointimal formation was achieved with long-term drug-release formulations than with drug-polymer combinations with shorter eluting times. Similar results have also been observed by Waseda et al comparing different polymer formulations with ZES.

Although drug release kinetics is of critical importance in suppressing NIH, the type of drug also plays an important role. The antiproliferative drugs associated with the greatest effects are paclitaxel and limus family drugs. These drugs differ in their mechanism of action and intracellular pharmacodynamics. Paclitaxel acts by stabilizing the microtubule polymer and blocking the progression of mitosis, triggering apoptosis or reverting to the G phase of the cell cycle without reaching the cell division phase. Sirolimus, everolimus, biolimus A9, and zotarolimus all bind to the FKBP12 protein, which subsequently binds and inhibits mTOR, blocking the transition from the G1 to the S phase. Conversely, tacrolimus and pimecrolimus act by binding FKBP506, which subsequently inhibits the calcineurin receptor, leading to a reduced intracellular growth factor signaling pathway. In the PAINT trial, Lemos et al compared 2 DESs with the same metallic platform and polymer but different released drugs (paclitaxel or sirolimus) and a BMS with the same metallic stent. At 9 months, the DES eluting sirolimus was associated with a significantly lower late loss compared with the DES eluting paclitaxel and the BMS.

Stent fracture (SF) can be defined as a complete or partial discontinuation in the strut structure at follow-up. SF is associated with 2 consequences: (1) loss of the local vascular support provided by the metallic strut, and (2) severe impairment of the local drug delivery. The most common consequence of SF is focal restenosis due to the decreased local drug delivery and impairment in NIH suppression. At IVUS assessment, partial SF is defined as the absence of at least one-third or 120° of stent struts for at least 1 frame; conversely, complete SF is defined as the total absence of stent struts for at
The most common risk factors for SF are right coronary artery lesions, vessel tortuosity, lesion length, moderate or severe calcifications, longer stents, SES use (due to the closed-cell design, as opposed to an open-cell design), myocardial bridges, and overlapping stents. The incidence of SF ranges from 1% to 8% and is associated with a significant increase in need for revascularization at follow-up. In particular, the LONG-DES-II study, which evaluated incidence and predictors of DES fracture in long coronary lesions, reported an incidence of SF of 1.7% and a subsequent restenosis rate at 6-month follow-up of 14%. Finally, stent cell design critically influences the risk of SF. In fact, in a recent meta-analysis, the incidence of SF was of 0.1% with PES (open-cell design) and approximately 2.3% with SES (closed-cell design).

Polymer disruption has been demonstrated in bench studies with both old- and new-generation DES. Disruption and spreading of polymer components may be associated with reduced effectiveness of the drug release and increased local inflammation. Stent implantation failure was demonstrated to be associated with significant polymer damage. Bifurcation lesions have been associated with a high risk of polymer damage, nonuniform drug release, and focal restenosis. Guerin et al. in a bench study using scanning electron microscopy to evaluate the polymer integrity of 5 different types of DES, observed that a kissing balloon was associated with a significantly greater coating damage to the ostial portion of all the stents tested. In particular, the Endeavor stent (Medtronic, Dublin, Ireland) showed a subtotal disruption of the polymer on the luminal face, whereas the other DES showed a more localized pattern of polymer rupture.

The magnitude of stent-induced flow changes and vascular response is substantially dependent on strut design (see Fig. 33-6). Strut shape and thickness and the strut-strut intersection arrangement are all associated with ISR. Across stent types, stents with hemodynamically favorable designs are associated with homogeneous ESS across the inner platform surface and lower risk of ISR in clinical practice. Heterogeneous ESS is the result of flow disruption generating zones of high ESS and zones of low ESS (see Fig. 33-6A). A homogeneous ESS can be achieved by reducing strut thickness and a streamlined strut shape (see Fig. 33-6B). Several studies demonstrated that a nonstreamlined strut drastically increases low ESS to more than 80%. Strut connector length also influences in-stent hemodynamics. A computational
comparison of 5 stents used in clinical practice demonstrated that minimal connector length in the cross-flow direction decreased the percentage of in-stent area with low ESS.

**HISTOPATHOLOGY OF IN-STENT RESTENOSIS**

Underlying ISR histopathology relates to the angiographic appearance and clinical severity of ISR. ISR with BMS has been extensively studied in postmortem\(^9,74\) and endarterectomy\(^75,76\) specimens. Although the pathologic substrate of vessel restenosis with POBA was represented essentially by chronic vessel recoil with negative remodeling, VSMC proliferation is the dominant pathologic process leading to restenosis after BMS and DES implantation. The main identifiable cellular components of NIH are α-smooth muscle actin–positive cells embedded in a collagen-rich extracellular matrix (ECM). The composition of the hyperplastic restenotic tissue evolves over time. NIH evolution can be categorized into an *early stage*, characterized by high cellular density in active proliferation within a proteoglycan-rich ECM, and a *late stage*, characterized by a high burden of mature and dense ECM with lower cellular density and proliferation rate.\(^76\) Chung et al\(^76\) described the ECM changes in ISR tissue over time. Late ISR was composed mainly of large amounts of proteoglycan-rich and collagen-rich ECM alongside a low number of proliferative VSMCs. Interestingly, the investigators observed a significant correlation between ECM composition and ISR severity, instead of cellular proliferation.

Histopathology of ISR varies between BMS and DES. In an interesting study, van Beusekom et al\(^77\) compared the pathologic features of atherectomy specimens obtained from restenotic tissue in BMS, DES, and de novo atherosclerotic lesions. ECM in de novo atherosclerotic lesions was more commonly collagen-rich, whereas BMS- and DES-ISR tissue was more commonly proteoglycan-rich. With both BMS- and DES-ISR, the cellular component was mainly composed by proliferated VSMCs. However, DES-ISR tissue was richer in fibrinoid tissue, indicating a more persistent incomplete vascular healing response. Quantitatively, DES-ISR was significantly lower in terms of mass and volume compared with BMS-ISR.
This difference is most likely related to the more prevalent focal nature of ISR with DES compared with BMS (see later section In-Stent Restenosis With Bare Metal Stents and Drug-Eluting Stents).

Chieffo et al\textsuperscript{78} compared the histopathology of ISR with BMS and a wide range of DES by means of light microscopy specimens obtained through directional coronary atherectomy. In both BMS- and DES-ISR, specimens were composed mainly of proteoglycan-rich smooth muscle cells and a fibrolipidic stroma. The authors found significant differences in VSMC phenotype across stent types. In particular, restenotic tissue was mainly composed of intermediate-synthetic VSMC phenotype in BMS and PES, of intermediate VSMC phenotype in ZES, of contractile-intermediate VSMC phenotype in SES, and of mostly contractile VSMC phenotype in tacrolimus-eluting stents. These differences in VSMC phenotype might reflect the differential responses to stent types and, in the case of DES, to the antiproliferative drug. Both BMSs and PESs were associated with an intermediate-synthetic phenotype, potentially partially explaining the high NIH burden observed with these stents.

Local vascular inflammation induced by vessel barotrauma following intracoronary stent implantation is a critical factor influencing the burden of subsequent neointimal hyperplastic response. Moreover, persistence of an inflammatory milieu is related to greater NIH thickening, remodeling, and subsequent ISR. Farb et al\textsuperscript{9} demonstrated that early after stent implantation, features of acute inflammation at the interface of the stent and arterial wall were almost always present. Moreover, the authors underscored the importance of vascular medial layer damage. In fact, NIH thickness was significantly greater when medial damage (arterial medial laceration or rupture) occurred.\textsuperscript{9} Wilson et al\textsuperscript{79} further clarified the role of chronic inflammation associated with first-generation DES implantation. Histopathologic analysis of stented porcine coronary arteries showed features of chronic inflammation with giant cells, granulomas, and eosinophilic infiltrations at long-term follow-up (between 90 and 180 days), whereas no evidence of inflammation was present with BMS. The main trigger for arterial chronic inflammation is represented by the presence of the durable polymer. Durable polymers induce and sustain chronic inflammation over time, which in turn is responsible for both delayed endothelialization and greater burden of NIH. Therefore, bioresorbable polymer DES design could be an attractive option in reducing the polymer-related inflammatory
response and subsequent risk of thrombosis and restenosis. Bioresorbable polymer DESs seem to be associated with improved safety and efficacy profiles compared with first-generation DESs.\textsuperscript{80}

Another potential mechanism influencing the features of ISR with BMS and DES is the delayed endothelialization phenomenon. From an autopsy registry, Joner et al\textsuperscript{81} compared the vascular histopathology of DES and BMS, observing that after 30 days DESs were associated with significantly delayed vascular healing manifested by incomplete endothelialization and significant fibrin persistence and accumulation. These pathologic differences may account for both DES failure events—ST and ISR. The higher prevalence of thrombotic components within DES-ISR led to the theory of the “thromborestenosis phenomenon.” Oikawa et al\textsuperscript{82} demonstrated, by means of IVUS, angioscopy, and histopathologic analyses, that thrombus and fibrin deposition are substantially more frequent in ISR lesions of SES compared with BMS. Therefore, chronic thrombus formation may play a role in the pathogenesis of ISR in DES, especially when delayed endothelialization occurs.

Finally, in-stent NA emerged as a potential mechanism of stent failure, being associated with both ISR and ST, and may account for the “late catch-up phenomenon” observed in DES trials at long-term follow-up.\textsuperscript{83,84} NA is defined as the presence within the neointima of atherosclerotic plaque elements like foamy macrophages in clusters with or without calcification, fibroatheromas, and thin-cap fibroatheromas. The pathobiology of NA can be described as a form of accelerated atherosclerosis secondary to delayed reendothelialization and severe endothelial dysfunction. Nakazawa et al\textsuperscript{36} described the incidence of NA in BMS, SES, and PES postmortem pathologic specimens (Fig. 33-9). Compared with BMS, the incidence of NA was significantly higher with DES (31% vs 16%; \(P < .01\)), whereas no differences were present between the 2 types of first-generation DESs. Importantly, NA occurred earlier with DES compared with BMS. In fact, the median stent duration with NA was shorter in DES than BMS (DES: 420 days; BMS: 2160 days; \(P < .001\)). Interestingly, SES was associated with a greater NA change compared with PES for implant durations of 2 years or less (SES 37% vs PES 21%; \(P = .021\)). The earlier development of NA in DES may be due to delayed stent endothelialization with reduced cell-to-cell contact and increased lipidic and macrophage intimal infiltration. NA and its role and
evaluation in ISR will be further discussed in the Imaging of In-Stent Restenosis section.

**FIGURE 33-9** A to C. Histologic section from a paclitaxel-eluting stent (PES) implanted in a left circumflex artery 14 months antemortem: (A) patent lumen with presence of moderate neointimal growth; (B) foamy macrophage infiltration plus cholesterol clefts within the neointima; and (C) presence of CD68-positive macrophages in the neointima surrounding the strut (*asterisk*). D to F. Pathologic specimens from a sirolimus-eluting stent (SES) with superimposed thrombosis: (E) evidence of thin-cap fibroatheroma with cap rupture and (F) presence of CD68-positive macrophages in the fibrous cap and in the necrotic core. G to I. Pathologic specimens from a bare metal stent (BMS) implanted 8 years before death with superimposed stent thrombosis: (G) presence of occlusive thrombus within the stent lumen and (H and I) presence of ruptured plaque with a large number of macrophages at the site of cap disruption. (Reproduced from Nakazawa G, Otsuka F, Nakano M, et al. The pathology of neoatherosclerosis in human coronary implants bare-metal and drug-eluting stents. J Am Coll Cardiol. 2011;57:1314-1322, Copyright © 2011, with permission from Elsevier.)
Predictors of ISR with BMS and DES are illustrated in Table 33-1. Among other factors, diabetes mellitus (DM) has been consistently identified as a strong clinical predictor of ISR with both BMS and DES.\textsuperscript{85} Moreover, DM patients present more frequently with a worse morphologic pattern with a prevalent proliferative (type III) and occlusive ISR (type IV).\textsuperscript{5,86} Kornowski et al\textsuperscript{87} observed that ISR in DM patients, compared with ISR in non-DM patients, is associated with higher burden of NIH, underlying the influences of impaired glucose homeostasis and insulin resistance in promoting cellular proliferation after vascular injury. The accentuated neointimal hyperplastic response in diabetics has been documented in several studies. An IVUS-ISR study in patients treated with BMS showed substantial differences in the degree of neointimal hyperplasia among diabetics (5.1 ± 2.8 mm\textsuperscript{2}) compared to nondiabetics (2.1 ± 2.0 mm\textsuperscript{2}).\textsuperscript{87} Moreover higher prevalences of heterogeneous patterns have been observed among diabetics.\textsuperscript{88}

Abbreviations: BMS, bare metal stent; DES, drug-eluting stent; E-ZES, Endeavor zotarolimus-eluting stent; ISR, in-stent restenosis; MLD, minimal lumen diameter; PES, paclitaxel-eluting stent.
Predictors From Bare Metal Stent Studies

Several factors are associated with specific morphologic patterns of ISR. Goldberg et al\(^89\) identified predictors of diffuse (≥10 mm) ISR and aggressive ISR (defined as the development of a longer or tighter lesion at follow-up compared with baseline) with BMS. Predictors of diffuse ISR were longer baseline lesion length, smaller final result achieved, and the use of coil stents. Conversely, predictors of aggressive ISR were female sex, MLD at baseline, lesion length, and stent length/lesion length ratio. Among these, MLD at baseline was the strongest predictor. The role of MLD as a predictor of TVR for ISR was confirmed in the CRUISE (Can Routine Ultrasound Influence Stent Expansion) trial.\(^90\) In this study, final in-stent MLD was also demonstrated to be a significant predictor of TVR.

Lesion-related characteristics impact the risk of ISR and specific ISR morphology. Elezi et al\(^91\) demonstrated in a study of 2602 patients the important influence of vessel size on ISR rate. In this study, patients with small-size vessels (<2.8 mm) had a significantly higher restenosis rate compared with patients with mid-size (2.8-3.2 mm) and large-size (>3.2 mm) vessels (38.6% vs 28.4% vs 20.4%, respectively; \(P < .001\)). The association persisted following multivariable adjustment. Within small vessels, a subsequent study performed by Hausleiter et al\(^92\) demonstrated that the main predictors in this lesion subset are diabetes, complex lesions (type B2/C), vessel stenosis diameter before intervention, stented segment length, balloon/vessel ratio, and stent design.

Finally, Hoffmann et al\(^93\) explored angiographic and IVUS predictors of ISR demonstrating 3 imaging variables consistently associated with ISR: ostial lesion location (odds ratio [OR], 4.01; \(P = .015\)), lesion site plaque burden (plaque/total arterial area) assessed by IVUS (OR, 1.25; \(P = .008\)), and final lumen area or MLD assessed by IVUS (OR, 0.24; \(P = .013\)). These predictors underscore the importance of IVUS-guided procedures to optimize PCI outcomes.

Predictors From Drug-Eluting Stent Studies

Predictors of ISR with DES are similar to those with BMS (see Table 33-1),\(^94\) in which clinical, procedural, and anatomic factors have been consistently
identified as independent predictors of restenosis and revascularization. However, with DES, procedural factors seem to have relatively more impact on the risk of restenosis compared with BMS. Kastrati et al, who analyzed predictors of ISR with SES and PES in a cohort of 1845 and 2093 target lesions, respectively, found that baseline clinical characteristics were not as strong predictors of ISR compared with angiographic factors such as vessel size, complex lesions, and final angiographic results. Moreover, differences in ISR rate among DESs might be more evident in small coronary arteries. Other potential risk factors for restenosis with SES were evaluated by Lemos et al in the RESEARCH (Rapamycin-Eluting Stent Evaluated at Rotterdam Cardiology Hospital) trial. The investigators identified treatment of ISR, DM, and total stented length as independent predictors of ISR ostial lesions.

Compared with BMS, DESs are more commonly associated with a focal pattern of ISR. Investigators studied the predictors of nonfocal ISR in DES. The investigators identified female sex, overlapping stent implantation, and PES use as independent predictors of nonfocal ISR. Lesion complexity is strongly associated with ISR with DES. In particular, PCI of chronic total occlusive lesions also carries a high risk of restenosis after successful stent implantation. In a prospective cohort of successfully revascularized chronic total occlusive lesions using DES, Lee et al reported an ISR incidence of 24% at 6 to 9 months, with a prevalence of diffuse ISR of 61%. Finally, in the new-generation DES era, the RESOLUTE-All Comers randomized trial reported insulin-treated diabetes, treatment of saphenous vein grafts, ostial lesions, ISR treatment, and right coronary artery as a target vessel as independent major predictors of TLR.

DES implantation appears to be effective in attenuating the burden of NIH compared with BMS. However, DM is still a strong independent predictor of TLR even in the DES era. Moreover, several reports have shown that the presence of DM may attenuate the benefits associated with newer versus first-generation DESs.

IN-STENT RESTENOSIS WITH BARE-METAL STENTS AND DRUG-ELUTING STENTS
Stent type critically influences the risk of ISR, its morphologic pattern, and its associated clinical outcomes. Introduction of DESs drastically reduced the incidence of ISR and subsequent need of TLR. However, even in the DES era, the risk of ISR still persists. SES and EES were demonstrated to be the 2 types of DES associated with the lowest incidence of TVR. However, over time, EES demonstrated a significant improvement in the safety profile compared with first-generation DESs. A summary of the incidence of ISR and relative prevalence of morphologic patterns with different types of DESs from randomized controlled trials is reported in Table 33-2, Figure 33-10, and Figure 33-11.

FIGURE 33-10 Median target vessel revascularization rates per 1000 patient-years of follow-up with bare metal stents (BMS) and first- and second-generation drug-eluting stents. EES, everolimus-eluting stents; E-ZES, Endeavor zotarolimus-eluting stent; PES, paclitaxel-eluting stent; R-ZES, Resolute zotarolimus-eluting stent; SES, sirolimus-eluting stent. (Results from Ban galore S, Fusaro M, Amoroso N, et al. Response to letter regarding article, “Short- and long-term outcomes with drug-eluting and bare-metal coronary stents: a mixed-treatment comparison Analysis of 117,762 patient-years of follow-up from randomized trials.” Circulation. 2013;127:e447.)
FIGURE 33-11 Prevalence of morphologic patterns of in-stent restenosis with first-generation drug-eluting stents and bare metal stents (BMSs). PES, paclitaxel-eluting stent; SES, sirolimus-eluting stent.

**General Comparison Between Bare Metal Stents and Drug-Eluting Stents**

There are 2 main differences in terms of ISR between BMSs and DESs: (1) the incidence (ISR is much more frequent with BMS), and (2) the morphology (diffuse patterns of ISR are more common in BMS, whereas DES-ISR is more frequently focal).\(^{104-110}\)

BMS-ISR is characterized by a uniformly distributed NIH along the stent longitude. ISR incidence and morphology with BMS vary across BMS generation. Early-generation BMSs were associated with higher incidence and diffuse patterns of ISR.\(^{111}\) However, even if later BMS platforms were associated a lower rate of ISR, a diffuse pattern remained the most commonly observed morphology.

Compared with BMS-ISR, DES-ISR is characterized by delayed development and a predominantly focal pattern. Park et al.\(^{105}\) described focal ISR in approximately 65% of 177 consecutive first-generation DESs, whereas Solinas et al.\(^{112}\) reported a focal ISR prevalence of 69.5% in 182 lesions. The different pattern of ISR between BMS and DES reflects the
delayed arterial endothelialization after DES implantation in relation to the effects of the antiproliferative drug and local polymer hypersensitivity.\textsuperscript{19,113-115} The pathobiology underlying the prevalent focal morphology of DES-ISR is most likely related to nonuniform drug delivery and subsequent local failure of the antirestenotic effect.\textsuperscript{19,115} Nonuniform drug delivery might be attributable to stent underexpansion, vessel barotrauma, repeated balloon postdilatation, extremely tortuous lesions, and SF.\textsuperscript{94,116,117}

\textbf{In-Stent Restenosis in First-Generation Drug-Eluting Stents}

Compared with PES, SES is associated with lower rates of ISR and with more prevalent focal morphology (see Fig. 33-11). A meta-analysis by Kastrati and colleagues\textsuperscript{118} reported an overall incidence of ISR of 9.3\% with SES and 13.1\% with PES (OR, 0.68; \textit{P} = .001). No differences were found in other outcomes. The superiority of SES over PES with respect to the ISR incidence was explained by the lower degree of LLL and a higher MLD with SES at follow-up. These findings were confirmed later in another larger meta-analysis.\textsuperscript{119} However, recently in the SIRTAX LATE (Sirolimus-Eluting Versus Paclitaxel-Eluting Stents for Coronary Revascularization) study, Raber and colleagues\textsuperscript{120,121} reported an ongoing reduction in the differences in MLD between PES and SES at 5 years. Although SES was superior in terms of LLL at 8 months, no differences were found at 5 years. This finding was explained by a late catch-up phenomenon and a higher delayed lumen loss observed with SES. Therefore, SES seems to be associated with superior NIH suppression and a lower risk of ISR compared with PES at mid-term, whereas this advantage is no longer maintained over a longer term follow-up.

Differences in ISR between SES and PES persisted across different lesion and patient subsets. The ISAR-DIABETES (Paclitaxel-Eluting Stent Versus Sirolimus-Eluting Stent for the Prevention of Restenosis in Diabetic Patients With Coronary Artery Disease) trial compared SES and PES in patients affected by DM.\textsuperscript{121} PES was associated with higher rates of LLL and a higher incidence of angiographic ISR (16.5\% vs 6.8\%). All patients with ISR in the SES group had a type I pattern (100\%). Conversely, among patients with PES-ISR, 76.4\% had type I, 5.8\% had type II, 5.8\% had type III, and 11.7\%
had type IV ISR. The ISAR-SMART 3 (Sirolimus- and Paclitaxel-Eluting Stents for Small Vessels) randomized trial reported lower LLL, ISR incidence, and TLR rates with SES.\textsuperscript{122} In particular, angiographic ISR was found in 19\% of the PES group compared with 11.4\% of the SES group. Regarding the pattern of ISR in the PES group, ISR type I was observed in 69.6\%, type II in 9\%, type III in 6\%, and type IV in 15\%. In the SES group, 80\% of lesions presented with type I pattern; of the remainder, 5\% had type III and 15\% had type IV ISR.

Differences in ISR between SES and PES may be related to several factors. First, the cellular mechanism of the 2 drugs is different. Sirolimus is an mTOR inhibitor, whereas paclitaxel is a microtubule-stabilizing agent leading to reduced cell division and mobility.\textsuperscript{123-126} In vitro studies show that VSMCs adopt a differentiated contractile phenotype under sirolimus and a synthetic phenotype under paclitaxel. Accordingly, a VSMC synthetic phenotype is more frequent in both PES-ISR and BMS-ISR as compared with SES, which may in turn influence the ISR pattern.\textsuperscript{78} Conversely, SES has been demonstrated to be associated with higher inhibition of NIH.\textsuperscript{127} Differences in polymer-triggered inflammatory response following PCI with PES and SES may also contribute to differences in ISR patterns. SES is more commonly associated with a granulomatous and eosinophilic reaction starting at 28 days, whereas PES is characterized by a lower inflammation burden but higher amounts of fibrin deposition, which was demonstrated to be a powerful inducer of cellular proliferation.\textsuperscript{16,17,19}

**In-Stent Restenosis in Second-Generation Drug-Eluting Stents**

New-generation DESs are associated with significantly improved efficacy and safety profiles compared with first-generation stent platforms. A meta-analysis including the COMPARE and SPIRIT II, III, and IV trials reported significantly lower rates of TLR with EES compared with PES.\textsuperscript{128} Conversely, many studies have shown that EES and SES are similar in terms of efficacy outcomes. A meta-analysis of 5 randomized trials comparing EES and SES showed no differences in terms of repeat revascularization between the 2 types of stents.\textsuperscript{129} However, an updated meta-analysis from the same authors reported significantly lower rates of definite ST with EES compared
with SES. Finally, a large meta-analysis of 13 randomized trials reported significant reduction in ST, TLR, and MI with use of EES compared with other types of DESs.

Regarding ZES, 2 versions of this stent platform exist: the Endeavor-ZES (E-ZES; Medtronic) and the Resolute ZES (R-ZES; Medtronic). The R-ZES actually largely replaced E-ZES due to a significant improvement in polymer composition and drug release kinetics. E-ZES demonstrated higher rates of ISR and TLR compared to SES. In addition, although the most common pattern of ISR was focal with both types of DES, E-ZES was associated with higher restenosis length (12.9 mm with ZES vs 6.46 mm with SES; \( P < .001 \)), higher percentage of volume obstruction (16.1% with ZES vs 2.7% with SES; \( P < .001 \)), and greater mean neointimal thickness (0.19 ± 0.07 mm vs 0.10 ± 0.06 mm; \( P < .001 \)). Compared to PES, E-ZES again showed a higher rate of ISR and higher in-segment LLL, NIH volume, and percent volume obstruction. These findings were attributed the intrinsic drug release kinetics of the E-ZES (95% eluted in the first 2 weeks after implantation). On the other hand, E-ZESs were associated with a lower rate of death or MI beyond 3 years, mainly due to lower rates of late ST and late MI events. Results of E-ZES from clinical trials drove the production of the R-ZES, which has an extended delivery of zotarolimus, with 85% of release occurring within 2 months and the remainder by 6 months. The initial results of the RESOLUTE clinical trial showed that R-ZESs were associated with lower LLL, ISR rates, and TLR compared with E-ZES. An IVUS-based study comparing E-ZES, R-ZES, ZoMaxx (Abbott, Chicago, IL), and Driver (Medtronic; all ZESs with different polymer and drug elution times) demonstrated lower NIH volume, percent neointimal obstruction, and LLL with the R-ZES. Interestingly, after multivariable adjustment, R-ZES correlated with neointimal suppression.

EES and R-ZES are actually the most commonly used commercially available new-generation DESs. Several randomized trials have reported that EES and R-ZES are similar in terms of efficacy profile, with comparable rates of restenosis and need of revascularization. The RESOLUTE-All Comers trial showed no differences in primary end point, showing the noninferiority of R-ZES compared with EES. However, R-ZES was associated with higher LLL at 13 months, but no significant difference in target lesion failure at 2 and 4 years (2 years, 12.6% R-ZES vs 12.2% EES; 4
years, 15.2% R-ZES vs 14.6% EES). An optical coherence tomography (OCT)-based substudy showed no differences in MLA, NIH volume, and percent neointimal volume obstruction between R-ZES and EES.\textsuperscript{142}

Observational studies related to patterns of ISR in first- and second-generation DESs are scarce. Lee et al\textsuperscript{143} reported an incidence of focal ISR of 50.5% with PES, 84.7% with SES, 84.6% with EES, and 85% with R-ZES, with a much lower incidence of diffuse intrastent ISR with second-generation DES (5.6% vs 40%).\textsuperscript{143} Of note, the proportion and distribution of margin-type focal ISR were similar between different generations of DES.

**In-Stent Restenosis in New-Generation Drug-Eluting Stents**

The emerging evidence of the effect of late polymer hypersensitivity on the risk of ST and the prolonged need of dual antiplatelet therapy led to the development of the bioresorbable polymer (BP) DES.\textsuperscript{144} The main potential advantages of BP-DESs are the avoidance of in situ chronic inflammation, delayed endothelialization and healing, and its associated pathologic consequences. The LEADERS (Limus Eluted From a Durable Versus erodable Stent Coating) trial compared the biodegradable polymer biolimus-eluting stent (BES) with SES.\textsuperscript{145} No differences were found in ISR rates, percentage stenosis, LLL, TLR, and TVR at 9 months. An OCT-based substudy of the LEADERS trial demonstrated that although the quantity of neointimal tissue was similar, BES was associated with improved stent strut coverage.\textsuperscript{146} Long-term results (1-4 years) have demonstrated a significant reduction in very late definite ST and TLR with BES compared with SES.\textsuperscript{147,148} These results were confirmed in 3 larges subsequent meta-analyses comparing BP-DES with first-generation and second-generation DESs using direct and indirect comparisons.\textsuperscript{80,149,150} In the same studies, there was no evidence of superiority of BP-DES over second-generation DESs.

Currently, BVS represents a technologic breakthrough in interventional cardiology. Early results with the BVS have been promising. The ABSORB trial, involving 101 patients, reported 2 cases of early ISR (<6 months; 2%), 1 case of late ISR (6-12 months; 1%), and 3 cases of very late ISR (>12 months; 3%).\textsuperscript{151,152} Two of the later cases of ISR were focal and located at
the proximal stent edge, suggesting that EVR may play a potential critical role in ISR with this class of stents. An OCT-based comparison at 1 year of BVS and EES showed similar rates of LLL, NIH thickness, and NIH composition.\textsuperscript{153} However, these studies to date have been small, and the processes leading to ISR in these devices warrant further investigation.\textsuperscript{152,154} Moreover, whether bioabsorbable stents have a role in treating ISR remains unknown.\textsuperscript{155}

\textbf{CLINICAL MANIFESTATIONS OF IN-STENT RESTENOSIS}

The time frame between stent implantation, ISR, and related symptoms is approximately 5 months with BMS and 8 to 13 months with DES.\textsuperscript{156-159} The pathophysiologic consequence of ISR is the development of obstructive coronary artery disease with reduction of myocardial perfusion and development of ischemic symptoms. ISR presentation ranges from stable angina to STEMI.\textsuperscript{158,159} The exact prevalence in clinical presentation of ISR with different types of stent is unclear. ISR with DES has a tendency to manifest more as a stable angina rather than with acute coronary syndrome (ACS). Conversely, studies evaluating ISR manifestations with BMS reported an unstable presentation as a prevalent finding.\textsuperscript{158-160} However, De Labriolle et al,\textsuperscript{161} in a study including more than 1900 patients hospitalized with BMS-ISR and 190 patients with DES-ISR, reported that an unstable presentation was noted in 78\% of patients. Patients with DES-ISR presented more often with an acute MI (4.3\% vs 1.6\%; \( P < .01 \)) and stable angina (30.9\% vs 19.1\%; \( P < .01 \)).\textsuperscript{161} Conversely, Rathore et al\textsuperscript{162} compared the clinical presentation, pattern, and angiographic outcomes in 838 patients with BMS-ISR (\( n = 487 \)) and SES-ISR (\( n = 351 \)). The authors found no differences in clinical presentation between the groups, and most of the patients had a stable presentation. With BMS, 2 larges prospective studies showed that more than 50\% of patients with BMS-ISR present with an ACS, with unstable angina being the prevalent clinical manifestation.\textsuperscript{160,163} Finally, Appleby and colleagues\textsuperscript{164} found no differences in clinical presentation between types of DES (SES and PES), and 78\% of patients had a chronic stable angina as the clinical presentation.
ISR presentation has a significant effect on clinical outcomes. A PRESTO (Prevention of Restenosis With Tranilast and Its Outcomes) trial substudy found that patients with ISR who presented with ACS had a higher incidence of recurrent MACE and binary restenosis compared with patients presenting with stable angina.165

IMAGING OF IN-STENT RESTENOSIS

Intravascular Ultrasound Assessment of In-Stent Restenosis

Intravascular imaging technologies have provided inestimable insights in coronary pathophysiology and underlying mechanisms in stent-induced vascular response, ST, and restenosis. In particular, IVUS analyses allowed the assessment of phenomena such as vascular remodeling, stent underexpansion, and the distribution and patterns of NIH. A classification system for DES-ISR according to IVUS has been proposed by Kang et al166:

- Focal ISR: defined as lumen area <4 mm$^2$ and length ≤10 mm, subcategorized by the location within the stent
  - Focal body type: confined to the body of stent
  - Focal marginal type: extending to the margins of stent
- Multifocal ISR: multiple focal lesions, with subcategories
  - Multifocal body type: confined to the body of the stent
  - Multifocal marginal type: involving stent margins
- Diffuse ISR: defined as MLA <4 mm$^2$ and length >10 mm, with subcategories
  - Diffuse body type: confined to the stent body
  - Diffuse marginal type: associated with stent involvement

In this study, which included 76 IVUS-assessed ISR lesions, a total of 42% had evidence of stent underexpansion and 93% had NIH area >50% of the stent. Importantly, total stent length was negatively correlated with minimal stent area. In patients with stent length >28 mm, underexpansion was evident
in 35% of minimum lumen sites. Therefore, the analysis showed that despite NIH being the predominant mechanism of ISR, a large portion of ISRs (~30%) show evidence of underexpansion, which is an important preventable mechanism of ISR. The same study evaluated NIH features according to the DES. Among SES, PES, and ZES, no differences in the angiographic or IVUS patterns of restenosis were observed, but a higher rate of significant NIH was found with PES. Moreover, PES and ZES were more commonly associated with >10 mm of significant NIH when compared to SES (32% vs 33% vs 9%; \( P = .038 \)). The same authors reported findings from 70 DES-ISR and 47 BMS-ISR lesions assessed by virtual histology IVUS (Fig. 33-12).\(^{167}\) DES-ISR featured more fibrous NIH, whereas a necrotic core and dense calcium were more prevalent in BMS-ISR. Importantly, older ISR lesions had in-stent tissue features characterized by the presence of necrotic core and dense calcium suggestive of NA (see Fig. 33-9).

**FIGURE 33-12** Virtual histologic intravascular ultrasound (IVUS) findings in a stent restenosis with evidence of neointimal neoatherosclerotic features at long-term follow-up. Follow-up of paclitaxel-eluting stent implantation at (A) 6 months, (B) 9 months, and (C) 22 months and bare metal stent implantation at (D) 48 months and (E) 57 months. Virtual histology IVUS analysis coded tissue as green (fibrotic), yellow-green...
(fibrofatty), white (dense calcium), and red (necrotic core). (Reproduced with permission from Kang SJ, Mintz GS, Park DW, et al. Tissue characterization of in-stent neointima using intravascular ultrasound radiofrequency data analysis. *Am J Cardiol*. 2010;106:1561-1565, Copyright © 2010, with permission from Elsevier.)

**Optical Coherence Tomography Assessment of In-Stent Restenosis**

OCT deepened our ability to characterize and understand the mechanisms and morphologic patterns of ISR. Gonzalo et al.\(^{168}\) proposed a morphologic classification according to quantitative and qualitative OCT parameters (Table 33-3 and Fig. 33-13). The relationship between OCT and angiographic ISR assessment was also evaluated (Fig. 33-14). The tissue coverage structure pattern at OCT was most commonly layered in diffuse ISR, homogeneous in marginal ISR, and similarly layered or heterogeneous in focal ISR. High backscatter was associated with diffuse ISR, whereas focal ISR was more likely to have low backscatter. Irregular lumen shape, intraluminal material, and microvessels were all more common in focal ISR. Irregular lumen shape and higher neointima symmetry ratio were also associated with unstable clinical presentation, whereas long ISR was correlated with stable presentation.
FIGURE 33-14 Focal (A) and diffuse (B) in-stent restenosis (ISR) evaluated with optical coherence tomography (OCT). Patient with angiographic focal ISR (A1, white arrow). Cross-sectional OCT image shows heterogeneous tissue with low backscatter (A2). Longitudinal OCT image shows a very focal restenosis (A3, white arrows).

Patient with angiographic diffuse ISR (B1, white bracket). Cross-sectional OCT image shows restenotic tissue with layered structure with high backscatter (B2).

Table 33-3 Qualitative and Quantitative Optical Coherence Tomography (OCT) Characterization of In-Stent Restenosis
### OCT Qualitative Assessment

| Restenotic tissue structure | • Homogeneous: uniform optical properties without focal variation in backscattering pattern  
|                           | • Heterogeneous: focal changes in optical properties and various backscattering pattern  
|                           | • Layered: concentric layers with adluminal high scattering layer and abluminal low scattering layer |
| Restenotic tissue backscatter | • High: predominant bright tissue with backscatter  
|                               | • Low: predominant dark tissue with low backscatter |
| Lumen shape                   | • Irregular: sharp delineation of lumen border that appears smooth and circular  
|                               | • Regular: irregular border with tissue protrusion from the vessel wall into the lumen |
| Intraluminal material         | • Presence: visible material within the vessel lumen  
|                               | • Absence: of same |
| Microvessels                  | • Presence: well-delineated structures <200 μm in diameter with a course within the vessel  
|                               | • Absence: of same |

### OCT Quantitative Assessment

- Mean lumen area (mm$^2$)
- Minimal lumen area (mm$^2$)
- Mean stent area (mm$^2$)
- Mean restenotic tissue area (mm$^2$)
- Restenotic tissue burden (%)
OCT characterization according to the time of clinical manifestation of ISR has also been studied. Gonzalo et al\textsuperscript{168} showed that early ISR (≤12 months) has a prevalent layered pattern (84.3%), whereas later ISR (>12 months) has a prevalent homogeneous pattern. At quantitative analysis, early ISR had a tendency to have smaller mean lumen area. No differences were found in restenosis length, restenotic tissue area, or restenotic tissue burden, according to timing of presentation.\textsuperscript{168} Habara et al\textsuperscript{169} also investigated the temporal relationships between DES-ISR (first generation) and OCT features. A total of 43 early (<1 year), 22 late (1-3 years), and 21 very late (>3 years) ISRs were compared. Angiography alone did not detect any differences between the groups. Conversely, quantitative OCT analysis showed differences in mean stent area, with the lowest area in the late ISR group and the highest in the very late ISR group. Qualitative OCT assessment showed that heterogenous intima with thin-cap fibroatheroma (TCFA)–like pattern, intraintimal microvessels, persistent ulcer-like appearance, disrupted intima with visible cavity, and intraluminal material were more common in very late ISR. These morphologic changes suggest a continuous remodeling of ISR tissue with the development of NA features.

OCT has been also used as a tool to characterize the relationship between ISR and NA. Kang et al\textsuperscript{170} reported a high prevalence of in-stent NA in very late DES-ISR (>20 months after PCI). A total of 52% of lesions had at least 1 site containing TCFA, 58% had at least 1 site of in-stent neointimal rupture, and 58% had evidence of thrombus. According to the interval time (<20 vs >20 months after PCI), patients with DES-ISR at >20 months had a higher incidence of single TCFA and multiple TCFA.

Similarly, an OCT study by Takano et al\textsuperscript{171} assessed the neointimal characteristics of BMS at an early (<6 months) and very late stage (>5 years). The investigators observed that the neointima often transforms over time into lipid-laden tissue with lumen narrowing. Interestingly, neovascularization processes expanded from the persistent area to intima with associated NA, suggesting that neoangiogenesis, which is closely associated with plaque progression, could also play a role in the development of in-stent NA. Finally, the authors found that lipid-laden intima was highly associated with ISR compared with no lipid-laden intima. These observations reinforce the theory that very late DES failure is strongly associated with in-stent neoatherosclerotic processes.
Alongside OCT, near-infrared spectroscopy (NIRS) has also been used to characterize the presence of NA within restenotic tissue. Ali et al\textsuperscript{172} characterized in-stent neoatheroma with OCT and NIRS in a consecutive series of patients with BMS- and DES-ISR. NA was defined at OCT as a signal-poor region with diffuse borders. The authors morphologically classified NA through OCT assessment as the following:

- Type I, thin-cap neoatheroma (TCNA): \geq 1 area of thin cap NA located between the lumen and the stent struts
- Type II, thick-cap neoatheroma (ThkNA): absence of thin cap; NA located between the lumen and the stent struts
- Type III, peristrut neoatheroma (PSNA): NA located around the stent struts
- Type IV, preexisting fibroatheroma (PEFA): native preexisting atherosclerosis displaying as poor region signals with diffuse border between the stent struts and the adventitia

The authors observed that NA was significantly more common in DES than BMS (68\% vs 36\%; \( P = .02 \)). Moreover, DES-ISR had a higher prevalence of TCNA. On NIRS assessment, DES-ISR had a greater total lipid burden and density. Finally, NA was more common at sites of culprit lesions in DES but not in BMS. Interestingly, the authors reported a correlation between the occurrence of periprocedural MI and NA type. Periprocedural MI occurred exclusively in DES, with almost half of the events attributable to luminal-type (I/II) NA within the target ISR lesion.

Differences in ISR OCT appearance between early- and new-generation DESs have also been evaluated. Kilickesmez et al\textsuperscript{173} compared OCT findings in ISR in first-generation DESs (SES and PES) versus second-generation DESs (ZES, EES, and BES) before and after 1 year. Features of NA were more prevalent with first-generation DESs, particularly in the early period; conversely, the prevalence of NA features was higher with second-generation DESs after 1 year. Over time, no differences were observed in the prevalence of lesions with NA features between stent generations.

In summary, the study of ISR morphology with OCT has greatly increased our understanding of the etiology and pathogenesis of ISR, particularly with respect to the nature and time course of NA with various stents. The relationship between ISR morphology determined at OCT and clinical
outcomes is a compelling and ongoing area of investigation.

**Computed Tomography Coronary Angiography Assessment**

Computed tomography coronary angiography (CTCA), despite several limitations, has been demonstrated to be useful in evaluating patients with previous intracoronary stent implantation developing new anginal symptoms with a suspicion of ISR. However, according to the present evidence, recommendations favoring a primary role in evaluating ISR are weak. Ehara et al demonstrated a negative predictive value (NPV) of CTCA for binary ISR of 98% alongside a relatively low positive predictive value (PPV) due to unassessable lesions. Artifacts in coronary stent evaluation include motion artifacts, beam hardening (artificial luminal narrowing and decreases in intraluminal attenuation values), and blooming. In particular, metal blooming (stents appear larger than they actually are) causes the stent to appear thicker, not allowing a proper evaluation of the stent lumen. Blooming artifact is more common in cases of overlapping stents, smaller stent diameter, and small vessels.

The role of 64-slice CTCA in evaluating ISR was explored in a large meta-analysis of observational studies (895 patients and 1447 stents) by Kumbhani et al. The overall sensitivity and specificity were both 91%, the NPV was 98%, and the PPV was moderately low at 68%. When nonassessable segments were included, overall sensitivity and specificity decreased to 87% and 84%, respectively, with a PPV of 53% and an NPV of 97%. The results of the present meta-analysis suggest that CTCA is useful to detect or exclude ISR; however, its PPV is low.

**MANAGEMENT OF IN-STENT RESTENOSIS**

The optimal treatment of ISR is still uncertain. DESs have been demonstrated to be safe and effective in the treatment of ISR. Current American College of Cardiology/American Heart Association guidelines gave a Class I recommendation for DES implantation in clinical restenosis after POBA or
BMS in patients able to comply with and tolerate a mandatory regimen of dual antiplatelet therapy (DAPT). For DES-ISR, the same guidelines gave a Class IIb recommendation for repeat PCI with balloon angioplasty, BMS, or DES containing the same drug or an alternative antiproliferative drug if anatomic factors are appropriate and the patient is able to comply with and tolerate DAPT. In every type of ISR, IVUS might be considered to determine the cause for ISR and help guide the treatment strategy.

ISR patterns may guide therapeutic strategies (Fig. 33-15). Focal DES-ISR, where mechanical factors, SFs, nonuniform strut distribution, and edge effects play a determinant role, might be effectively treated by POBA or drug-eluting balloon (DEB). Conversely, diffuse DES-ISR might be treated with repeat stent implantation. Drug resistance is another potential mechanism of DES failure; therefore, in this case, patients may benefit from repeated stenting with a DES eluting a different drug. Diffuse ISR has been shown to be associated with higher rates of TLR (up to 85%) after successful intervention. Of note, most of these studies used percutaneous transluminal coronary angioplasty as a treatment modality for ISR intervention. Kini et al reported a rate of TLR after treatment of ISR with rotational coronary atherectomy, directional coronary atherectomy, and excimer laser of 46% in diffuse-type ISR and 14% in focal-type ISR. However, irrespectively of the pattern of BMS-ISR, as confirmed by a meta-analysis performed by Dibra et al of 4 randomized studies comparing SES or PES with balloon angioplasty or vascular brachytherapy, DESs are markedly superior in terms of TLR and angiographic restenosis compared to conventional techniques (balloon angioplasty and vascular brachytherapy). Edge ISR represents a small subgroup of ISR lesions that apparently have benign angiographic appearance but are associated with high rates of TLR. A substudy from the RIBS (Restenosis Intra-Stent: Balloon Angioplasty Versus Elective Stenting) trial registry demonstrated that the use of stents in this subgroup of lesions significantly reduced the need for TLR when compared to balloon angioplasty. After multivariable correction for other confounders, stent implantation was the only independent predictor of freedom from TVR (hazard ratio, 0.15; \( P = .003 \)). The recent RIBS-V trial, which compared EES and paclitaxel-eluting balloon (PEB) in BMS-ISR, found that even though both techniques provided excellent results, EES appeared superior to PEB in terms of acute and late angiographic results. This result was also consistent
in patients with diffuse ISR.

Regarding ISR in DES (SES, PES, ZES, and BES), the recent ISAR-DESIRE (Intracoronary Stenting and Angiographic Results: Drug-Eluting Stents for In-Stent Restenosis) III trial, which compared PEB, PES, and POBA, showed that, independent of the baseline pattern of ISR, PEB and PES are markedly superior to POBA in preventing recurrent TLR. Of note, POBA was more commonly associated with a higher incidence of recurrent ISR with diffuse pattern (POBA 39% vs PES 21% vs PEB 21%). Conversely, PES and PEB were more commonly associated with focal-type recurrent ISR (POBA 31% vs PES 41% vs PEB 46%); however, these differences were not statistical significant. Previously, the ISAR-DESIRE II trial demonstrated no differences in the treatment of SES-ISR with SES or PES. Of note, no significant differences were observed in the pattern of recurrent ISR between the 2 types of DES. The similar efficacy of both treatments was also recently confirmed in diabetic and nondiabetic patients by Kufner et al.
**Bare Metal Stent Restenosis**

Currently, PCI with DES implantation is the preferred treatment for BMS-ISR. The safety and efficacy of DES implantation for the treatment of BMS-ISR have been demonstrated in several randomized controlled trials. In the ISAR-DESIRE trial, 300 patients with BMS-ISR were randomized to treatment with SES, PES, or POBA alone. At 6 months, binary angiographic restenosis and TVR rates were significantly lower with DESs compared with POBA alone. Among DESs, SES was associated with a trend toward lower rate of binary angiographic restenosis and significantly lower rates of TVR and LLL compared with PES.\(^{184}\) Similarly, in the RIBS-II (Restenosis Intrastent: Balloon Angioplasty Versus Elective Sirolimus-Eluting Stenting) trial, 150 patients with ISR were randomized to treatment with SES or POBA. At 9 months of follow-up, SES was associated with lower rates of recurrent restenosis and higher MLD and lumen volume at IVUS assessment compared with POBA.\(^{185}\) Long-term follow-up at 4 years of the RIBS-II trial demonstrated sustained clinical efficacy with SES, with lower rates of TLR and MACE.\(^{186}\) Recently, results from the RIBS-V (Restenosis Intrastent of Bare Metal Stents: Paclitaxel-Eluting Balloon Versus Everolimus-Eluting Stent) trial have been published.\(^{187}\) This study evaluated the safety and efficacy of DEB versus EES in patients with BMS-ISR. EES was associated with significantly larger MLD and lower percent diameter stenosis. However, LLL and binary restenosis rates were low and similar in both groups. Finally, no differences in TVR were observed between groups at 9 months. Therefore, this study demonstrated excellent clinical midterm results with both DEB and EES; however, EES provided superior late angiographic findings. Certainly, long-term follow-up is needed to characterize the efficacy of DEB over time.

Brachytherapy was initially proposed as a potential treatment for ISR. However, 2 randomized controlled trials comparing brachytherapy with DES implantation failed to show any benefit associated with this technique. The TAXUS V ISR trial randomly assigned 396 patients with clinical ISR to treatment with brachytherapy or PES.\(^{188}\) At 9 months, PES was associated with lower LLL, angiographic binary restenosis, and higher MLD. The angiographic superiority of PES over brachytherapy was confirmed at 2 years of follow-up, whereas no differences were observed in clinical outcomes.\(^{189}\) In the SIRS (Sirolimus-Eluting Stents Versus Vascular Brachytherapy for In-Stent Restenosis) trial, 384 patients with clinical BMS-ISR were randomly
assigned to either brachytherapy or SES-PCI. Similarly to the TAXUS V ISR trial, SES was associated with better clinical and angiographic outcomes at 9 months compared with brachytherapy. Conversely, at 5 years of follow-up, there were no significant differences in clinical outcomes between the 2 strategies. Considering the complexity and the costs associated with brachytherapy, DES implantation is the preferred strategy for treatment of BMS-ISR.

**Drug-Eluting Stent Restenosis**

DES-ISR is becoming an increasingly frequent problem because of the important number of DESs implanted worldwide each year. Moreover, the optimal treatment for DES restenosis is currently uncertain. As described previously in this chapter, endothelial antiproliferative drug resistance is a potential mechanism of DES-ISR. In the ISAR-DESIRE 2 study, the use of different DESs for the first DES-ISR has been tested. A total of 450 patients with clinical SES-ISR were randomized to either SES or PES implantation. At 6 to 8 months of follow-up, there were no differences between SES and PES in late loss, binary restenosis, or TLR. Moreover, no differences were observed in terms of clinical outcomes. Conversely, the RIBS-III (Restenosis Intrastent: Balloon Angioplasty Versus Drug-Eluting Stent) trial, a prospective, multicenter nonrandomized study, yielded different results. A total of 363 patients were included. The different DES strategy was used in 274 patients (75%), whereas implantation of a DES with similar drug elution was used in 89 patients (25%). At a median follow-up of 278 days, the different DES strategy was associated with greater MLD and lower recurrent restenosis rates. These results remained consistent following adjustment for baseline confounders; however, the nonrandomized nature of this study makes these results less reliable.

Another important issue in the management of ISR is the duration of DAPT following ISR treatment. A substudy from the PRODIGY (Prolonging Dual Antiplatelet Treatment After Grading Stent-Induced Intimal Hyperplasia) trial reported a lower incidence of the composite of death, MI, or stroke in patients with ISR treated with long (24 months) DAPT compared with a short (6 months) regimen. Despite the limitation of this analysis (only 224 patients with ISR were included), these data provide preliminary evidence that patients treated for ISR might benefit from prolonged DAPT.
Finally, a very recent network meta-analysis of randomized controlled trials has shown that DEB and DES for ISR treatment (both BMS- and DES-ISR) are associated with significantly lower TLR rates compared with POBA, whereas no differences in MI or mortality were observed. Interestingly, the risk for MI or all-cause mortality was lowest with DEB but this did not reach statistical significance.

Currently, 2 randomized controlled trials evaluating different treatments for DES-ISR are ongoing. The ISAR-DESIRE IV (ClinicalTrials.gov identifier: NCT01632371) trials will test the superiority of cutting balloon plus PEB versus PEB alone for the treatment of ISR within limus-eluting stents. Therefore, this trial will test the efficacy of cutting balloon in the treatment of ISR associated with the release of an antiproliferative drug of a different family compared with the restenotic DES. Theoretically, the application of a cutting balloon prior to deployment of PEB may increase the bioavailability of paclitaxel within the restenotic tissue with subsequent improvement in the efficacy of PEB. Conversely, the RIBS-IV (ClinicalTrials.gov identifier: NCT01239940) trial will randomize 310 patients with DES-ISR to receive treatment with DES or EES implantation.

**CONCLUSIONS**

DESs critically improved the safety and efficacy of PCI by reducing the need for TLR and TVR across all types of coronary lesions and patient subsets. In a contemporary era, the rates of ISR with DES are less than 8 to 10% at 3 to 4 years of follow-up. However, limitations still exist, especially in very complex lesions and diabetic patients. Next-generation stent platforms have to further improve DES performance by implementing novel antiproliferative drugs, thinner stent struts, more favorable stent designs, and improved stent material biocompatibility. Routine implementation of intracoronary imaging may be critical in optimizing stent implantation and improve long-term PCI outcomes. Finally, BVSs, which represent a technologic breakthrough in the field of coronary stents, have the potential advantages of similar efficacy in treating coronary stenosis along with the ability to restore native vascular physiology. Further studies are warranted to better identify the factors associated with ISR in the current era and establish the optimal strategies for its prevention and treatment.

Coronary Atherectomy: Concepts and Practice

Creighton W. Don
Lou Vadlamani
Mark Reisman

BACKGROUND

Coronary atherectomy continues to be an important tool for percutaneous coronary intervention (PCI), particularly as the population ages and more patients present with complex calcified coronary artery disease. Early studies using rotational and laser atherectomy failed to demonstrate a clear advantage over angioplasty alone, and as such, atherectomy of straightforward atherosclerotic disease is not commonly used. With the very low restenosis rates of second-generation drug-eluting stents (DESs) in many lesion types, contemporary practice is to use atherectomy primarily as adjunctive therapy for plaque modification of calcific lesions that cannot be crossed with devices or dilated with balloons to enable DES delivery.

Utilization of atherectomy composes approximately 3% of PCIs in the United States and between 0.8% and 3.1% worldwide (Table 34-1). Yet, as the population ages, more PCIs are performed in higher risk patients with more complex coronary artery disease, and in a recent evaluation of patients undergoing PCI, 33% were found to have moderate to severe coronary calcification (Fig. 34-1). Furthermore, the extent of vessel calcification is often underappreciated fluoroscopically. In one study, significant
calcification seen by intravascular ultrasound (IVUS) was seen only 50% of the time fluoroscopically,\textsuperscript{5} which is often the cause for “rota-regret” when a stent cannot be delivered or dilated.

**FIGURE 34-1** Prevalence of moderate to severe calcification in 1800 patients undergoing percutaneous coronary intervention (COMPARE study).\textsuperscript{4} ACC, American College of Cardiology; AHA, American Heart Association; CTO, chronic total occlusion.

Table 34-1 Percentage of Atherectomy by Total Percutaneous Coronary Interventions by Country
Vessel calcification remains a major independent predictor of PCI failure and adverse outcomes (Fig. 34-2), and atherectomy is a critical component to improve PCI success in these situations. Some studies are already starting to show an increasing trend in the number of operators and centers performing atherectomy.

Rotational atherectomy is the most widely used form of atherectomy, although utilization of laser and orbital atherectomy has been increasing. The majority of clinical data regarding coronary atherectomy is based on evaluation of the Rotablator device (Boston Scientific, Marlborough, MA). As such, this chapter will focus primarily on rotational atherectomy, with more brief discussion of the potential utility of other atherectomy devices.

**RATIONALE FOR AThERECTOMY**

The early experience with coronary atherectomy focused on plaque reduction and lesion debulking, given the residual stenosis and need for repeat revascularization in an era in which PCI was limited to balloon angioplasty. Several devices were developed and approved for use, but clinical trials found minimal benefit and potentially harm compared to angioplasty. Directional coronary atherectomy and laser atherectomy have fallen out of favor given their association with coronary perforations and similar rates of restenosis and adverse events compared with patients undergoing angioplasty alone.\(^{10}\)

In the coronary stenting era, in which restenosis rates with DES are less than 3% annually,\(^{11}\) atherectomy is used primarily for plaque modification and lesion preparation rather than debulking. Rotational atherectomy has remained a useful tool for its ability to preferentially ablate calcific and fibrotic disease to help facilitate stent delivery,\(^{12}\) avoiding the barotrauma caused by repeated high-pressure balloon inflations that can lead to vessel dissection or perforation.\(^{13,14}\)

Furthermore, forceful advancement of DES through narrow, calcified lesions may cause stent polymer damage, which could be avoided with proper lesion preparation using atherectomy.\(^{15}\) In the ROTAXUS (Rotational Atherectomy Prior to Taxus Stent Treatment for Complex Native Coronary Artery Disease) study, among patients who underwent an angioplasty-stenting strategy, stent loss was observed in 2.5% of patients, and 12.5% of these patients ultimately crossed over to atherectomy, whereas no stent loss was observed among patients randomized to the atherectomy strategy.\(^{12}\)

The ROTATE Multicenter Registry demonstrated that patients undergoing
planned rotational atherectomy had fewer balloon inflations, less radiation exposure, lower contrast volumes, and shorter procedure times than those undergoing provisional atherectomy for device delivery failure or balloon expansion failure (Fig. 34-3).\textsuperscript{16}
In addition to this, atherectomy would potentially modify a calcified lesion to allow optimal stent expansion and improve lumen gain.\textsuperscript{12,17} This may have particular benefits for PCI with bioresorbable scaffolds that may have lower radial strength and greater recoil than metal stents that demand more complete vessel preparation to allow stent delivery and more complete apposition.\textsuperscript{18,19} Although the use of atherectomy for debulking atherosclerotic tissue has fallen out of favor in the era of DES, plaque reduction remains useful in specific situations such as bifurcations or ostial disease, reducing disease at the carina to avoid geographic miss, and plaque shift.\textsuperscript{20-22} The list of potential benefits of atherectomy to optimize PCI are listed in Table 34-2.

ROTATIONAL AHERECTOMY

The Rotablator rotational atherectomy system was developed by David C. Auth, PhD, PE, at the University of Washington over a period of 13 years. After years of experimentation and animal studies, on January 6, 1988, Fourrier et al. performed the first procedure in a human coronary artery. At the same time, Zacca and colleagues performed the procedure in the peripheral vasculature in humans. Since then, multiple clinical trials and registries have demonstrated the efficacy of rotational atherectomy, which has become the most commonly used coronary atherectomy device worldwide.

The components of the Rotablator rotational atherectomy system include the burr, drive shaft, turbine, and console (Fig. 34-4).
FIGURE 34-4 Rotablator components.

**Burr**

The Rotablator burr is a nickel-plated brass ellipse coated with diamond.
crystals between 20 and 30 μm in size on the leading edge, on average extruding only 5 μm from the surface, forming an abrasive sanding surface. There are no diamond chips on the trailing edge, so atherectomy is only achieved with forward motion of the burr. For the coronary arteries, burrs are available in sizes of 1.25, 1.5, 1.75, 2.0, 2.15, 2.25, 2.38, and 2.5 mm. The inner diameter of the guide catheter must be at least 0.01 mm (0.004 in) greater than the burr size to provide adequate clearance for device advancement and withdrawal. The later section on guide catheters describes this in greater detail.

The burr is bonded to a drive shaft housed in a 4.3-Fr, 135-cm-length Teflon sheath and connected to a turbine within the advancer. Potential injury to the arterial wall (by the spinning drive shaft) is prevented by the Teflon sheath, which also acts as a conduit, delivering flush at 7 to 13 mL/min when activated.

**Advancer**

Compressed nitrogen powers a turbine within the advancer that rotates the shaft and burr at speeds of 150,000 to 200,000 rpm. The turbine is controlled by the console and activated by a foot pedal. The advancer has a knob that controls the movement of the burr during atherectomy. The knob can be locked down to avoid movement of the burr during advancement through the coronary guide. The back end of the advancer has a brake that locks the advancer onto the wire and prevents the coaxial guide wire from spinning along with the burr. The break is released by pressing the black button on the end of the advancer, which needs to be released when withdrawing the device.

**Console and Foot Pedal**

The console regulates the flow of compressed air, which controls the turbine speed. A fiberoptic light probe monitors the rotational speed and displays it on the console tachometer. Depressing the foot pedal initiates rotation of the burr and activates the breaking system. The button on the right of the foot pedal toggles between the rotation used for atherectomy and DynaGlide, which rotates the burr at a constant 30,000 rpm to prevent stalls. DynaGlide is used for withdrawing the system through the guide and helping to
disentangle an entrapped burr.

**BASIC PRINCIPLES AND MECHANISMS**

The high-speed rotations of the Rotablator are effective in increasing lumen diameter through plaque ablation but can also have deleterious effects that may weaken the vessel adventitia, leading to perforations and vessel aneurysms, or cause microcavitations, hematologic effects, and embolization of microparticulate debris that can lead to no reflow.

*Mechanisms and Physiologic Effects*

The Rotablator system is analogous to a low-powered rotary sander. High-speed rotational atherectomy effectively ablates calcified, inelastic atherosclerotic tissue while sparing healthy, elastic tissue, leading to lumen enlargement and reduction of cross-sectional atherosclerotic plaque area. There is also minimal trauma to normal “healthy” tissue. Data from human and animal studies confirm these findings.\(^{23-25}\)

The 2 principles that govern the operation and effectiveness of the Rotablator system are *differential cutting* and *orthogonal displacement of friction*.

**Differential Cutting**

Differential cutting is the ability to selectively ablate one material while preserving the integrity of the other, based on differences in the composition and texture of the substrate. The elasticity of the normal tissue deflects the ablative surface, whereas the inelastic properties of diseased tissue engage the cutting surface. A common analogy to differential cutting is shaving. Whiskers are relatively inelastic compared to skin, and a razor will preferentially cut these while sparing the skin. The atherectomy burr tends to spare healthy, elastic tissue, while calcium, fibrous tissue, fatty deposits, and intimal hyperplasia (restenotic tissue) increase the inelastic properties of vascular tissue, making it susceptible to ablation by the cutting edges of the
atherectomy burr.

**Orthogonal Displacement of Friction**

Orthogonal displacement of friction is essential in allowing easy passage of the burr through diseased and tortuous vascular segments. The sliding motion and high rotational speeds virtually eliminate the longitudinal friction vector, allowing for unhindered advancement and withdrawal of the burr. This principle is similar to a corkscrew, in which the twisting motion reduces the friction on the surfaces and facilitates movement of the corkscrew. The faster it is turned, the easier it is to remove it.

These 2 basic principles allow for the burr to effectively ablate diseased and atherosclerotic tissue, with lower risk of harming normal tissue. This was confirmed with early animal studies using cholesterol-fed New Zealand white rabbits. After treatment, the minimum lumen diameter (MLD) was reduced from 81% ± 9% to 38% ± 22% ($P < .001$, paired $t$ test). Histologic specimens showed effective intimal plaque removal, with minimal medial injury and no medial or intimal dissections. Similar results were shown by Ahn et al\textsuperscript{27} in cadaveric human coronary arteries.

**Debulking and Plaque Modification**

Quantitative coronary angiography has been used to evaluate the efficiency of rotational atherectomy in debulking lesions. Early studies using quantitative coronary angiography in 109 patients showed that a predictable MLD can be achieved across the range of burr sizes. Expressing MLD as a burr ratio (MLD/burr size), the Rotablator achieved immediate results of 72% ± 19% of the burr selected (ie, a 2.0-mm burr predicted an MLD of approximately 1.4 mm). Mintz et al\textsuperscript{25} confirmed this using IVUS. There was minimal injury to the media and adventitia of adjacent tissue. Measured 24 hours later, the burr ratio increased to 84% ± 15%.\textsuperscript{28}

Guide wire bias, however, preferentially orients the burr toward either the inner or outer curvature of an angulated lesion and causes unequal force to be exerted on one region of the vessel wall, resulting in a much larger, eccentric lumen. The Rotablator burr creates a force vector that not only ablates the vessel media and creates an elliptical lumen,\textsuperscript{29} but can also form deep vessel
dissections or “rota-gutters,” aneurysms, and perforations (Fig. 34-5).

**FIGURE 34-5** Formation of a deep vascular dissection by rotational atherectomy. A. Angiogram showing severe calcification along an angulated lesion (white solid arrow). There is a calcified plaque before atherectomy with the wire in contact with the vessel wall (I), and plaque modification after the debulking intervention with a channel formation (II). The diameter of the channel (solid white double arrow) is exactly the same diameter of the 1.25-mm burr that was used. After stent placement (III), some segments still showed the presence of the channel (asterisk) behind the struts (white dashed arrow). (Used with permission from Attizzani GF1, Patrício L, Bezerra HG. Optical coherence tomography assessment of calcified plaque modification after rotational atherectomy. *Catheter Cardiovasc Interv.* 2013;81(3):558-561.)

In some studies, sequential IVUS imaging and electron microscopy have shown not only plaque reduction, but also ablation of media volume and damage to the smooth muscle layer, albeit without change in the external elastic membrane diameter. Nevertheless, unequal ablation of tissue,
Atherectomy of calcium, and disruption of the media layer change vessel compliance in such a way that allows for device delivery and full expansion, even with minimal initial lumen gain. In more contemporary studies of atherectomy adjunctive to stenting, significant increases in lumen areas were documented despite use of primarily smaller 1.5-mm burrs.\textsuperscript{12,16,34} For these reasons, the maximal burr size should not exceed 70% of the vessel diameter, and floppy wires or guide and wire positioning techniques can be used to reduce eccentric cutting of the vessel media layer. Atherectomy of extremely angulated lesions may need to be avoided.

**Thermal Effects**

Thermal injury can lead to smooth muscle proliferation, increasing restenosis rates, as well as cause red blood cell aggregation and platelet activation.\textsuperscript{35-37} Increased temperatures are generated with longer, more continuous engagement of coronary lesions with the spinning burr and aggressive ablation with excessive decelerations (14,000-18,000 rpm), whereas an intermittent or oscillating “pecking” technique can limit decelerations and reduce the temperature changes.\textsuperscript{38} Minimizing thermal injury using this technique may prevent vessel trauma and smooth muscle proliferation that may increase restenosis.

**Microparticulate Debris**

The vast majority of microparticulate debris produced by rotational atherectomy is generally 2 to 10 μm and smaller, compared to red blood cells and capillaries, which are about 6 to 10 μm\textsuperscript{26,27}; however, about 2% to 10% of particles are 10 to 20 μm and larger when using the larger burr sizes.\textsuperscript{27,39} A recent study of the orbital atherectomy device reported an average particulate size of 2 μm, with approximately 1% of particles being larger than 9.5 μm. Most of this debris passes through the capillaries and is cleared by the reticuloendothelial system.\textsuperscript{27} Transient perfusion defects can be observed on single-photon emission computed tomography imaging, but these appear to resolve after 48 hours and are not necessarily clinically significant.\textsuperscript{40} Other studies have shown similar defects with PCI that may not differ significantly from rotational atherectomy.\textsuperscript{41}
The rapidly spinning Rotablator burr is also known to form relatively large gas bubbles dissolved in blood called microcavitations, which appear to collapse quickly. During activation of the burr, transient enhancement of echocardiographic contrast is seen in the area of the myocardium subtended by the artery, which disappears immediately after the burr rotation is stopped. Microcavitations may transiently reduce myocardial blood flow.42

Nevertheless, more significant no reflow or vessel closure during the procedure, associated with hypotension, is clinically relevant, and steps should be taken to minimize such events. It is recommended that each atherectomy run last no longer than 30 seconds to restore normal myocardial blood flow and allow time for microparticles to clear from the distal vasculature. Administration of prophylactic vasodilators or mixing verapamil and nitroglycerine with the RotaGlide lubricant may help reduce no reflow.43,44

**Platelet Aggregation**

The high rotational speed of the burr establishes a shear field and affects both erythrocytes and platelets. A study using 8 samples of porcine blood exposed to a spinning burr demonstrated evidence of platelet aggregation as measured by optical microscopy.38 The number of aggregates was affected by the speed of the burr. Larger platelet aggregates (>60 μm in diameter) were seen in all 8 samples at 180,000 rpm and in only 1 of 8 samples at 140,000 rpm. These findings support the importance of lowering the burr speed to minimize the hematologic impact of rotational atherectomy. The combination of lower rotablation speeds and the use of glycoprotein IIb/IIIa inhibitors during atherectomy has also been shown to reduce platelet aggregation45 and the incidence of periprocedural myocardial ischemia46 and infarctions in patients.47

These observations establish the basic foundation for understanding the mechanism of rotational atherectomy and provide general principals to mitigate the untoward effects of atherectomy (Table 34-3). Smaller burr/artery ratios, management of guide wire bias, and avoidance of severely angulated lesions will help avoid significant damage to the vessel media layer. Heat generation and thermal injury can be minimized by advancing the device gently and intermittently and avoiding significant decelerations. Use
of smaller burrs, limiting atherectomy runs to 30 seconds, and prophylactic administration of vasodilators may reduce the impact of downstream microparticulate embolization. Platelet aggregation and other hematologic affects can be controlled by lowering the rotational speeds and the use of platelet inhibitors.

**Table 34-3 Recommended Techniques to Address Complications Associated With Atherectomy**

<table>
<thead>
<tr>
<th>Complication</th>
<th>Causes</th>
<th>Recommendation</th>
</tr>
</thead>
</table>
| **Perforations and aneurysms**| Burr oversizing, forceful burr advancement, angulated lesions and guide wire bias causing deep fissures, and eccentric cutting of the vessel media layer | • Smaller burrs for angulated lesions  
• Start with smaller burrs for plaque modification, with maximal burr size <70% of the vessel diameter  
• Rota Floppy wire and guide wire positioning to reduce guide wire bias in angulated lesions  
• Avoidance of severely angulated vessels |
| **Restenosis**                 | Thermal injury predisposing to intimal hyperplasia                      | • Intermittent “pecking” technique rather than continuous lesion engagement  
• Limit each atherectomy run to 30 seconds  
• Avoid excessive decelerations |
| **Slow flow**                 | Microparticulate debris and platelet aggregation                        | • Use smaller burrs (~1.5) if possible  
• Limit each atherectomy run to 30 seconds  
• Start with lower burr speeds ~140,000 to 160,000 rpm  
• Appropriate platelet inhibition  
• Prophylactic vasodilators |
| **Burr entrapment**           | Forceful advancement of the rotational burr or atherectomy within a dissection | • Careful use of the 1.25 burr  
• Graded upsizing of the burr  
• Use of the Intermittent “pecking” technique  
• Avoid decelerations >5000 rpm |

**PROCEDURAL CONSIDERATIONS AND TECHNIQUE**

**Guide Catheters**

The internal diameter of the guiding catheter should be at least 0.01 mm (0.004 in) larger than the burr. Therefore, a 5-Fr guide with an inner diameter of 1.47 mm (0.058 in) can only allow delivery of the 1.25-mm burr. A 6-Fr guide with an inner diameter of 1.80 mm (0.071 in) can accommodate the 1.25-, 1.5-, and 1.75-mm burrs. A 7-Fr guide with an inner diameter of 2.05 mm (0.081 in) can accommodate up to a 2.0-mm burr; however, larger guides provide greater clearance to facilitate advancement of the burr through the
guide, so an 8-Fr guide may be preferable for the 1.75-mm burr. An 8-Fr guide with an inner diameter of 2.28 mm (0.090 in) can accommodate up to a 2.15-mm burr. A 9-Fr guide would be needed for the 2.25- and 2.38-mm burrs, and a 10-Fr guide would be needed for the 2.5-mm burr. Since 9-Fr and 10-Fr guides are rarely used in the coronaries in the contemporary era, the larger burr sizes are primarily used in peripheral interventions. Operators must be attentive to the specifications of guide catheters from different manufacturers as inner diameters may vary.

Guide extension catheters may facilitate burr delivery to distal, tortuous lesions, but the inner diameter of these catheters limits what sizes can be used. Although the inner diameter of the 6-Fr Guideliner (Vascular Solutions, Minneapolis, MN) is 1.42 mm (0.056 in) and that of the 6-Fr Guidezilla (Boston Scientific) is 1.45 mm (0.057 in), there is minimal clearance for the 4.3-Fr Rotablator drive shaft, and device advancement is not easy. The 8-Fr Guideliner inner diameter is 1.80 mm (0.071 in), which could allow for the 1.25- and 1.5-mm burrs to be advanced.

Coaxial guide positioning is important to ensure easy of passage of the Rotablator burr and avoid trauma to the coronary ostia. The guide can also be used to modify the trajectory of the guide wire to change the direction of the ablation plane, which is important in atherectomy of proximal lesions that are highly angulated or are affected by guide wire bias.

**Guide Wires**

The Rotablator spins over a 0.009-in stainless steel wire with a radiopaque platinum 0.014-in spring coiled tip. The larger tip diameter prevents the burr from spinning beyond the tip of the wire, so the radiopaque dip must be positioned distal to the lesion, because the burr cannot track over this larger segment. Every attempt should be made to keep the guide wire from prolapsing or coiling, because any rotation during burr activation can result in fracture or trapping of the tip in the vessel wall.

Two types of guide wires are currently available. The Floppy RotaWire (Boston Scientific) has a long, tapered shaft that maximizes flexibility to reduce vessel straightening and help relieve unfavorable wire bias in tortuous vessels. On the other hand, in highly calcified vessels, the floppy wire may bias the Rotablator vector preferentially toward normal tissue, leading to eccentric atherectomy or potential dissections. The RotaWire Extra Support
wire (Boston Scientific) is a stiffer-bodied wire that increases vessel straightening to help steer the burr through heavily calcified and ostial lesions, but it may create pseudolesions and lead to ablation of normal tissue.

It is possible to angle the guide catheter and manipulate the guide wire to orient the burr closer to the lesion, particularly when treating proximal eccentric and angulated lesions. Pulling or pushing on the wire can direct the burr force vector to the inner or outer curve of the lesion—a concept that has been referred to as *directional* rotational atherectomy.

**Burr Selection, Advancement, and Trouble Shooting**

Early plaque debulking strategies incorporated a 2-burr approach, with the burr-to-artery ratio of the first burr being approximately 0.5 to 0.6, and that of the second approximately 0.75 to 0.8. In the stenting era, in which the goal is plaque modification, a single burr with a burr-to-artery ratio of at most 0.6 to 0.7 is sufficient, in conjunction with angioplasty and stenting. A burr-to-artery ratio of less than 0.5 is helpful for total occlusions, sharply angulated lesions, or long lesions. Less aggressive atherectomy has been associated with lower rates of restenosis and helps reduce periprocedural complications. 48,49

Once the burr is advanced into the coronary artery, it should be placed just proximal to the lesion—the so-called *platform segment*. The burr is activated in this position, where it can rotate unimpeded, because if the burr is activated while in contact with the vessel wall, the risk of injury is significantly increased.

After positioning the burr in the proximal position, it is important to relieve the tension on the system by pulling back on the advancer knob to prevent the burr from jumping forward into the lesion when the device is activated, increasing the risk of dissection. Once the operator is certain that the tension on the burr has been released, the burr is activated in the platform segment and then advanced to the lesion. Rotation speeds of 140,000 to 160,000 rpm are ideal to optimize atherectomy and reduce complications.

Ablation of the lesion should be performed using a “pecking” technique to reduce thermal injury and embolization. Burr advancement should be gentle. Monitoring the decelerations and avoiding excessive decelerations of >5000 rpm helps to avoid aggressive atherectomy. Contrast injections can be performed to evaluate the progress of the burr and identify any problems with
burr orientation or burr-to-artery relationship. The duration of each run should last 15 to 30 seconds, with an interval of 30 seconds and longer between each run to allow for myocardial perfusion and clearance of microparticles. Longer rest periods may be needed to allow for electrocardiographic changes, hypotension, chest pain, or bradycardia to resolve. Once there is no tactile resistance as the burr crosses the treated segment or when no decrease in revolutions per minute are noted during burr advancement, the burr should be removed.

**Complications**

**Bradycardia**

Bradycardia and heart block are often seen in patients undergoing atherectomy of right or left dominant circumflex coronary arteries, most likely due to microparticulate emboli leading to a parasympathetic effect on the heart. Atherectomy using larger burrs, longer runs, or more revolutions per minute and treating lesions affecting a greater myocardial territory are more likely to induce heart block.

Routine temporary pacemakers are not required when using smaller burrs at lower revolutions per minute, but operators should stop atherectomy runs when transient atrioventricular nodal block occurs and be prepared to place a temporary wire or address this with pharmacologic (eg, atropine) or mechanical maneuvers (eg, coughing) if it does not resolve quickly.

**No Reflow**

The major clinical complication rates for rotational atherectomy are similar to those reported for balloon angioplasty and include death in 0.9% of patients, Q-wave myocardial infarction (MI) in 1.3%, and emergency bypass surgery in 1.9%, even in the context of higher risk lesions. There is, however, a trend toward a higher rate of non–Q-wave MI (6%), defined as a creatine kinase–myocardial band (CK-MB) level elevated to more than twice the normal value. Most of these complications can be avoided by using proper procedural technique and pharmacotherapy.

However, lesions with thrombus, with extensive dissection, and in
saphenous vein grafts should be avoided. The choice of guide catheter (eg, based on vessel takeoff, need for support), guide wire, and burr size should be determined at the start of the procedure.

It is worthwhile to note that use of glycoprotein IIb/IIIa inhibitors has been shown to reduce postprocedural elevation of cardiac enzymes by almost 50%, which may translate to a reduction in long-term adverse events.\textsuperscript{32,33} Glycoprotein IIb/IIIa use has also been shown to attenuate the transient wall motion abnormality sometimes associated with rotational atherectomy,\textsuperscript{34} and in vitro studies have shown that abciximab can reduce platelet activation caused by a high-speed burr.\textsuperscript{35} Although there is significant benefit in using these agents, care is needed when lesions are at high risk for perforation, because the level of anticoagulation could have catastrophic effects.

Vasospasm can sometimes complicate rotational atherectomy; therefore, it is important to have vasodilating agents such as nitroglycerine (100-200 μg) available during the procedure. Some operators prefer to use a cocktail of nitroglycerine, verapamil, and heparin in a flush solution for continuous infusion, and some data support this approach.\textsuperscript{36} Intracoronary adenosine administration has also been shown to reduce the rates of no reflow.\textsuperscript{37} RotaGlide lubricant is also usually added to the flush solution to reduce friction between the drive coil and guide wire. Vasopressors should also be readily available; dopamine, epinephrine, and phenylephrine are the usual agents.

**Burr Entrapment**

The Rotablator burr can be advanced forward too quickly, insufficiently atherectomizing the lesion, and then pushed beyond the lesion. Since the atherectomy surface on the Rotablator is only on the proximal surface, it is possible that the burr cannot be withdrawn back through the vessel in this situation. It is also possible that the burr becomes embedded in a fibrotic and calcified lesion and the device stalls and will not rotate. Extremely calcified lesions and tortuous vessels increase the risk for entrapment.\textsuperscript{50} A 1.25-mm burr is the most likely to inadvertently be forced through a lesion given its smaller size and lower profile shape compared to the larger burrs. Purposeful, but careful, burr advancement during atherectomy helps to avoid this complication, but it cannot always be avoided.
Gently withdrawing the burr using DynaGlide, with constant low revolutions per minute, typically will disentangle a stalled device; however, this is occasionally insufficient to remove the device.

Expanding the lesion with an angioplasty balloon may reduce the resistance of the lesion and allow the burr to be withdrawn. If an 8-Fr guide is used, a second wire and 1.5-mm balloon can be passed alongside the rotablation catheter, and an attempt can be made to pass a wire alongside the entrapped rotablation burr and angioplasty the resistant lesion. A second guide can be used from a second access site, or a smaller guide can be upsized by cutting the distal hub off of the rotablation burr, removing the smaller guide and advancing a larger guide over the rotablation shaft. Alternatively, once the distal hub of the rotablation burr is cut, the outer plastic sheath covering the burr can be removed. This will allow for a second wire and balloon to be passed through a 6- or 7-Fr guide.

A telescoping 5-Fr guide to provide countertraction and a gooseneck snare to provide negative traction have been described to successfully remove entrapped rotablation burrs. The hub of the rotablation catheter and the outer plastic sheath need to be removed so a telescoping “mother-in-child” guide can be advanced over the rotablation shaft assembly or the snare, and the snare microcatheter will fit alongside the Rotablator within the guide. Additionally, the distal end of the rotablation wire is 0.014 in and can be withdrawn and used to pull back on the rotablation burr, which has a 0.009-in lumen.

**CLINICAL STUDIES**

The first atherectomy device for coronary arteries was a directional atherectomy device approved by the US Food and Drug Administration (FDA) in 1990, followed by the approval of the excimer laser and Rotablator in 1993. There were no other coronary atherectomy devices approved until Cardiovascular Systems Incorporated’s Diamondback 360 in 2013.

The FDA approval of the Rotablator was based on several nonrandomized studies, the most important of which involved a multicenter registry that included 2953 procedures involving 3717 lesions from patients who underwent rotational atherectomy for primary treatment of coronary artery disease or as adjunctive therapy to balloon angioplasty. The study was
published in 1995 and compiled data from 1988 to 1993, at a time when angioplasty was the primary mode of coronary intervention and atherectomy was used as a sole therapy. The procedural success rate was 85% with atherectomy alone and 95% with adjunctive balloon angioplasty. The rate of periprocedural MI was 9.5%, mortality 0.8%, and urgent coronary artery bypass graft (CABG) 2.0%. Dissections were noted in 13.1%, perforations in 0.7%, and abrupt closure in 3.6% of patients.

The early use of atherectomy focused on plaque debulking using progressively larger burrs to maximize lumen gain with angioplasty. As stent technologies improved, the practice of aggressive atherectomy using burr-to-artery ratios >0.7 gave way to the practice of less aggressive atherectomy using lower ratios for plaque modification, in order to deliver and deploy stents. Short- and long-term complications associated with atherectomy have decreased significantly from its early use in the early 1990s. In the contemporary era, where optimal atherectomy techniques are employed and stents are used routinely, the frequency of acute complications such as no reflow, dissections, and perforations has been maintained at a low rate over the past 20 years (Fig. 34-6). The long-term major adverse cardiovascular events (MACE), mortality, and target vessel revascularization (TVR) rates have decreased, along with routine use of stents, less aggressive debulking strategies, and drug-eluting platforms (Table 34-4).

![FIGURE 34-6 Periprocedural and in-hospital outcomes in clinical studies of atherectomy between 1995 and 2014.](image)

Complication rates for the CARAT study reflect the “small burr” arm of the study. The dissection rate of the DART study refers to severe, flow-limiting dissections, similar to the definition used...
in other studies. The definition of myocardial infarction (MI), a major adverse cardiovascular events (MACE), varies across studies.

Abbreviations: MACE, major adverse cardiac events; MI, myocardial infarction; TVR, target vessel revascularization.

With the availability of lower profile devices and routine use of stents, the use of atherectomy has generally moved away from plaque debulking to plaque modification, but it has also evolved into new uses such as treating in-stent restenosis, ostial and bifurcation lesions, saphenous vein grafts, or chronically occluded lesions.

**Atherectomy Versus Angioplasty**

Three major studies have compared angioplasty to atherectomy alone (see Table 34-4). The ERBAC (Excimer Laser, Rotational Atherectomy, and
Balloon Angioplasty Comparison) study compared 685 patients with symptomatic coronary disease randomized to balloon angioplasty, excimer laser, or rotational atherectomy.\textsuperscript{56} Patients who underwent rotational atherectomy had the highest rate of procedural success (89.2%), defined as a <50% residual stenosis, compared with those who underwent excimer laser angioplasty (77.2%) or balloon angioplasty (79.7%; \(P < .01\)). Acute inhospital complications were similar, but TVR was 42.4% in the rotational atherectomy group and 46.0% in the excimer laser group, which was higher than in the angioplasty group (31.9%; \(P = .01\)).

The COBRA (Comparison of Balloon Angioplasty Versus Rotational Atherectomy) multicenter randomized trial enrolled 502 patients with complex coronary artery disease to angioplasty or rotablation.\textsuperscript{57} Procedural success was higher with atherectomy (85\% vs 78\%; \(P = .04\)), and crossover from angioplasty to rotablation was 10\%, which was more than twice as frequent as the converse (\(P = .02\)). Patients undergoing high-pressure balloon angioplasty were also twice as likely to need bailout stenting (15\% vs 6\%; \(P < .01\)). Otherwise clinical outcomes, including TVR (percutaneous transluminal coronary angioplasty 51\% vs rotablation 49\%; \(P = .33\)), were the same at hospital and at 6-month follow-up.

The multicenter, randomized DART (Dilation Versus Ablation Revascularization Trial Targeting Restenosis) study compared rotational atherectomy with balloon angioplasty in 446 patients with lesions in small coronary arteries (<3 cm) without severe calcification.\textsuperscript{58} Procedural success, acute lumen gain, and long-term lumen diameter were similar between groups. In-hospital complications and 12-month mortality, MI, MACE, and TVR rates were similar (see Table 34-4).

It is clear that rotational atherectomy is safe compared to angioplasty, but it also has the potential to improve procedural success in complex coronary artery disease, particularly in lesions that are highly fibrotic or calcified where dissections are likely to occur with high-pressure balloon angioplasty.

**Debulking Versus Plaque Modification**

In the pre-stent era, larger atherectomy burrs could be used to maximize lumen gain or allow for greater stent expansion. Aggressive atherectomy, however, can increase the risk for deeper dissections, abrupt vessel closure, and increased distal embolization.
The STRATAS (Study to Determine Rotablator and Transluminal Angioplasty Strategy) study\(^{59}\) randomized patients to either an “aggressive” strategy (n = 249; maximum burr-to-artery ratio >0.7 alone, or with adjunctive inflation ≤1 atm of an oversized balloon) or a “routine” strategy (n = 248; maximum burr-to-artery ratio ≤0.70 and routine balloon inflation ≥4 atm). Final MLD was 1.97 mm for the routine strategy and 1.95 mm for the aggressive strategy, and clinical success was also equivalent. CK-MB elevations were greater in the patients receiving aggressive atherectomy, but MIs or other major complications were not significantly different. Emergency bypass surgery was needed in 2% of patients in the routine strategy and in none of the aggressive strategy patients.

At 6 months, 21.1% of the patients receiving routine atherectomy versus 23.5% of those receiving aggressive rotational atherectomy had target lesion revascularization. Angiographic follow-up showed MLD of 1.26 mm in the routine group versus 1.16 mm in the aggressive group. Excessive burr decelerations greater than 5000 rpm were significantly associated with restenosis (\(P = .01\)).

The Coronary Angioplasty and Rotablator Atherectomy Trial (CARAT)\(^{60}\) also compared a lesion-debulking strategy (burr-to-artery ratio >0.7) to achieve maximal debulking versus a lesion modification strategy, in which a burr-to-artery ratio ≤0.7 was used to modify lesion compliance. Among the 222 patients in the study, there were no differences in procedural success, the extent of immediate lumen enlargement, in-hospital ischemic complications, or late TVR. Patients randomized to the large-burr group, however, were more likely than the lesion modification group to experience serious angiographic complications (5.1% vs 12.7%; \(P < .01\)) immediately after atherectomy.

When aggressive atherectomy is combined with stenting, used electively or as a bailout for acute vessel closure, larger lumen diameters can be achieved while mitigating the impact of acute complications. Kobayashi et al\(^{49}\) retrospectively compared 126 patients who had undergone aggressive atherectomy with a burr-to-vessel ratio of ≥0.8 with 703 patients who had undergone routine atherectomy. There were more periprocedural MIs among patients with aggressive atherectomy but no other differences in clinical events. At follow-up, the MLD in the aggressive atherectomy group was significantly higher by 35% and late lumen loss significantly lower by 40%.\(^{49}\)
Although aggressive debulking can be harmful, stepwise burr selection and avoiding long passes and drops in rotation speed help to reduce the damage to the vessel wall and reduce the volume of microparticulate debris and platelet activation. Thus, even though aggressive atherectomy offers no advantage over more routine burr sizing for angioplasty, with careful technique and the use of stenting, more aggressive atherectomy can be performed. A burr-to-artery ratio <0.7 should generally be used to reduce acute periprocedural risks, but some situations may require more aggressive debulking to optimize stent delivery and maximal stent expansion.

**Atherectomy and Stenting**

Stenting can treat acute complications of atherectomy and improve long-term vessel patency. Early studies using bare metal stents showed only modest improvements over atherectomy with angioplasty (see Table 34-4). Moussa et al\(^6^1\) reported the earliest experience in using routine bare metal stents following atherectomy in 75 patients. Plaque modification was achieved using a burr-to-artery ration of 0.61 ± 0.12 and angioplasty prior to stenting. Stent implantation was successful in 93.4% of patients. Five patients had major complications, including a left main dissection, 2 acute vessel closures due to subintimal stenting, a vessel perforation, and acute stent thrombosis.

The frequency of these acute complications reported in studies over the past 20 years has not changed dramatically (see Fig. 34-6). More than 10 years after the study by Moussa et al,\(^6^1\) despite significant improvements in stent technology, other investigators reported similar rates of no reflow, abrupt closure, dissection, perforation, and periprocedural mortality in a retrospective study of 516 patients treated between 2003 and 2007. The long-term outcomes with bare metal stents were only modestly better than prior angioplasty studies, even in contemporary studies, demonstrating a similar long-term incidence of MACE to angioplasty studies, primarily due to the need for repeat revascularization. The TVR rates for atherectomy with bare metal stenting ranged from 12.3% to 38.2% (see Table 34-4).

DESs have improved the outcomes of patients undergoing atherectomy by reducing TVR. As a result, MACEs have also declined, even though mortality and MI rates have remained unchanged or are slightly higher. The long-term follow-up results of several observational studies are shown in Table 34-4. The later studies had longer lengths of follow-up, and several
studies primarily evaluated higher risk patients with significant calcification. The only randomized study comparing atherectomy to angioplasty in the era of routine use of DESs was the ROTAXUS trial (Rotational Atherectomy Prior to Taxus Stent Treatment for Complex Native Coronary Artery Disease).\(^\text{12}\)

Abdel-Wahal et al\(^\text{12}\) randomized 240 patients to a strategy of balloon angioplasty/stenting or primary atherectomy followed by angioplasty/stenting with paclitaxel-eluting stents. Patients had moderate to severe calcification, and most patients had American College of Cardiology (ACC)/American Heart Association (AHA) type B2/C lesions. Acute complications were the same between both groups, including dissections, perforations, no/slow flow, and periprocedural MI (Table 34-5). There was no difference in MACE, MI, TVR, or mortality at 9-month follow-up (Fig. 34-7). Immediate gain in lumen diameter was higher in the atherectomy arm, but at angiographic follow-up, the late lumen loss was higher, making any gains in lumen size negligible.

**FIGURE 34-7** Nine-month follow-up from the ROTAXUS study comparing a strategy of rotational atherectomy (RA) with paclitaxel-eluting stent (PES) placement versus standard therapy with angioplasty and stenting. Cumulative incidence curves for
death (A), myocardial infarction (B), target vessel revascularization (C), and major adverse cardiac events (D) in the RA + PES and standard therapy groups. Abbreviations: CABG, coronary artery bypass graft; MACE, major adverse cardiac events; PCI, percutaneous coronary intervention.

Strategy success was significantly higher in the rotablation arm of the study (92.5% vs 83.3%; P = .03), with a 12.5% crossover rate from the routine angioplasty group to the rotablation arm (P = .02). Notably, stent loss was observed in 2.5% of patients receiving routine angioplasty group and in no patients receiving an atherectomy-first strategy.

Although these complications did not impact overall MACE rates, switching strategies adds time to the procedure, and stent loss can be a
potentially major surgical emergency. Planned atherectomy was shown to improve procedure efficiency and reduce contrast and x-ray exposure in the ROTATE registry of 667 patients from 8 centers who underwent rotational atherectomy and stenting for calcific coronary artery disease (see Table 34-3). Patients who underwent planned atherectomy were compared to those with ad hoc atherectomy. The planned atherectomy patients were more likely to have insulin-dependent diabetes (16.2% vs 10.7%; \( P = .04 \)), peripheral vascular disease (24.0% vs 16.8%; \( P = .02 \)), and renal insufficiency (33.2% vs 15.9%; \( P < .01 \)). The majority of patients had ACC/AHA type B2/C lesions. There were more patients with unprotected left main (12.0% vs 4.3%; \( P < .01 \)) and bifurcation lesions but fewer chronic total occlusions (CTOs) (5.3% vs 9.5%; \( P = .03 \)) among the planned atherectomy group. Despite these baseline differences, the hospital and 1-year MACE, mortality, MI, stroke, and TVR rates were the same.

In patients undergoing provisional rotational atherectomy, delivery device failure occurred in 73.1% of patients and balloon expansion failure occurred in 26.9%. Among patients with failed balloon expansion, adverse hospital outcomes were double those in patients with delivery device failure (in-hospital MACE: 7.1% vs 16.9%; \( P = .01 \); and MI: 6.2% vs 14.5%; \( P = .02 \)). In the propensity analysis, adjusting for baseline differences that may have contributed to selection bias, there was a trend toward increased periprocedural MACE for ad hoc atherectomy (odds ratio, 0.59; 95% confidence interval [CI], 0.33-1.05; \( P = .07 \)).

Patients with nondilatable lesions who undergo high-pressure balloon inflation may be more likely to have overt dissections or microdissections that may increase the risk for adverse complications during subsequent atherectomy. In this regard, there may be some benefit to a planned atherectomy approach upfront or a staged approach to allow for vessel healing after failed angioplasty.

**Orbital Atherectomy**

The FDA approved Cardiovascular Systems Incorporated’s Diamondback 360 orbital atherectomy device in 2013 for use in calcified coronary lesions based on data from the ORBIT I and ORBIT II studies. The device is available for peripheral arterial interventions and consists of an eccentrically mounted, diamond-coated burr that orbits over an atherectomy guide wire at
speeds of 80,000 to 130,000 rpm using an electrical drive (Fig. 34-8). The current device lacks burring elements on the polished stainless steel tip, but achieves atherectomy as the crown’s orbital diameter expands radially by centrifugal force, achieving channels 1.25 to 1.75 times greater than the crown size, depending on the number of revolutions per minute chosen and the speed of advancement (ie, higher revolutions per minute and slower advancement theoretically allow for larger lumen diameters). The device only requires a 6-Fr guide, so a larger radius of atherectomy can be achieved without changing burrs or guides.

**FIGURE 34-8** Cardiovascular Systems Incorporated’s Diamondback 360 orbital atherectomy device. (Reproduced with permission from Cardiovascular Systems, Inc., Saint Paul, MN.)

The ORBIT II study was a nonrandomized, single-arm, multicenter study
of 443 patients designed to show noninferiority to historical performance goals based on prior atherectomy studies in patients with calcified coronary lesions. All patients had fluoroscopic or IVUS evidence for severe calcification of a significant coronary lesion, with 74.1% of patients having ACC/AHA type B2/C lesions. Successful stent delivery was achieved in 97.7% of patients, and the rates of acute complications were similar to prior studies (see Fig. 34-6). The overall in-hospital MACE, MI, death, and TVR rates were 9.8%, 9.3%, 0.5%, and 0.7%, respectively. The outcomes at 12 months are in line with previously published studies of atherectomy in patients with severe calcification (see Table 34-4). Stent type was a strong predictor for TVR, as only 4.7% of patients receiving DESs required revascularization at 1 year, compared to 15.1% of patients receiving bare metal stents. At 2 years, the rates of MACE, MI, mortality, and TVR were 19.4%, 9.7%, 7.5%, and 8.1%, respectively. The 3-year follow-up has only been reported in abstract form at the time of writing.

Orbital atherectomy has been used in over 50,000 patients for peripheral arterial disease and, based on the ORBIT study, has been shown to have low periprocedural and long-term complication rates, consistent with contemporary studies of rotational atherectomy. The greater debulking that can be achieved with a single atherectomy crown passed through a 6-Fr guide allows for procedural efficiency and more interventions using radial access. Theoretically, the circumferential atherectomy may help overcome guide wire bias and differential atherectomy associated with the Rotablator. Nevertheless, it remains to be seen what specific advantages or disadvantages orbital atherectomy may have in general use.

**Excimer Laser Atherectomy**

Excimer laser atherectomy uses 308-nm ultraviolet light delivered through a fiberoptic catheter to deliver both photochemical and thermal energy to debulk atherosclerotic lesions. It is approved by the FDA for use in long and moderately calcified coronary atherosclerotic lesions, CTOs, saphenous vein grafts, balloon resistant lesions, and in-stent restenosis. It has been shown to have comparable results to rotational atherectomy in the ERBAC study. Although its use in native coronary artery disease had declined given early problems with coronary dissections and perforations, it is still used with some regularity for in-stent restenosis, balloon/device noncrossable lesions, and
Directional coronary atherectomy is rarely used for coronary interventions, and most devices are no longer available in the US market. The randomized studies comparing directional atherectomy to angioplasty showed increased lumen gain, but no differences in clinical outcomes or reductions in lesion revascularization, and coronary perforation rates of approximately 1%.\textsuperscript{10}

**ATHERECTOMY FOR SPECIFIC SITUATIONS**

Although the most common use of atherectomy is aimed at plaque modification of calcified coronary arteries to facilitate stent delivery and expansion, there are several less common indications where atherectomy remains uniquely useful. Niche applications for atherectomy include ostial lesions, bifurcations, in-stent restenosis, and CTOs.

**Ostial Lesions**

Ostial lesions are associated with a high incidence of recoil, and delivering a stent perfectly can be challenging, which contribute to the increased restenosis rates associated with these lesions.\textsuperscript{64} Reducing ostial calcium and fibrosis reduces slippage of the balloon or stent during deployment and facilitates more precise landing of stents.

In a small series of 63 patients, rotational atherectomy was used with angioplasty to achieve immediate angiographic success in 92\% of patients, but at 6 months, 43\% of patients had significant restenosis. A retrospective comparison of non–aorto-ostial lesions among 44 patients who underwent debulking prior to angioplasty and bare metal stenting versus 42 patients who underwent angioplasty and stenting alone demonstrated that atherectomy achieved larger lumen diameters (2.30 ± 0.91 mm vs 1.86 ± 0.80 mm; \( P = .03 \)) and a lower cumulative restenosis rate (39.5\% vs 59.5\%; \( P = .04 \)) at 6 months.\textsuperscript{65}
Despite the immediate benefits of reducing lesion recoil and plaque shift and optimizing stent delivery using atherectomy, the longer term restenosis rates remain high. Nevertheless, because treatment options for patients with significant ostial disease remain limited, atherectomy will continue to be a useful interventional tool for this patient subset.

**Bifurcation Lesions**

Bifurcation lesions pose a unique challenge because true Medina 1,1,1 lesions can lead to loss of side branches and have a high restenosis rate. Although dedicated stent strategies can achieve improved immediate results, they have been associated with higher restenosis. Atherectomy can facilitate stent delivery and full stent expansion to highly calcified and angulated bifurcations.

Atherectomy itself, however, can potentially cause plaque shift. Walton et al\(^6\) evaluated 418 patients with 320 side branches who underwent rotational atherectomy and reported a side branch occlusion rate of 7.5%. Side branch diameter of <2.0 mm and ostial narrowing ≥50% were associated with compromised flow. Among patients with side branch loss, 29% experienced MI.

Compared to routine angioplasty, however, the incidence of these complications may be reduced with atherectomy. Dauerman et al\(^6\) evaluated patients undergoing PCI of true bifurcation lesions involving both the main and side branches and compared patients who underwent atherectomy versus angioplasty alone. They reported more transient side branch occlusions but overall higher procedural success with atherectomy (97.5% vs 73.3%; \(P = .01\)), lower residual stenosis, and no differences in MI. At 12-month follow-up, MACE rates were 30% in the atherectomy group and 56% in the angioplasty group (\(P = .05\)), and TVR was nearly halved by atherectomy (27.5% vs 53.3%; \(P = .05\)).

One strategy to help maintain patency during main branch atherectomy or stenting is to debulk the side branch. In a retrospective study of 40 patients with bifurcation lesions who underwent stenting of a main branch with side branch rotational atherectomy,\(^2\) no acute side branch closures or perforations were observed, and 80% of side branches did not require stents. At mean follow-up of 21.3 months, mortality was 2.5%, MI was 2.5%, and TVR was 5%.
The routine use of DESs can improve the outcomes of bifurcation PCI. In a study of 337 patients who underwent atherectomy for bifurcation disease reported by Dai et al, significant reductions in TVR rates (5.0% vs 15.7%; \( P < .01 \)) and MACE rates (12.0% vs 20.2%; \( P = .04 \)) were observed among patients receiving DESs compared to those with bare metal stents or angioplasty alone at a mean follow-up of 52.2 months. The very low restenosis rates speak to the efficacy of DESs, but also affirm the safety of an atherectomy strategy that allows adequate stent delivery.

**In-Stent Restenosis**

Although DESs have reduced rates of in-stent restenosis (ISR), even in the best case scenario, ISR occurs in 2% to 4% of patients within the first year, and ISR that occurs much later is more likely to represent calcified and fibrotic neoatherosclerosis that may be resistant to high-pressure balloon angioplasty and require atherectomy.\(^{68,69}\) The early use of rotational atherectomy to treat ISR developed in an era prior to the availability of DESs, and so the ISR at that time most likely represented softer neointimal hyperplasia that yields easily to balloon angioplasty. The BARASTER (Balloon Angioplasty Versus Rotational Atherectomy for Intra-Stent Restenosis) multicenter registry demonstrated lower MACE and TVR rates among patients receiving atherectomy and angioplasty compared to angioplasty alone.\(^{70}\) The ROSTER study (Rotational Atherectomy Versus Balloon Angioplasty for Diffuse In-Stent Restenosis) showed improved acute lumen gain and lower revascularization compared to angioplasty (32% vs 45%; \( P = .04 \)).\(^{71}\) In contrast, the ARTIST study (European Angioplasty Versus Rotational Atherectomy for Treatment of Diffuse In-Stent Restenosis Trial)\(^{72}\) demonstrated worse outcomes with atherectomy.

Laser atherectomy has been shown to be superior to angioplasty in debulking restenotic tissue for increasing lumen diameter and stent expansion\(^{73}\) and may also prove useful for treating balloon-resistant ISR and improving long-term outcomes. In the EXCITE ISR (Excimer Laser Randomized Controlled Study for Treatment of Femoropopliteal In-Stent Restenosis) trial, angioplasty with adjunctive excimer laser atherectomy was compared to angioplasty alone for femoral nitinol stents.\(^{74}\) Adjunctive
Atherectomy was associated with a higher procedural success rate (93.5% vs 82.7%; \( P = .01 \)) with fewer complications, higher 6-month freedom from target lesion revascularization rate (73.5% vs 51.8%; \( P < .01 \)), and lower 30-day major adverse event rate (5.8% vs 20.5%; \( P < .01 \)).

Routine use of atherectomy for ISR is not common; however, the increasing presentation of neoatherosclerotic lesions may make this necessary in certain circumstances (Fig. 34-9) where it can prove to be highly effective.

**Underexpanded Stents**

Rotational atherectomy can be used for ablation of metal stents in situations
where highly calcified lesions have not been not properly treated and the deployed stent cannot be expanded further. This is particularly useful when multiple layers of stents have already been placed in an unexpanded lesion, as shown in the example of stepwise burr sizing and stent ablation in Figure 34-10. This should be performed with extreme caution given the risk for embolization of large metal fragments\textsuperscript{75} or burr entrapment in the metal stent.
FIGURE 34-10 Ablation of stents using rotational atherectomy in a patient with 4 layers of stents in a nondilatable lesion. A. Angiogram showing narrowed, subtotally occluded stent. B. After percutaneous coronary intervention (PCI): Angiogram showing expanded stent and improved flow. C. Narrowed segment of 4 unexpanded stents (3.9 mm², 1.8 × 2.5 mm). D. After PCI: Minimally changed narrowed segment of stent (cross-sectional area, 5.7 mm²; 1.9 × 3.4 mm). E. Four stent layers with tissue between each stent. F. After PCI: Multiple stent layers with reduced tissue between each stent. PCI involved stent ablation with rotational atherectomy using 1.5-, 1.75-, and 2.0-mm burrs, followed by laser atherectomy with contrast injections, high-pressure ballooning, drug-coated balloon deployment, and brachytherapy.
Laser atherectomy also has utility in treating underexpanded or nondilatable stents, where heat energy from the laser “bubble” can be used to modify tissue outside the stent struts, allowing balloon dilation of the lesion. The ELLEMENT registry (Excimer Laser Lesion Modification to Expand Nondilatable Stents) described 28 patients with underexpanded stents despite high-pressure balloon inflations who underwent laser-assisted stent dilatation. This technique was successful in 27 cases with an improvement in minimal stent diameter (from 1.6 ± 0.6 mm at baseline to 2.6 ± 0.6 mm after procedure) and stent area by IVUS (3.5 ± 1.1 mm² to 7.1 ± 1.9 mm²).

**Chronic Total Occlusions**

The presence of significant calcium is a major predictor of failure to open a CTO. CTOs are often highly calcified with flush occlusions that can be “balloon-uncrossable,” despite successful guide wire crossing. One example is shown in Figure 34-11. In this case, after crossing the calcified lesion into the true lumen distally, no balloon or microcatheter could be passed. A small balloon was ruptured in the proximal cap, but no gear could be passed distally. A 0.9-mm excimer laser catheter was used to perform atherectomy with contrast, which softened the proximal cap sufficiently to allow passage of a microcatheter tip just beyond the CTO, although no further. The coronary wire was exchanged for a Floppy RotaWire, and rotational atherectomy was performed using 1.25- and 1.5-mm burrs, which then allowed angioplasty and stenting.
FIGURE 34-11 Severely calcified chronic total occlusion requiring atherectomy. A. Severely calcified, chronically occluded circumflex. B. Wire is across lesion, but balloons and microcatheters could not cross, so a 0.9-mm excimer laser was used to perform atherectomy. C. A microcatheter was then advanced across the lesion, and rotational atherectomy was performed followed by angioplasty and stenting. D. Final angiogram.

The BAROCCO (Balloon Angioplasty Versus Rotational Angioplasty in Chronic Coronary Occlusions) study showed that in chronic coronary occlusions with stump-like occlusions, the primary success rate is higher with
the rotational atherectomy technique.\textsuperscript{79} The multicenter DOCTORS study evaluated 266 patients with CTOs deemed appropriate for atherectomy who were randomized to an angioplasty or atherectomy strategy (either rotational or directional) prior to stenting.\textsuperscript{80} There was more periprocedural MIs in the atherectomy group, but a trend toward lower TVR (23.8\% vs 34.6\%; \textit{P} = .07) at 6-month follow-up and lower MACE at 12-month follow-up (27.5\% vs 39.8\%; \textit{P} = .033). Periprocedural MI is typically higher in patients with CTOs undergoing atherectomy, but other acute complications appear to be similar to standard angioplasty in such patients.\textsuperscript{80,81}

CTOs are often fibrotic and calcified, making them resistant to wire crossing, stent delivery, and deployment. Once a coronary guide wire is positioned properly across a severely calcified CTO, atherectomy is frequently required, especially if the wire traverses the calcified “true” lumen, instead of a subintimal track that may bypass the calcium. In these cases, laser and rotational atherectomy can be key components in the CTO toolbox.

**Saphenous Vein Grafts**

The use of rotational atherectomy in saphenous vein grafts is contraindicated for the Rotablator, given concerns about embolization of soft, thrombotic debris. There are situations, however, when the lesion in a graft is highly fibrotic or calcified and resistant to balloon dilation. In such situations, rotational atherectomy has been used successfully without apparent embolization of significant debris (Fig. 34-12).\textsuperscript{82}

CONCLUSION

The clinical application of rotational atherectomy has evolved considerably, from being used as a primary debulking device to being used more adjuntively for plaque modification to facilitate stent delivery and optimize stent expansion. Yet as bioresorbable scaffolds are increasingly used, more aggressive vessel preparation and debulking may once again be obligatory to improve vessel compliance to allow complete scaffold expansion, giving atherectomy an even greater role as this technology is adopted. Furthermore, there are specific situations that will require atherectomy, such as dense fibrotic/calcific ISR, calcific complex lesions, and CTOs.

Atherectomy can be performed safely with optimal burr selection and proper ablation techniques, and as a result, complication rates have been significantly minimized, with few changes in the acute complications reported in contemporary studies. Although atherectomy devices have not changed dramatically over the past 25 years, the increasing prevalence of significant calcific and complex coronary artery disease has ensured that
these devices remain relevant to the contemporary practice of interventional cardiology.

**MULTIPLE CHOICE QUESTIONS**
1. Which of the following rotational atherectomy techniques is associated with increased microparticulate debris and platelet aggregation?
   A. Using a burr-to-artery ratio <0.7
   B. Allowing decelerations of the burr >5,000 rpm
   C. Limiting atherectomy speeds to 140,000 to 160,000 rpm
   D. Limiting atherectomy runs to less than 30 seconds
   E. Using a back-and-forth pecking motion instead of continuous lesion engagement

2. Which of the following is not a complication associated with rotational atherectomy?
   A. Abrupt vessel closure and no reflow
   B. Coronary dissections and perforations
   C. Transient heart block
   D. Increased mortality
   E. Asymmetric atherectomy and formation of deep eccentric fissures and aneurysms

3. The ROTATE multicenter registry retrospectively compared patients undergoing percutaneous coronary intervention (PCI) who had planned atherectomy versus those who required ad hoc atherectomy. Which of the following was not associated with planned atherectomy?
   A. A 35% reduction in fluoroscopy time
   B. Reduction in average contrast use by 70 mL
   C. A slight increase in total procedure time
   D. No differences in major adverse cardiac events (MACE), death, myocardial infarction (MI), and stroke, but an increase in target vessel revascularization (TVR) at 1 year
   E. A significant reduction in in-hospital myocardial infarctions and MACE compared to patients who underwent rotational atherectomy after balloon expansion failure

4. The ROTAXUS study randomized patients with calcific coronary artery disease to a strategy of planned rotational atherectomy followed by angioplasty and stenting or to a strategy of angioplasty and stenting. The findings of this study include all of the following except:
   A. 2.5% of patients in the standard therapy group experienced stent loss,
whereas no patients in the atherectomy group experienced this complication.

B. Among patients with planned atherectomy, there was a larger increase in lumen diameter but greater late lumen loss compared to the standard therapy group.

C. No differences in mortality, MI, TVR, or MACE were seen between the 2 strategies at short- and long-term follow-up.

D. Strategy success was higher for the atherectomy group.

E. Coronary dissections, tamponade, and no/slow flow were more commonly associated with rotational atherectomy.

5. Which of the following statements about atherectomy is false?

A. Using atherectomy to achieve maximal debulking has been shown to be a superior strategy to plaque modification.

B. Differential cutting allows rotational and orbital atherectomy burrs to selectively ablate inelastic tissue while sparing elastic tissue.

C. Slower advancement of the orbital atherectomy burr achieves a larger area of atherectomy.

D. Orbital atherectomy achieves debulking by applying centrifugal force on the vessel wall.

E. Heat energy from laser atherectomy can be used to treat calcific and fibrotic tissue outside of underexpanded stents.

ANSWERS

1. B

Most clinical studies have reported no reflow and abrupt vessel closure rates associated with rotational atherectomy of approximately 1%. Larger burrs, a burr-to-artery ratio of 0.7 to 0.8, atherectomy speeds >160,000 rpm, and long continuous atherectomy runs have been shown to increase platelet aggregation. An increase in acute angiographic complications has been associated with larger burr sizes, but without an impact on clinical outcomes. Thermal injury can also be caused by long runs of continuous engagement of the coronary lesion with the atherectomy burr or by decelerations >5000 rpm, which indicate more friction and force being applied to the vessel wall.
Thermal injury can lead to red blood cell aggregation and platelet activation and has been associated with increased restenosis. Therefore, it is recommended that a back-and-forth pecking motion be used, instead of forceful advancement of the burr.

2. D

In the major clinical trials comparing a strategy using rotational atherectomy versus a strategy using routine therapy, there have been no differences in short- or long-term mortality. Abrupt vessel closure and no reflow occur about 1% of the time during atherectomy. Treatment with prophylactic vasodilators such as nitroprusside, adenosine, and verapamil has been shown to reduce the incidence of this complication. Coronary dissections and perforations were seen in 3.3% and 1.7% of patients, respectively, in the ROTAXUS study and 3.4% and 1.8% of patients, respectively, in the ORBIT II study. Transient heart block can be seen, particularly with interventions on the right coronary artery or dominant left circumflex. Smaller burr sizes and shorter runs significantly diminish the occurrence of these events such that many operators do not prophylactically place temporary pacemakers. When atherectomy is performed, however, a transvenous pacer and appropriate pharmacologic agents should be readily available. Wire bias in an angulated and eccentric lesion can lead to preferential atherectomy of the inner or outer curve of the lesion, which may dispose to fissures and aneurysms.

3. C

Planned atherectomy had lower fluoroscopy time, lower contrast use, and shorter procedure times than procedures in which atherectomy was used ad hoc for failure to deliver stents/devices or for balloon expansion failure. Patients with failed balloon expansion had worse outcomes compared with those who had atherectomy for device delivery failure (in-hospital MACE: 16.9% vs 7.1%; \( P = .01 \); in-hospital MI: 14.5% vs 6.2%; \( P = .02 \)). In-hospital MACE, MI, mortality, stroke, and TVR were equivalent between the planned and ad hoc atherectomy groups. At 1-year follow-up, the adjusted outcomes were similar with the exception of TVR, which was higher for the planned atherectomy group (odds ratio, 1.73; 95% confidence interval [CI], 1.04-2.89; \( P = .04 \)).

4. E
Coronary dissections and tamponade were the same between the 2 groups, and no/slow flow was actually higher in the standard therapy arm. There were no differences in clinical outcomes between the 2 randomized arms of the ROTAXUS study, but there were significant procedural differences noted. In the standard therapy group, stent loss was reported in 2.5% of cases, whereas no stent loss was observed among patients randomized to the atherectomy strategy. A total of 12.5% of patients in the standard therapy arm crossed over to atherectomy, and strategy success was inferior in this group (83.3% vs 92.5% for atherectomy; \( P = .03 \)). Periprocedural outcomes were similar between the standard therapy and atherectomy groups (dissection, 3.3% vs 3.3%; no/slow flow, 0.8% vs 0%; heart block, 0% vs 0.8%; perforations, 0.8% vs 1.7%; tamponade, 0.8% vs 0.8%; \( P = \) not significant for all comparisons). Acute luminal gain was larger for the atherectomy patients (1.56 ± 0.43 vs 1.44 ± 0.49 mm; \( P = .01 \)), but late lumen loss was greater at 9 months (0.44 ± 0.58 vs 0.31 ± 0.52 mm; \( P = .04 \)). At 2 years, MACE occurred in 29.4% of the atherectomy patients versus 34.3% of the angioplasty patients (\( P = .47 \)). Target lesion revascularization (TLR) was 13.8% versus 16.7% (\( P = .58 \)) and TVR was 19.3% versus 22.2% (\( P = .62 \)) for the atherectomy versus angioplasty strategies, respectively.

5. A

Aggressive atherectomy for debulking has not been shown to be equivalent to a less aggressive plaque modification strategy. The CARAT and STRATAS studies compared aggressive atherectomy using burr-to-artery ratios >0.7 with less aggressive atherectomy using burr-to-artery ratios <0.7. Aggressive atherectomy is associated with more complications without any improvement in clinical outcomes or minimal lumen diameter. Differential cutting is the ability to selectively ablate one material while preserving the integrity of the other, based on differences in the composition and texture of the substrate. The elasticity of the normal tissue deflects the ablative surface, whereas the inelastic properties of diseased tissue engages the cutting surface. The orbital atherectomy crown’s orbital diameter expands radially by centrifugal force, achieving channels 1.25 to 1.75 times greater than the crown size, depending on the rpm chosen and the speed of advancement (ie, higher rpm and slower advancement theoretically allow for larger lumen diameters). The ELLEMENT registry described expansion of underexpanded stents in balloon nondilatable lesions using laser-assisted stent dilatation.
Percutaneous Coronary Intervention in Chronic Total Occlusion

James M. McCabe
William L. Lombardi

A coronary artery chronic total occlusion (CTO) is defined as an occlusion present for 3 or more months, which will feature classic histopathologic changes (Fig. 35-1). Although considered separately in this book, the treatment decisions for coronary revascularization should focus on coronary physiology and ischemia rather than specific anatomic considerations. To that end, the indications for treatment of CTOs should be indistinguishable from 95% coronary lesions. However, once the decision to treat a CTO percutaneously is chosen, the technical aspects of this treatment diverge significantly from standard coronary intervention. For many interventionalists, CTOs continue to represent a major technical challenge.
FIGURE 35-1 Histopathology of preservation of vessel architecture, including a multilayered structure in which the intima and neointima (including atherosclerotic plaque) is distinguishable from the muscularis and adventitia and, importantly, in which the external elastic lamina remains intact. This preservation of gross architecture is the pathologic feature that most enables percutaneous recanalization.

Percutaneous coronary intervention (PCI) is invariably predicated upon a steerable guide wire spanning the target lesion and acting as a rail over which devices can be delivered. Typically, this wire is tracked in the vessel lumen using angiography as a guide. In the absence of a visible lumen during angiography, tracking the coronary vessel and ensuring an intraluminal position can be difficult. Thus, the primary challenge of CTO PCI lies in initially traversing the target lesion with a guide wire. In recent years, important strategic and technical advancements have been made that facilitate overcoming this essential challenge in a reproducible fashion.\(^1\) Most major PCI programs now have, or are planning for, specialized competence in contemporary CTO procedures. An understanding of the field has become
essential knowledge for all interventionalists and arguably for any cardiologist who advises patients regarding revascularization options. The goal of this chapter is to describe the technical and strategic considerations necessary to understand CTO PCI.

Angiography for CTO PCI should emphasize simultaneous dual injections to visualize the antegrade and retrograde coronary flow, thus defining the extent of the lesion. Access choice is up to the operator’s discretion recognizing that 2 arterial access points are typically required. Frequently, at least 1 of the access points is 8 Fr to facilitate specific techniques described below. The relative merits of potentially larger sheath/guide sizes via femoral access can be weighed against the reduction in vascular complications and improved patient comfort when radial access is used. When femoral access is chosen, long (45-cm) sheaths can overcome iliac tortuosity and increase guide catheter support. Guiding catheter size is usually limited to 6-Fr from the radial approach, although sheathless 7-Fr systems are increasingly common. Good passive support with coaxial alignment is crucial, especially in complex CTO procedures. Although the choice of the guiding catheter shape is generally dictated by personal experience, it is important for operators to seek a guide with optimal support at the onset of the procedure rather than accepting one with merely satisfactory support. The radial operator should be familiar with active guide manipulation to augment “pushability,” and all operators should be versed in balloon anchoring and mother-and-child techniques to improve support when needed.

Even if the distal vessel bed is opacified by ipsilateral collaterals, this opacification can be limited following wire or catheter advancement, resulting in preferential collateral shift to contralateral collaterals during the procedure. Therefore, to achieve the best diagnostic angiography (ie, to fill the entire collateral bed), contralateral injection should be performed at the start of the procedure if any visible contralateral collaterals are present. Operators from the EuroCTO Club have used contralateral injection in 62% of their cases, whereas dual injection was used in 78% of cases in a more recent North American series. Dual-injection collateral analysis is performed best using low magnification, so that the entire coronary tree is visualized without panning. Careful study of the collaterals not only provides important information in choosing the most appropriate collateral, but will also alert the operator to the risk of ischemia and hemodynamic or electrical instability if the wired collateral becomes occluded. Three typical collateral pathways are
demonstrated in Figures 35-2, 35-3, and 35-4. A careful and detailed review of the angiogram is critical for creating primary and alternative CTO treatment strategies to optimize the efficacy, efficiency, and safety of the procedure.

**FIGURE 35-2** Typical fine, moderately tortuous transseptal collateral connecting the left anterior descending artery (LAD) to the right posterior descending artery. Transseptals are the most commonly employed collaterals for retrograde chronic total occlusion techniques and can serve to access an occluded dominant right coronary artery or dominant left circumflex artery from the LAD, or in the opposite direction, to access an occluded LAD from a dominant right or left circumflex. Another transseptal is visible arising from the distal LAD. Because transseptal collaterals are generally contained within septal myocardium, their rupture rarely poses a hazard with respect to tamponade.
FIGURE 35-3 A large, dominant, and tortuous transapical epicardial collateral supplies the right posterior descending artery from the distal left anterior descending artery. This collateral is likely to become kinked and thus occlude when instrumented with a guide wire or microcatheter, resulting in loss of visualization of the distal target and the potential for ischemia. Collaterals of this configuration are rarely helpful as conduits for retrograde access.
Anticoagulation during CTO PCI is best achieved with unfractionated heparin (UFH) because it allows for titration of the anticoagulant effect. The desired activated clotting time (ACT) recommended by many operators during retrograde CTO PCI to minimize the risk of donor vessel (ie, the vessel that provides the collateral) and guide thrombosis is >350 seconds, as opposed to the more routine 250 seconds used in typical PCI. Bivalirudin requires ongoing coronary circulation and exposure to blood to maintain its pharmacotherapeutic effect and therefore has the potential for higher guide catheter thrombosis rates in CTO PCI. As with all PCI, preloading with a P2Y$_{12}$ adenosine diphosphate (ADP) receptor inhibitor and aspirin is important to reduce the risk of acute stent thrombosis and periprocedural myocardial infarction.
PREDICTION OF CHRONIC TOTAL OCCLUSION CROSSING DIFFICULTY

Predicting the difficulty of CTO crossing with a guide wire is important for case selection and procedural planning. The Multicenter CTO Registry of Japan (J-CTO) score is determined by assigning 1 point to each of the following 5 variables: (1) previously failed lesion, (2) blunt type of entry, (3) calcification, (4) bending, and (5) occlusion length. Patients are classified into 4 difficulty groups: easy (J-CTO score of 0), intermediate (a score of 1), difficult (a score of 2), and very difficult (a score of 3 or higher). The J-CTO score correlated well with the probability of successful guide wire crossing within 30 minutes (87.7%, 67.1%, 42.4%, and 10.0%, respectively)\(^8\) and was recently validated in an independent single-center Canadian cohort.\(^9\) Recent reports using a hybrid-based CTO algorithm have shown that the J-CTO score predicts an increasing need for retrograde procedures to achieve success (Fig. 35-5). More recently, the Prospective Global Registry for the Study of Chronic Total Occlusion (PROGRESS CTO) score has been developed to predict procedural success using hybrid methodologies.\(^10\)
The hybrid approach to chronic total occlusion (CTO) percutaneous coronary intervention (PCI) uses sentinel features of the coronary anatomy to guide the initial approach to CTO recanalization. Antegrade approaches are favored by a clearly identified nonostial occlusion inlet (proximal cap), a large and well-visualized target segment beyond the distal cap, the absence of severe calcification or tortuosity, and the absence of an important side branch adjacent to the distal cap that might be excluded during dilation and stenting of a subintimal tract. Retrograde approaches are favored when suitable collaterals or bypass grafts exist through which delivery of PCI equipment to the distal cap appears feasible and when the anatomy does not favor an antegrade approach. An important feature of hybrid CTO procedures is the predisposition to timely changes of strategy when progress toward the goal of recanalization stalls.

**SPECIFIC APPROACHES AND TECHNIQUES**
Antegrade Guide Wire Approach

Antegrade guide wire–based recanalization of CTOs has been and remains the most common approach worldwide.\textsuperscript{11-13} In general, an over-the-wire catheter is delivered to the proximal cap on a workhorse wire, and then CTO-specific wires and wire tip shapes are applied. The approach of gradually escalating wire stiffness to achieve crossing has been generally abandoned in favor of an antegrade wire modification strategy that employs 3 or 4 wires chosen so that each performs a specific and different function based on their different characteristics. Historically, operators have started with tapered soft polymer jacketed wires when attempting antegrade wire crossing of CTOs. Recent data have shown that this wire type has a very low initial success rate. As such, most high-volume CTO programs would typically start with a stiffer polymer jacketed wire or a Gaia second wire with a rapid escalation to a tapered stiff wire. Modern wire modification strategies, also referred to as step-up/step-down techniques, start as described earlier, but then may step up to stiff, spring-coil tapered wires to overcome any hard, calcified, or fibrotic segments of the occlusion. Such a step up should then be matched by a step down to a soft, polymer/hydrophilic wire once the microcatheter is delivered into the calcified cap so that one does not exit the vessel but instead continues tracking along the occluded segment.\textsuperscript{7} Due to a rapidly expanding range of CTO guide wires, it is incumbent on the CTO specialist to have an organized approach to wire choice that keeps pace with evolving global experience and new guide wire designs.\textsuperscript{14}

Balloons or catheters should never be advanced over a wire unless it is certain that the wire is in the architecture of the vessel (within the boundary of the external elastic lamina). Wire perforations that occur within the occluded segment are usually benign but can become catastrophic if larger equipment is advanced outside the vessel, thereby enlarging the breach. Moreover, once the distal true lumen is accessed, the CTO crossing wires should be exchanged for workhorse wires to avoid distal plaque disruption/dissection and, in particular, to prevent inadvertent distal perforation of small vessels and delayed tamponade.\textsuperscript{15}

Antegrade Dissection/Reentry

The primary mode of failure when recanalizing a chronically occluded vessel
is failure of the wire to enter the distal true lumen. Frequently, the wire may instead reside within plaque or the subintimal plane downstream from the occluded segment. Reentering the true lumen from this position with standard wire techniques can be extremely challenging. However this problem has been greatly simplified with the development of dedicated reentry technologies designed to overcome the challenges a subintimal position. The CrossBoss catheter, Stingray balloon, and Stingray reentry guidewire (Boston Scientific, Natick, MA) address this limitation and provide a much more reproducible and systematic method for successfully gaining reentry into the distal coronary lumen. The CrossBoss catheter is a metal-braided, over-the-wire support catheter with a 1-mm rounded distal tip that can be used to support standard guide wire manipulation or can be advanced using rapid rotation, with or without the wire lead (Fig. 35-6). Without the wire lead, this catheter can cross from a subintimal position into the distal true lumen in approximately 30% of lesions. But most frequently, when advancing this catheter without a leading wire, it will continue within the subintimal space, creating a controlled subintimal dissection plane. Alternatively, it can enter into a side branch, which is important to recognize to avoid perforation. If the CrossBoss catheter reaches the vessel distal to the chronic occlusion in a subintimal position, or if a standard wire strategy leads to subintimal or sublesional position beyond the occlusion, coronary reentry can be systematically achieved with the Stingray coronary reentry technologies. The Stingray balloon is a 1-mm thick, over-the-wire balloon catheter with 3 exit ports (1 distal port and 2 180° diametrically opposed side ports). When the balloon is inflated, it effectively wraps the artery with 1 of the 2 exit ports, necessarily directed toward the adventitia with the other port directed toward the lumen. Using fluoroscopy and collateral angiography, operators can select the luminal-facing port with the dedicated Stingray reentry wire to create a pathway from the subintimal position to the distal true lumen (Fig. 35-7). Occasionally, a subintimal position can cause hematoma of the tissue plane, which, when it extends downstream, can compress the distal vessel true lumen. Decompression of this subintimal hematoma can be performed with aspiration of this tissue plane through the equipment residing there. The Stingray balloon or other microcatheters within that tissue plane can be used for this purpose with a subintimal transcatheter withdrawal (STRAW) technique. In general, the antegrade dissection/reentry technologies have been highly successful at crossing chronically occluded segments and regaining
access to the distal vessel true lumen with low complication rates, even in early experiences and refractory cases.\textsuperscript{16,17}

**FIGURE 35-6** The CrossBoss Catheter shown here is used to make a controlled dissection at the point of the planned reentry with the Stingray balloon. This catheter uses blunt dissection to avoid perforation and ensures a small channel to prevent hematoma and compression of the reentry zone. (Image provided courtesy of Boston Scientific. Copyright © 2017 Boston Scientific Corporation or its affiliates. All rights reserved.)
The BridgePoint (Boston Scientific) dedicated antegrade dissection and reentry system. After establishing an antegrade subintimal tract using a CrossBoss (A) or other low-profile catheter or small angioplasty balloon, the Stingray balloon (B) is delivered and inflated in a position adjacent to the preferred segment for reentry. The flat profile of the Stingray balloon leads to its self-orientation circumferentially within the arterial wall such that 1 of the exit ports inevitably faces the arterial lumen. This port can then be selected using the dedicated steerable Stingray guide wire designed to facilitate puncture back into the lumen.

The Retrograde Approach

In 2005, Katoh and colleagues pioneered the modern era of retrograde CTO recanalization by introducing new techniques such as targeted septal or epicardial collateral crossing, retrograde lesion crossing, and management of the subintimal space through the use of balloon dilation for connecting antegrade and retrograde channels. Currently, retrograde procedures account for 15% to 34% of specialist CTO PCI procedures recorded in dedicated European and US registries. These methods require access to the distal CTO vessel from a collateral or, occasionally, a bypass graft vessel.
with successful placement of a support microcatheter into the distal target vessel.\textsuperscript{23}

**Retrograde Wire Crossing**

The term \textit{retrograde wire crossing} refers to lesion crossing in a distal-to-proximal cap direction where the wire traverses directly into the proximal vessel true lumen. This phenomenon is relatively uncommon and is successful in less than 30\% of retrograde procedures.\textsuperscript{18} When it is successful, the standard approach after successful retrograde wire manipulation includes placing the wire followed by the microcatheter into the antegrade guide catheter ostium and then exchanging the wire for a long wire to be externalized in a retrograde to antegrade direction. The externalized wire, which for ease of use should be a specialized externalization wire, particularly the RG3 (Asahi Intecc, Nagoya, Japan) but may also be the R350 (Vascular Solutions, Minneapolis, MN) or ViperWire Advance (CSI, Saint Paul, MN), is then used as the interventional platform to complete the PCI procedure. It is important for the portion of the retrograde guide wire that is across the fine collaterals to remain covered by a microcatheter to protect that collateral vessel from laceration and perforation. Equally important is careful attention to the retrograde guide to prevent guide-induced donor vessel injury.

**Retrograde Dissection and Reentry Techniques**

Controlled antegrade and retrograde subintimal tracking (CART; Fig. 35-8) with intentional dissection followed by reentry has become the dominant retrograde technique for successful crossing of CTOs. The principle of this technique is to create a subintimal dissection at the occluded vessel segment with limited extension, thereby creating a channel for wire crossing. The current evolution of this technique, termed \textit{reverse CART}, uses retrograde delivery of a microcatheter from the distal vessel true lumen into the CTO segment either with traditional wire or so-called “knuckle-wire” techniques. An antegrade wire is then simultaneously advanced distal to the equipment delivered in retrograde fashion. Over the antegrade wire, balloon dilation of the subintimal occlusion segment can be performed. This balloon should be matched to the vessel size to create a large subintimal pathway around the
occlusion. This dissects the 2 spaces occupied by antegrade and retrograde equipment to create a single, common space that is in continuity with the proximal true lumen; the retrograde wire can then be advanced into the true lumen (see Fig. 35-8).

**FIGURE 35-8** Controlled antegrade and retrograde tracking (CART): (1) Through directed penetration or knuckling, antegrade and retrograde guide wires are brought into overlap within the occluded segment; wires may be on opposite sides of the internal elastic lamina (one subintimal and the other within the occluded true lumen, 1a), both within the occluded true lumen (1b), or both in a subintimal plane (1c). Regardless, a balloon is advanced over one or the other wire (2), inflated/deflated (3), and then withdrawn leaving behind iatrogenic dissection often including breaches of the internal elastic lamina within the occluded segment (4) that allow the retrograde wire to be moved into a plane common with the retrograde wire, and then advanced into the patent proximal true lumen (5) and ultimately externalized. CART was originally described with the balloon positioned on the retrograde wire; the term reverse CART refers to the now common practice of positioning the balloon on the antegrade wire.

Ultrasound observations suggest this maneuver is easiest when both the antegrade and retrograde guide wire are on the same side of the internal elastic lamina, either both within the subintimal space or both within the
original true lumen. The most common reason for failure of this technique is use of undersized balloons, a problem overcome with experience and use of intravascular ultrasound for optimal balloon sizing and positioning. After the retrograde wire is advanced into the antegrade guide, externalization of the retrograde wire is performed as described earlier. The use of an antegrade daughter catheter such as a GuideLiner (Vascular Solutions) positioned immediately proximal to the reverse CART segment can expedite retrograde wire capture and externalization.

**HYBRID STRATEGY FOR CHRONIC TOTAL OCCLUSION PERCUTANEOUS CORONARY INTERVENTION**

Contemporary antegrade, retrograde, and dissection and reentry techniques are complementary and necessary to meet the full spectrum of challenges inherent to CTO PCI. Exploring sequential CTO crossing options can increase success, shorten procedure times, and reduce radiation exposure. The CTO expert operator needs broad skill sets, versatility, and flexibility to accommodate the wide range of anatomic scenarios present in chronic occlusions. Although significant variability exists among many operators with respect to procedural approaches, the hybrid method for CTO PCI is an effort to standardize initial and provisional technique selection based on patient anatomy (see Fig. 35-5). The implementation of the hybrid method requires skill-set development in optimal wire manipulation, dissection/reentry strategies, and retrograde techniques. The development and adoption of only 1 or 2 of these skill sets will ultimately limit the operator who wishes to approach all patients with appropriate indications for revascularization. Failure to develop a comprehensive skill sets will likely lead to underutilization of revascularization in patient subgroups that may derive great benefit from revascularization.

**TREATMENT OF LESIONS RESISTANT TO DILATION**
Although the most common form of failure in CTO PCI is an inability to obtain wire control of the proximal and distal vessel true lumen, occasionally other challenges present themselves. An inability to deliver equipment or, once delivered, dilate a crossed lesion represents another potential obstacle to successful CTO PCI. It is paramount to confirm that the guide wire is in the vessel architecture or in the distal true lumen before ever proceeding with an over-the-wire catheter or before applying various dilation strategies. The vessel architecture can usually be determined fluoroscopically by observing calcium deposits or other signs of the vessel outline moving or “dancing” in sync with the interventional guide wire. The distal true lumen can be determined by contralateral angiography (antegrade angiography should be avoided in such scenarios to avoid hydraulic artery dissection). After maximizing guide catheter support with either guide extension or anchor balloon techniques, dottering the lesion with the initial over-the-wire system should be attempted. In general, if a Corsair microcatheter (Asahi Intecc) or Turnpike Spiral microcatheter (Vascular Solutions) will not cross the lesion, the initial step is to advance and inflate to high pressure (14-16 atm) a small balloon (1.2-1.5 mm in diameter) as deeply as possible within the lesion to modify the proximal cap. When using small balloons, it is important to use longer balloons (15-20 mm) because the largest profile of these balloons is at the midshaft marker, and thus, the balloon tip will often penetrate the occlusion more readily. If this fails to allow passage of larger balloons, the next maneuver is to intentionally rupture the small balloon so as to modify the plaque morphology with barotrauma. If this fails to enable crossing, the Tornus catheter (Asahi Intecc) or Turnpike HardTip (Vascular Solutions) may be useful. If these maneuvers fail, more aggressive techniques such as the use of coronary laser or rotational atherectomy can be used. Rotational atherectomy and laser can be used even when the wire is not in the distal lumen, provided it is still within the vessel architecture. The advantage of the excimer laser (eg, the 0.9-mm Turbo Elite; Spectranetics, Colorado Springs, CO) is that it may be used on any 0.014-inch guide wire. However, rotational atherectomy requires exchanging the guide wire to a dedicated rotowire, and this may not be feasible when a resistant lesion prevents distal placement of any microcatheter. In situations where the distal true lumen has not been reached, the last 2 cm of the radiopaque wire tip can be removed prior to placement in the artery, thereby providing further reach with the burr (a short segment of the radiopaque portion of the wire should be preserved to prevent
the burr from proceeding off the end of the guide wire). Alternatively, the wire can be looped further down the vessel prior to atherectomy. Rotational atherectomy in the subintimal space should only be attempted by very advanced CTO operators with extensive experience assessing wire position in relation to vessel architecture. Performing rotational atherectomy in this situation demands the use of small (1.25-1.5 mm) burrs, maintenance of a high number of revolutions per minute (>170,000 rpm), and scrupulous avoidance of stalling and thus trapping of the device in a distal subintimal position. If all of these techniques fail to achieve balloon crossing and/or balloon dilation of the lesion, success can often be achieved by deliberately entering the subintimal space proximal to the anatomic cap, effectively moving the functional cap proximally and bypassing the point of resistance. This is done in an antegrade direction by intentionally dissecting the coronary proximal to the cap with a 1:1 noncompliant balloon and then accessing the subintimal space with a prolapsed polymer jacketed wire. Reentry into the true lumen is then planned distal to the lesion in question but prior to any major branches using the Stingray reentry system or using a retrograde approach with retrograde dissection and reentry techniques. This concept essentially employs the subintimal space as a bypass tract to go around the uncrossable or undilatable lesion.

It is beyond the scope of this chapter to cover all the potential intraprocedural challenges that will occur while performing CTO PCI on a wide array of coronary anatomies. It is critical, however, that the expert CTO operator be facile with a wide array of technologic- and technique-based solutions to manage the numerous potential difficulties involved in revascularization of occluded coronary arteries.

**CONCLUSION**

Although still very challenging, a growing cohort of global interventional programs have developed high-volume CTO programs. This work, in concert with transcatheter structural therapies and peripheral programs, provides a full complement of treatments for patients with advanced cardiovascular disease. There is growing clinical evidence in regard to the importance of complete revascularization in patients with coronary atherosclerotic disease (Fig. 35-9). The ability to open CTOs has now led to an era where complete
revascularization can be achieved in most patients.

**FIGURE 35-9** Kaplan-Meier curve showing differences in mortality between those with failed versus successful percutaneous coronary intervention (PCI) procedures targeting a chronic total occlusion (CTO). Successful intervention was associated with a significant decrease in mortality (hazard ratio, 0.71; 95% confidence interval, 0.62-0.82; \( P < .001 \)). Data draw from nearly 15,000 patients enrolled in a population-based PCI registry from the United Kingdom.24

Intervention in Venous and Arterial Grafts

John S. Douglas, Jr.

HISTORICAL DEVELOPMENT

The surgeon’s use of saphenous veins and a variety of arterial conduits to bypass obstructive coronary atherosclerotic disease preceded percutaneous revascularization by about a decade. In that relatively short period of time, the inferiority of venous compared to arterial grafts and the potential for atheroembolization with vein graft manipulation at surgery had become apparent. When Andreas Gruentzig reported the first 50 patients treated with percutaneous coronary angioplasty in 1979, 5 had undergone saphenous vein graft (SVG) dilatation, and 3 (60%) had developed restenosis, leading him to surmise “the different kind of disease may explain the high incidence of recurrence in graft stenosis” and to question the wisdom of percutaneous SVG intervention. In the more than 35 years since that observation, interventional cardiologists have struggled with the indications for SVG intervention because of higher acute complications, more restenosis than was observed in native coronary arteries and arterial grafts, rapid disease progression in nontarget sites, and high late cardiac event rates. By 1983, outcomes of SVG intervention had been more completely characterized, and the first left internal mammary artery intervention had been reported. In a subsequent summary of several thousand reported cases of balloon angioplasty in SVGs, procedural mortality was less than 1%, Q-wave
infarction occurred in less than 2% of cases, and emergency surgery was required in 0.3% to 4% of cases. A gradient was observed in SVG restenosis rates, with very high rates approaching 70% at proximal anastomoses and progressively lower rates in more distal locations (see discussion mid-SVG and distal anastomosis). Subsequent maturation of graft percutaneous coronary intervention (PCI) occurred with improved understanding of patient and lesion selection, application of stents and embolic protection strategies, prediction and prevention of complications, and use of intravascular imaging as discussed below. Unfortunately, the goal of procedural and long-term safety and optimal durability of graft PCI has been illusive following treatment with SVGs.

**BARE METAL STENTS IN SAPHENOUS VEIN GRAFTS**

Use of stents in SVG intervention was supported by the report in 1995 of the Palmaz-Schatz multicenter registry experience in over 500 patients with the following favorable outcomes: procedural success, 97%; stent thrombosis, 1.4%; in-hospital mortality, 1.7%; urgent surgery, 0.9%; and restenosis in 18% of de novo lesions and 46% of restenotic lesions. In the Saphenous Vein De Novo (SAVED) trial, 220 patients with SVG stenosis of at least 50% and angina or objective evidence of ischemia were randomized to deployment of a Palmaz-Schatz stent or balloon angioplasty. Patients with lesion lengths requiring more than 2 stents, myocardial infarction within 7 days, or graft thrombus were excluded. Patients who underwent stent implantation had a higher procedural efficacy, defined as a reduction in stenosis to less than 50% of the vessel diameter with the assigned therapy (92% vs 69%; \( P < .001 \)). Patients assigned to stents had a larger increase in lumen diameter immediately (1.92 vs 1.21 mm; \( P < .001 \)) and a greater net gain in lumen diameter at 6 months (0.85 vs 0.54 mm; \( P = .002 \)). There was more bleeding in stented patients due to warfarin anticoagulation. Major in-hospital complications were otherwise similar in the 2 groups, although there was a trend toward fewer non-Q-wave myocardial infarctions in the stent group. This observation led some operators to investigate a strategy of direct stenting in SVGs, attempting to minimize distal atheroembolization.
In the SAVED trial, restenosis occurred in 37% of stented patients and in 46% of patients treated with balloon angioplasty ($P = .24$). Event-free survival at 240 days (freedom from death, myocardial infarction [MI], or repeat revascularization) was significantly higher in stented patients (73% vs 58%; $P < .03$). It was noted that late lumen loss was significantly greater in patients who had high-pressure stent deployment (≥16 atm), suggesting that high-pressure stent expansion may be undesirable in SVGs. Less aggressive stent expansion was also supported by an intravascular ultrasound study of over 200 SVGs that showed that stent expansion to ≥100% of the reference cross-sectional area was associated with significantly more non–Q-wave infarctions (29% vs 17%; $P = .05$) and similar rates of target vessel revascularization at 1 year (31% vs 26%; $P = .3$).\(^7\)

Observational reports of intervention in SVGs suggested that outcomes were somewhat better in 1995 to 1998 compared to earlier years (1-year event-free survival of 71% vs 59%; $P < .001$) and that use of stents had a protective effect.\(^8\) However, in an analysis of over 600 SVG patients in 5 large randomized trials, major adverse cardiac event (MACE) rates were twice that observed in native-vessel intervention.\(^9\)

**EMBOLIC PROTECTION DEVICES**

In the past decade, the importance of atheroembolic MI complicating PCI has become increasingly apparent, especially in SVG interventions. In relatively simple SVG lesions, stenting resulted in MI in 15% to 20% of patients. The rate of MI increased with lesion complexity, length, and estimated plaque volume,\(^10\) and in approximately 1000 patients who underwent SVG intervention, creatine kinase (CK)-MB elevation was the best independent predictor of late mortality.\(^11\) Strategies to prevent atheroembolic infarction have evolved over the years from occlusion aspiration to the use of filters. The first embolic protection device (EPD) method tested was the PercuSurge Guardwire system (Medtronic, Dublin, Ireland), which used a 0.014-inch guide wire with a compliant distal occlusion balloon. Inflation of the guide wire balloon interrupted blood flow, and stent deployment was followed by aspiration and balloon deflation. Use of this system in 24 SVG stent procedures was found to prevent infarction in 23 patients, and 95% of aspirates had typical atherosclerotic debris.\(^12\) However, it was the Saphenous
Vein Graft Angioplasty Free of Emboli Randomized (SAFER) trial that unequivocally and singularly demonstrated in a randomized study the value of embolic protection during SVG intervention. In 801 patients randomized to PercuSurge Guardwire or unprotected stent implantation, 30-day MACE was reduced by 42% with use of the Guardwire (from 16.5% to 9.6%; \( P < .001 \), primarily due to reduced infarction from 14.7% to 8.6%; \( P = .008 \)).\(^{13}\) In SAFER, use of EPD was demonstrated to be beneficial over a wide range of lesion lengths (even very short lesions), and this strategy was shown to be cost effective. Advantages of this technique included its low profile, which permitted crossing severe stenoses, and the ability to capture small particles and soluble vasoactive molecules such as endothelin and serotonin as well as coagulation components that have been shown to be liberated during SVG PCI.\(^{14}\) Disadvantages included the need to completely occlude the vein graft for several minutes, which was not well tolerated by some patients, and the requirement for several disease-free centimeters beyond the lesion to place the occlusion balloon. The complexity of this form of embolic protection compared to filters led to underutilization, and it was eventually removed from the market.

The effectiveness of filter-based embolic protection during SVG stent implantation was evaluated in the FilterWire EX During Transluminal Intervention of Saphenous Vein Grafts (FIRE) trial, a randomized study of 650 patients in 65 centers.\(^{15}\) Thirty-day MACE rate was 9.9% with the filter-based EPD and 11.6% with PercuSurge with virtually identical rates of MI (9% vs 10%) and death (0.9% vs 0.9%). Advantages of filter-based EPD included ease of use, maintenance of flow, avoidance of ischemia during stenting, and good visualization. Disadvantages included the need to cross the lesion with a somewhat bulky filter device that might require predilation, which has been shown to increase MI; the need for a substantial “landing zone” beyond the lesion; and the inability to remove soluble factors and particles smaller than the filter pores (<100 μm) (Fig. 36-1). The latter factors may not be clinically important based on comparisons such as FIRE. In addition, there can be difficulty with filter withdrawal due to inability to pass the retrieval catheter through a newly placed stent. This is especially true when the stent is in an aorto-ostial location with stent struts protruding into the aorta. Guide catheter–induced distortion of the newly placed ostial stent or entrapment of the filter on the distal stent edge can lead to major complications including stent embolization and thrombosis.\(^{16}\) Finally, filters
have finite limits as to the amount of debris that can be captured with maintenance of flow. Large atheroembolic or thrombotic loads can result in filter occlusion and the appearance of no reflow (Figs. 36-2 and 36-3). The optimal strategies, should this occur, include aspiration of the stagnant “dye” column, which frequently contains suspended particles; removal of the filter; and placing another filter if more interventional work is required. A variety of filters are currently available and appear to be equally effective.

FIGURE 36-1 A 79-year-old woman with unstable angina was found to have severe stenosis in a saphenous vein graft (SVG) to the left anterior descending coronary
artery (upper left), which had been placed 24 years earlier. The right coronary artery was occluded. She was somewhat forgetful and was not judged to be a good candidate for repeat surgery. Following placement of a FilterWire (Boston Scientific, Marlborough, MA) for distal protection and using an Amplatz left guide catheter, the lesion was predilated safely (upper right). A stent was selected to extend from the SVG ostium well beyond the lesion (lower left). Note the position of the filter. Following stent deployment, an excellent angiographic result was obtained (lower right). There was a moderate amount of atherosclerotic debris in the filter and no evidence of periprocedural myocardial ischemia or infarction. Had the patient been younger and better suited for repeat surgery, this option may have been used. The current ability to offer distal protection to enhance procedural safety and drug-eluting stents to ameliorate restenosis has significantly improved SVG percutaneous coronary intervention outcomes.
Chest Pain and ST Elevation

No Reflow!
FIGURE 36-2 A. Very complex lesion in mid portion of saphenous vein graft (SVG) to left anterior descending artery in an elderly man who was not a good candidate for repeat coronary artery bypass grafting (CABG). The lesion was ulcerated, with large plaque volume and probable thrombus. B. A filter was placed distally, and a 4.0 × 20 bare metal stent was deployed. The patient developed chest pain and ST-segment elevation (C), and there was no flow in the SVG (D). A manual aspiration catheter was used to aspirate the “dye” column in the SVG, and no reflow persisted after administration of adenosine distally through the aspiration catheter (E). The filter was removed, and Thrombolysis in Myocardial Infarction (TIMI) grade 3 flow was immediately restored and ST segments normalized. The filter contained a large amount of plaque material sufficient to prevent flow through the filter (see Fig. 36-3). Several factors probably contributed to no reflow: (1) large lesion volume resulting in atheroembolization; (2) obstruction of the filter by plaque material; (3) release of vasoconstrictors such as endothelin and serotonin; and (4) clot embolization. The patient had a small non–Q-wave myocardial infarction and no other complications. Strategies that may have minimized the risk of no reflow include (1) pretreatment with a small-vessel dilator such as nitroprusside, adenosine, or calcium channel blockers (see “No Reflow Following SVG PCI” section); and (2) a smaller stent, because this stent was slightly oversized.
FIGURE 36-3 A. The Filter-Wire (Boston Scientific, Marlborough, MA). B. Filter obstructed by embolized plaque material resulting in no reflow. Image provided courtesy of Boston Scientific. © 2017 Boston Scientific Corporation or its affiliates. All rights reserved.

A third form of EPD, known as PROXIS, which used a proximal occluding balloon, was tested in a randomized trial and was comparable to either filter or Guardwire.\textsuperscript{17} Advantages of proximal occlusion included protection during wire passage, side branch protection, and no need for a distal parking segment, a problem in many patients that prevented use of filters and PercuSurge. Unfortunately, as with the Guardwire, the complexity of proximal occlusion-aspiration and the requirement for graft occlusion for several minutes resulted in little usage and withdrawal of the device from the market.

The early report of Liu et al\textsuperscript{10} showing that plaque volume was a predictor of MI in SVG PCI was extended by Coolong and colleagues.\textsuperscript{18} They showed
in about 4000 patients that degeneration score and plaque volume were the most important predictors of MI, but the presence of thrombus, advanced age, and active smoking also contributed. When the occurrence of MACE was analyzed relative to these predictors, embolic protection was beneficial across all risk groups, implying that embolic protection should be used routinely in all suitable patients undergoing PCI in old SVGs as recommended in the 2011 PCI guidelines. However, data from the National Cardiovascular Date Registry indicated that embolic protection was used in only 21% of 49,325 senior patients who underwent SVG PCI and that acute and 3-year outcomes were not better in propensity score–matched patients in whom EPDs were used. In addition, in the recent ISAR-CABG (Is Drug-Eluting Stenting Associated With Improved Results in Coronary Artery Bypass Grafts?) study in which 610 patients underwent stent implantation in SVGs, the occurrence of MACE at 30 days was only 4% despite the use of embolic protection in <5% of patients. These observations cause one to question whether practices in place at the time of SAFER may have led to an increased rate of MI in the control group. For example, 40% of control patients underwent postdeployment stent dilation, a practice currently avoided by most experienced operators because further stent expansion frequently leads to no reflow. In addition, postdilation was carried out with a balloon that had a mean diameter of 4.2 mm, whereas the mean reference vessel diameter was only 3.4 mm. Use of a balloon larger than the reference vessel increased MI in the study by Iakovau et al. In addition only 27% of patients in the Guardwire arm underwent postdilation of the stent. These practice patterns may have contributed to the higher rate of periprocedural MI in the SAFER control group.

**ATHEROABLATIVE AND THROMBECTOMY STRATEGIES**

Debulking procedures in SVGs using directional atherectomy, the transluminal extraction catheter, and the excimer laser have been shown to have increased complexity and costs without evidence of improved outcomes. Consequently, atheroablative strategies do not play a significant role in current percutaneous intervention in venous or arterial grafts.
Mechanical thrombectomy is currently feasible with a variety of techniques, including aspiration with guide catheter, guide catheter extenders, or monorail aspiration catheters or by Angiojet thrombectomy (Boston Scientific, Marlborough, MA) (Fig. 36-4). Although proof of benefit is lacking, anecdotal experiences have convinced most practitioners that proceeding with PCI in the face of a large thrombus burden is rarely advisable when mechanical thrombectomy or some other strategy to eliminate or reduce thrombus is feasible (see later “Large Thrombus Burden” section).

**FIGURE 36-4** More than a decade after coronary artery bypass graft (CABG) a 61-year-old man presented 12 hours after onset of crushing chest pain and was found to have a normal electrocardiogram and troponin I level of 5 ng/mL. The saphenous vein graft (SVG) to the right coronary artery was occluded (A). Other grafts were patent, and the inferior left ventricular wall was mildly hypokinetic. Aspiration thrombectomy restored normal flow and revealed 2 SVG stenoses (B). Following deployment of 2 stents, the SVG was widely patent throughout (C). There were no complications. A very large amount of thrombus was removed at the time of the initial aspiration (D). It is highly unlikely that percutaneous coronary intervention results would have been favorable without clot removal, yet there is a small risk of systemic embolization.

**DRUG-ELUTING STENTS IN SAPPHENOUS VEIN GRAFTS**

Observational studies of the use of drug-eluting stents (DESs) in SVGs
suggested that they were safe and relatively effective. A multicenter registry of over 1000 patients who underwent SVG PCI reported that, at 9 months, patients receiving DES had significantly lower rates of death or MI (hazard ratio [HR], 0.52) and target vessel revascularization (HR, 0.36) compared to patients treated with bare metal stents (BMSs), and at 2 years, the mortality rate was lower (HR, 0.60). Multiple meta-analyses comparing DES with BMS in SVG have been published. In a meta-analysis, Mamas and colleagues analyzed 20 studies with over 5000 patients and reported no safety concerns and a 36% decrease in MACE in DES-treated patients. Three randomized trials have been published comparing sirolimus-eluting stents (SESs) or paclitaxel-eluting stents (PESs) with BMS in SVGs. Vermeersch et al randomized 75 patients to SES or BMS and found reduced restenosis at 6 months with SES, but at 3 years, target vessel revascularization was similar, suggesting a “catch-up” phenomenon, and SES-treated patients had a higher mortality. In the second randomized trial, 80 patients were randomly assigned to receive PES or BMS, and at 1 year, outcomes were more favorable with PES with respect to restenosis (11% vs 57%; P < .0001) and target lesion revascularization (5% vs 28%; P = .003), and clinical outcomes were better in PES-treated patients at 3 years.

The third randomized trial, ISAR-CABG, was the only study powered to compare clinical outcomes. Six-hundred ten patients were enrolled and randomly assigned to receive a DES (sirolimus or paclitaxel eluting) or BMS. Inclusion criteria were broad, and clinical characteristics of the 2 groups were similar. Outcomes at 1 year are reported in Table 36-1. The incidence of MACE, the primary end point, was 15% with DES and 22% with BMS, a 36% risk reduction. Target lesion and target vessel revascularization rates were significantly lower in DES-treated patients. There were no significant differences in all-cause mortality, MI, or definite or probable stent thrombosis. The 36% reduction in MACE is the same reported in a meta-analysis and in the stent registry. It is important to note that follow-up in ISAR-CABG was only 1 year and that longer term outcomes are needed.

Table 36-1 Clinical Outcomes at 1 Year in ISAR-CABG
Three recent publications of large registries reported somewhat differing long-term results. In a Danish registry, there was no benefit of DES with respect to death or stent failure at 3 years.\textsuperscript{28} However, in a large cohort of 709 propensity score–matched pairs of patients, the need for target vessel revascularization at 4 years was significantly less in DES-treated patients (21% vs 28%; \( P = .004 \); a 24% risk reduction).\textsuperscript{29} In patients with diabetes or stented segments \( \geq 30 \) mm, the number of procedures needed to prevent a target vessel revascularization was 8 and 7, respectively. In a report of stent implantation in SVGs from 63 Veterans Affairs hospitals for a 4-year period ending in 2011, DES use was associated with lower mortality in propensity-matched patients.\textsuperscript{30} Whether some late erosion of benefit with DES in SVG is related to the well-described delay in neointimal hyperplasia observed with DES in SVG is uncertain but plausible.

Virtually all the data available regarding long-term pathologic and clinical studies of DES in SVGs involve first-generation SESs and PESs. However, second-generation stents, which have been shown to be superior in native coronary arteries, are currently being implanted in SVGs. In an observational single-center study, 2-year outcomes of patients receiving second-generation everolimus-eluting stents (EESs; \( n = 88 \)) were shown to be superior to those of patients receiving first-generation SESs or PESs (\( n = 243 \)) with respect to MACE (18% vs 35%; \( P = .003 \)), target lesion revascularization (1% vs 12%; \( P = .005 \)), and target vessel revascularization (7% vs 25%; \( P < .001 \)).\textsuperscript{31} However, patients in the 2 groups were treated at different time periods and subject to selection bias. Although the use of DES in SVGs is somewhat controversial,\textsuperscript{32} given the paucity of long-term clinical outcome data and cost-effectiveness of current stents in SVGs, they do appear to be safe and confer at least short-term benefit, and their use is supported by the 2011 PCI guidelines.\textsuperscript{19} Patients most likely to benefit are those with diabetes, long

lesions, SVGs <3.5 mm in diameter, and the ability to comply with long-term dual antiplatelet therapy.

**COVERED STENTS**

The results of randomized trials comparing polytetrafluoroethylene (PTFE)-covered stents with BMSs in SVGs were not encouraging.\(^{33,34}\) Six-month MACE rates were higher in patients receiving covered stents due to more MIs and late occlusion. However, PTFE-covered stents remain an important, potentially lifesaving adjunct for treatment of patients with SVG or left internal mammary artery (LIMA) graft perforation.

**PATIENT AND LESION CHARACTERISTICS**

*Time Since Coronary Artery Bypass Graft*

The type of graft lesions encountered is largely determined by the length of time that has passed since the patient underwent coronary artery bypass graft (CABG) surgery. The longer the interval, the higher is the probability of encountering bulky, friable, thin-capped atherosclerotic SVG lesions with high atheroembolic potential. Recurrent myocardial ischemia within days of CABG is commonly due to acute SVG thrombosis, but venous or arterial anastomotic lesions or uncorrected native coronary disease may be encountered. Among 145 patients with early postoperative ischemia evaluated with coronary angiography, 60% had graft stenosis or occlusion, 10% had incomplete revascularization, and no cause was apparent in the remainder.\(^3\) Seventy-four patients underwent repeat revascularization (PCI or CABG). Similar experience was reported by Thielmann and colleagues,\(^{35}\) who performed urgent catheterization in 2% of over 5000 patients very early after CABG because of suspected graft failure. Graft failure was confirmed in 71 patients, and repeat revascularization was performed in 60%. PCI in this setting is a Class I indication in American College of Cardiology (ACC)/American Heart Association (AHA) guidelines and can be lifesaving.
Some insight into the frequency and timing of graft failure in the modern era can be gleaned from the use of routine intraoperative angiography at Vanderbilt University and several reports of routine angiography performed at 1 year following surgery. Zhoa et al\textsuperscript{36} reported that in patients undergoing routine angiography in the operating room immediately after completion of bypass surgery, 12% of bypass grafts had problems severe enough to require some form of intervention, and one-half of patients underwent open-chest PCI. In 3 studies reporting angiographic results at 1 year (PREVENT IV, PRAGUE-4, and ROOBY), graft failure rates were surprisingly high (40%-50% of SVGs and up to 11% of LIMA grafts). These results are sobering and strongly support angiographic evaluation when postoperative ischemia is suspected. The need for treatment of anastomotic lesions early after surgery is more common with off-pump and minimally invasive surgery in our experience. Development of anastomosis edema is a confounder that should be considered (see later section “Distal Anastomosis Lesions”).

**Proximal Graft Lesions**

Lesions at the origin of LIMA or right internal mammary artery (RIMA) grafts are quite rare, but stent implantation at these sites has been described. In most cases, these lesions predated CABG, suggesting a need to ensure conduit patency before surgery, especially in patients with large atherosclerotic burdens. Aorto-ostial SVG lesions are much more common and are difficult to treat effectively due to elastic recoil and restenosis and difficulty in achieving optimal stent placement. In a study of 320 consecutive patients with stent implantation for SVG aorto-ostial stenoses, about half of whom had debulking with atherectomy, 1-year target lesion revascularization was about 20%, and event-free survival was 70%. Atherectomy prior to stenting conferred no benefit. Results of the use of DESs at this site in large numbers of patients have not been reported. Aorto-ostial lesions in older SVGs have a high risk of distal embolization, and use of filters is recommended for embolic protection in bulky lesions with the caveat that filter retrieval following ostial stent implantation may be difficult.\textsuperscript{16}

**Mid-Graft Lesions**

Internal mammary artery grafts are “immune” to atherosclerosis; mid-RIMA
or -LIMA graft lesions are rare and most likely the result of operative trauma. Atherosclerotic lesions in the shaft portion of SVGs appear with increasing frequency beginning about 3 years after CABG. Data from the SAFER trial showed that even with the shortest lesions (<10 mm in length), a 77% reduction in 30-day MACE was experienced when embolic protection with PercuSurge was used (2.2% vs 8.1%). Although the risk of atheroembolic MI is highest with complex lesions, this observation in simple lesions supports routine use of a distal protection strategy during stent implantation in most de novo SVG lesions where the anatomy permits it (see earlier “Embolic Protection Devices” section). Exceptions are the lesion appearing within a year or 2 of surgery and in-stent restenosis, where intimal hyperplasia is the usual pathology and embolic complications are rare. Most operators use DESs in mid-SVG lesions. However, higher restenosis rates of stented sites in SVG compared to native vessels and more rapid progression of untreated moderate lesions in SVGs strongly support PCI of native vessel sites rather than SVG whenever possible.

**Distal Anastomosis Lesions**

In our experience, PCI of distal anastomosis lesions in SVGs or LIMA grafts has been safe even immediately after surgery, but there are isolated reports of suture line disruption. In addition, the European guidelines caution against treatment at this time because of the risk of perforation. We have observed moderate imperfections in LIMA anastomosis a day or so postoperatively that disappear on subsequent restudy, suggesting the presence of edema. Japanese colleagues reported similar observations in a group of patients undergoing early routine catheterization to evaluate results of off-bypass versus on-bypass surgery, leading a noted surgeon to question, “Does the internal thoracic artery graft have self-reparative ability?” Recurrent symptoms 1 to 12 months following surgery are frequently due to anastomotic lesions, with 3 to 4 months being the most common time. If balloon angioplasty results are good, stent implantation is not required. Anastomotic lesions occurring years after surgery are increasingly atherosclerotic, and stent implantation is the preferred treatment. Results of DESs for this site have not been reported in significant numbers, but most operators use them routinely in older lesions. When a bulky and presumably atherosclerotic distal anastomosis lesion is encountered, there is no embolic
protection strategy available, and a very careful risk-benefit analysis should be carried out, including consideration of native-vessel PCI and surgery. If stent implantation is planned, direct stent implantation without predilation should be considered.

**Intermediate SVG Stenosis**

Patients with moderate untreated stenosis in SVGs have a much higher late cardiac event rate than those without (45% vs 2%), leading some operators to have a lower threshold for intervening with stent implantation. Rodes-Cabau et al conducted a pilot trial randomizing 57 patients with intermediate SVG stenosis (30%-60% narrowing) to DES or medical therapy alone and reported lower late cardiac events in stent-treated patients out to 3 years. A large prospective randomized trial was initiated to further explore this strategy. Fractional flow reserve and intravascular imaging strategies with optical coherence tomography, useful in guiding native coronary intervention, have not been adequately studied in SVGs.

**Large Thrombus Burden**

Lesion-associated thrombus is a predictor of complications, especially periprocedural MI. In the SAFER trial, baseline SVG thrombus was associated with higher mortality (3.0% vs 0.9%; \( P = .04 \)), more no reflow (9.9% vs 3.4%; \( P = .001 \)), and higher 30-day MACE (17.4% vs 10.4%; \( P = .006 \)). This striking difference in outcomes occurred despite the fact that 50% of patients in SAFER received embolic protection with PercuSurge, which reduced complications (odds ratio [OR], 0.625; \( P = .02 \)). Some experienced operators attempt to reduce thrombus prior to stent implantation by administration of antithrombotic therapy along with glycoprotein IIb/IIIa platelet receptor inhibitors for a few days or by infusing thrombolytic agents locally. However, mechanical thrombectomy was shown to be superior to thrombolytic therapy and is the most common approach, combined with a distal protection strategy if possible (see later section “Thrombectomy in Saphenous Vein Grafts”).

**The Restenosis Lesion**
Restenosis following stent implantation in an SVG is common. When disease in the SVG appears to be confined to the in-stent restenosis lesion, repeat intervention can be conducted with such a low risk of atheroembolization that distal protection is not routinely implemented. Exceptions include patients with restenosis many years following stent implantation in whom neoatherosclerosis may be the pathology. Because repeat restenosis following BMS implantation occurs subsequently in almost one-half of such patients, treatment with DESs has become standard therapy.

**ST-Segment Elevation MI in the Post-CABG Patient**

In a recently reported large observational study, Gruberg et al reported outcomes of 15,628 patients with ST-segment elevation MI (STEMI), 6% of whom (n = 969) had a history of prior CABG. Patients with prior CABG were older, had more comorbidities, and had longer door-to-balloon times, and the target vessel was a vein graft in 53%. In post-CABG patients, there was a trend for increased short-term mortality risk if the treated lesion was in a bypass graft (OR, 2.2; \( P = .07 \)), and a similar trend was reported at 1 year in a single-center study of 249 post-CABG patients. The ACC/AHA Task Force report on early management of acute MI classified primary PCI for vein graft recanalization to be a Class IIa indication, that is “acceptable, of uncertain efficacy and may be controversial; weight of evidence in favor of usefulness/efficacy.” Strategies that should be considered in primary SVG PCI include consideration of native-vessel options whenever possible and optimal management of the large thrombus burden frequently encountered (see above).

**Chronic Total SVG Occlusions**

Intervening on a recently occluded SVG in the setting of an acute coronary syndrome is frequently a formidable task due to the large amount of thrombus commonly present and its increasing resistant to removal or lysis as time goes by (Figs. 36-4 and 36-5). PCI in the presence of a large thrombus burden carries a risk of distal embolization with aspiration thrombectomy, and there is a small risk of systemic embolization. In the presence of a chronic SVG occlusion, problems are magnified, and the risk-benefit ratio becomes even less favorable, accounting for the Class III indication (not
helpful, possibly harmful) in the 2011 PCI guideline statement. However, in a recent summary of 4 reports of attempted PCI of chronic SVG occlusion with a total of 94 patients, successful recanalization was achieved in 72% with in-hospital MI in 7%, no in-hospital deaths, and improvement in angina in 80%.47

FIGURE 36-5 A 66-year-old man presented to the emergency department with chest pain of 2 hours in duration. Clopidogrel had been discontinued a few days earlier due to anticipated surgery related to diabetes and a poorly healing foot ulcer. There was a history of coronary artery bypass grafting (CABG) × 3 12 years earlier. Electrocardiogram revealed anterior ST-segment elevation (A), and emergency coronary angiography revealed an occluded saphenous vein graft (SVG) to the left
anterior descending artery (LAD) (B). The native coronary arteries were occluded. Radial artery graft to right coronary and left internal mammary artery to ramus intermedius artery were patent. Percutaneous coronary intervention was initiated, and immediately after guide wire passage, slight antegrade flow was observed in the SVG to LAD with large thrombus burden (C). Aspiration was performed with a large amount of clot removed (D), with return of a normal flow but significant proximal SVG stenosis (E). Following placement of a filter, a 3.5 × 23 drug-eluting stent was deployed with excellent angiographic results (G). Tirofiban was administered intravenously for 18 hours due to the large clot burden. Initial troponin of 0.55 ng/mL increased to 200 ng/mL 8 hours after procedure. Echocardiogram 1 year later revealed anterior hypokinesis and an ejection fraction of 45% to 50%.

**FIGURE 36-6** A. Severe stenosis was observed in the saphenous vein graft to the left anterior descending artery in an elderly man 16 years after coronary artery bypass grafting. B. A 3.5-mm stent was deployed with full expansion of the stent at 18 atm. C. A type 3 perforation was noted. Optimal treatment of this complication includes immediate balloon inflation and consideration of strategies to seal the perforations. Consideration of a second guide catheter for deployment of a covered stent is a good strategy.

**The Diabetic Patient**

A study of over 2000 patients who underwent PCI of SVG lesions at Emory University pointed out the poor 5-year survival of diabetics compared to nondiabetics (60% vs 82%; \( P = .001 \)). Event-free survival at 5 years was also significantly lower (23% vs 37%; \( P = .001 \)). DESs were not used during this experience.
EQUIPMENT

The guide wires, balloon catheters, stents, thrombectomy devices, and available distal protection equipment are described in detail in the chapters devoted to these topics. The reader is referred to these chapters for review of the devices themselves.

STEP-BY-STEP PROCEDURE

Periprocedural Pharmacotherapy

The author premedicates patients with clopidogrel 600 mg loading dose or another P2Y\textsubscript{12} inhibitor, aspirin 325 mg, diphenhydramine 50 mg, a calcium-blocking drug such as diltiazem 60 mg orally, and a thrombin inhibitor. Unfractionated heparin is preferred in graft intervention because it can be reversed in the event of graft perforation. Patients with obvious thrombus may receive glycoprotein IIb/IIIa platelet receptor inhibitors, but their routine use has not been shown to be beneficial in SVGs and has a Class III indication in the 2011 PCI guidelines.

Guide Catheter Selection and Manipulation

For in situ LIMA or RIMA interventions, 6- or 7-Fr internal mammary artery (IMA) catheters are used from a homolateral radial artery or femoral approach. A 0.035-inch angle tip glide wire facilitates entering the subclavian artery or innominate artery, if needed. If entry into the IMA is difficult, a straight lateral view is obtained, and the tip of the IMA catheter is rotated anteriorly. Extreme care is taken to avoid traumatizing the ostium of the IMA, especially when balloon catheters and guide wire are withdrawn and the guide catheter can be pulled into the IMA.

For SVG and free arterial graft intervention, 6- or 7-Fr multipurpose guide catheters are used for down-going grafts to the right coronary artery. Hockey stick or Amplatz shapes are used for grafts that arise from the anterior aorta and supply left anterior descending (LAD) or diagonal arteries (see Fig. 36-1), and Amplatz shapes are favored for grafts to the circumflex distribution,
especially when their initial portion is superiorly oriented. Amplatz guide catheters provide superior “backup,” which becomes especially important when embolic protection strategies are applied. If ostial narrowing is present or the graft is small, a side-hole guide catheter is preferred. It is important to keep in mind that a 7-Fr guide catheter is required to deliver larger covered stents (≥3.5 mm) to treat SVG perforations. Guide catheter extenders are occasionally helpful when anatomy is difficult.

**Selection of Optimal Views**

For LIMA or RIMA interventions at the distal anastomosis with LAD or diagonal arteries, a straight lateral view, with cranial angulation if needed, is one of the best views and is frequently coupled with a 30° right anterior oblique view to provide 2 roughly orthogonal views. When SVG intervention is carried out, at least 1 and preferably 2 views are needed that are roughly 90° from the longitudinal axis of the graft, free of overlap and foreshortening, and display the entire length of the lesion. With aorto-ostial lesions, it is difficult but critically important to avoid foreshortening, which prevents precise placement of the stent in relation to the ostium of the graft.

**Selection for Embolic Protection**

The reader is referred to the Chapter 35 for a more complete review of this topic. In general, an embolic protection strategy is recommended, when the anatomy is suitable, in all interventions on de novo lesions in SVGs 3 years old or older. A filter can be used even when it is anticipated that ischemia would not be well tolerated. Examples include grafts supplying large myocardial segments, moderate-sized myocardial segments in the presence of left ventricular dysfunction, or last remaining vessel. When there is insufficient room for a filter beyond the lesion, direct stent implantation without predilation is advisable, and the stent diameter should be equal or slightly smaller than the reference vessel. A slightly longer stent is recommended when the risk of atheroembolism is increased to avoid longitudinal plaque shift outside the stented segment.

**Guide Wire Selection**
In the presence of a very tortuous internal mammary artery graft, a 0.014-inch floppy guide wire with hydrophilic coating is frequently the best choice and usually permits passage of a balloon catheter. Routine use of over-the-wire balloons and stents is advisable in LIMA graft interventions to facilitate guide wire exchange. In order to be able to pass a stent, it may be necessary to exchange for a stiffer guide wire or insert a “buddy wire.” Use of a guide catheter extender may be helpful, but there is some risk of injuring the graft. Use of a stiff wire may straighten the IMA and even occlude it. When this happens, it may be necessary to change to a less stiff wire once the stent is in the approximate target site, to remove the buddy wire, or to deploy the stent using landmarks such as surgical clips. Removal of a stiff guide wire from a straightened IMA is best accomplished via an over-the-wire balloon catheter with care not to drag the guide catheter into the IMA origin. Selection of a guide wire for SVGs follows principles used in native-vessel intervention, with middle-weight wires commonly being chosen.

**THROMBECTOMY IN SAPHENOUS VEIN GRAFTS**

When a large thrombus burden is present, PCI is risky, as discussed earlier. Angiojet thrombectomy is the most effective method for clot removal and is favored when the thrombus is large. Placement of a temporary pacemaker is usually required for treatment of SVGs supplying right and dominant circumflex coronary arteries because of bradycardia caused by adenosine release from red cells. Placement of a filter should be considered in the presence of a large thrombus, but there is some risk of embolizing clot when placing the filter. Proximal thrombi may be aspirated by a guide catheter or guide catheter extender, and smaller distal thrombi can be removed by manual aspiration catheters. It is important to keep in mind that there is a risk of cerebral emboli when aspirating thrombi from grafts, and deep seating guide catheters is advisable when it can be safely accomplished. Consideration of native-vessel PCI is warranted when thrombus-laden SVGs are encountered.
STENT SELECTION

DESs have become the default strategy despite the lack of hard long-term data supporting their use in SVGs. Currently, their use in large SVGs is constrained by the geometric expansion limits of the available devices. As noted earlier, data from the SAVED trial and ultrasound studies suggest that in SVG PCI, stent sizing and expansion pressures should be conservative.\(^5\)\(^-\)\(^7\) This strategy will also minimize the risk of SVG perforation and avoid, to a degree, the extrusion of atheroma through stent struts with subsequent embolization. A thoughtful approach to SVG PCI is recommended, including direct stenting,\(^6\) minimal catheter manipulations, avoiding postdilation of stents, slightly longer stents to trap as much atheroma as possible, and routine use of embolic protection. When distal protection could not be applied in the past due to anatomic constraints, use of self-expanding stents without postdilation minimized the risk of atheroembolization in the author’s experience. Currently, a self-expanding coronary stent is not available.

THE VALUE OF INTRAVASCULAR IMAGING

Use of intravascular ultrasound (IVUS) is valuable in measurement of luminal diameter and percent stenosis and has shown that nominal or slight undersizing of stents in SVGs results in less plaque extrusion and periprocedural MI with similar long-term outcomes.\(^7\) IVUS has also demonstrated in SVGs that the mechanism that commonly underlies development of acute coronary syndromes (ie, plaque rupture) is similar in SVGs and native coronary arteries. Optical coherence tomography, which has higher resolution than IVUS, has demonstrated in SVGs increasingly frequent presence of thin fibrous caps and thrombus with increasing clinical acuity and much greater lesion complexity than was suggested angiographically.\(^42\)

AVOIDING AND TREATING
COMPLICATIONS

SVG Perforation

The preceding sections highlight some of the most important tips to avoid perforation, namely avoiding oversized balloons and stents and unnecessarily high pressure inflations. Despite these cautionary measures, SVG perforations are encountered, perhaps because of the frequent use of long balloons and stents and the capability of stent delivery balloons to reach pressures exceeding 20 atm. Accepting minor imperfections such as a short segment of incompletely expanded stent may be preferred over extremely high inflation pressures that risk perforation and balloon rupture–induced injury. With the use of long balloons and stents, long tears may occur that are difficult and sometimes impossible to seal, even with PTFE-covered stents. Long inflations, covered stents, and coils can be invaluable in the event of a serious perforation, and covered stents and coils should be immediately available. When a “free” perforation occurs, it is usually advisable to control it with the balloon that caused the perforation while gathering necessary tools to definitively seal it. In some cases, it is advisable to place a second larger diameter guide catheter from a femoral approach to accommodate the bulky, covered stent required to seal a large SVG that has been perforated. Placing a second guide catheter offers the major advantage of avoiding a too-hasty exchange for the covered stent, risking loss of guide wire position, which can be catastrophic.

No Reflow Following SVG PCI

The etiology of no-reflow during SVG intervention is multifactorial and includes vasospasm, but most important is microembolization of plaque and thrombus. As shown in SAFER, effective distal protection significantly reduces no reflow (from 9.9% to 3.4%; \( P < .001 \))\(^{13} \) and should be used whenever possible in SVG PCI procedures involving de novo lesions in SVGs in place for \( \geq 3 \) years. Participation of microvascular spasm in no reflow is strongly suggested by the fact that endothelin and serotonin, both vasoconstrictors, are liberated during SVG PCI,\(^ {14} \) by reduced no reflow when calcium channel blockers are administered prior to SVG PCI, by a beneficial
treatment effect of microvasculature dilators (nitroprusside, adenosine, and calcium blockers), and by the lack of benefit of nitroglycerin. When no reflow occurs or is anticipated, intracoronary administration of 100 to 300 μg of diltiazem, verapamil, or nitroprusside or 10 to 30 μg of adenosine is conservative and may be repeated. A prolonged intragraft high-dose infusion of adenosine (200 μg/min for 10 minutes) has been shown to protect microvascular function and prevent no reflow. Based on the work of Japanese colleagues, the author has adopted a strategy of aspirating the stagnant dye column when no reflow occurs. In patients with no reflow, direct aspiration of the dye column was more effective than calcium channel blockers in restoring flow and avoiding balloon pumping and death. Aspirates most often contained plaque gruel, with <10% containing thrombus. Although glycoprotein IIb/IIIa platelet receptor inhibitors are sometimes administered in patients with no reflow, this strategy has not been formally tested.

LONG-TERM PHARMACOTHERAPY AFTER PERCUTANEOUS CORONARY INTERVENTION

Following graft intervention and stent implantation, patients are at risk for stent thrombosis and/or restenosis and progression of disease in other portions of the graft. Patients should routinely receive optimal lipid-lowering therapy and aspirin, and there is an accumulating body of evidence supporting extended dual antiplatelet therapy. In a recent long-term observational study of over 400 patients who were event free at various intervals following SVG PCI, cessation of clopidogrel was associated with a clustering of death or MI within 90 days.49 Five-year event-free survival was significantly better in patients who received long-term dual antiplatelet therapy.

CONCLUSION

Recurrence of symptoms following CABG is a commonly encountered clinical problem that can often be ameliorated by PCI. Safety of graft PCI has
been enhanced by the advent of distal protection strategies and more effective and easily applied thrombectomy devices. Intermediate-term results have been improved by DESs. Although the interventional cardiologist has never been in a better position to effectively treat this patient subgroup, outcomes following SVG PCI remain suboptimal compared to native coronary intervention, engendering caution in selection of this strategy and highlighting the need for further investigation and native-vessel intervention whenever possible. Following graft PCI, long-term lipid-lowering therapy and dual antiplatelet therapy are the norm.

**MULTIPLE CHOICE QUESTIONS**

1. The use of embolic protection in saphenous vein graft (SVG) stent implantation in the randomized SAFER trial was associated with which of the following outcomes?
   A. No impact on occurrence of major adverse cardiac events (MACE)
   B. 10% reduction in MACE
   C. 20% reduction in MACE
   D. 40% reduction in MACE

2. The rate of SVG failure at 1 year after coronary artery bypass graft (CABG) in routinely performed angiographic studies was shown to be which of the following?
   A. 5%
   B. 10%
   C. 15%
   D. ≥20%

3. Use of slightly oversized stents in SVGs has been associated with which of the following outcomes?
   A. Reduced target vessel revascularization
B. Reduced periprocedural infarction  
C. Increased periprocedural MACE  
D. Reduced restenosis  

4. Use of drug-eluting stents in SVGs compared to bare metal stents was associated with which of the following in randomized trials?  
   A. Reduced mortality  
   B. Reduced myocardial infarction  
   C. Reduced stent thrombosis  
   D. Reduced restenosis  

5. When used in SVGs prior to stent implantation, atheroablative strategies were shown to be associated with which of the following?  
   A. Increased cost and reduced restenosis  
   B. Increased cost and similar restenosis  
   C. Similar cost and outcome  
   D. Increased complications  

**ANSWERS**

2. D  
3. C  
4. D  
5. B
INTRODUCTION

ST-segment elevation myocardial infarction (STEMI) composes approximately 25% to 40% of myocardial infarction (MI) presentations. There has been remarkable progress in the treatment and clinical outcomes in STEMI patients over the past 2 decades. Where available within a reasonable time period, reperfusion with percutaneous coronary intervention (PCI) has been accepted as the preferred reperfusion strategy for STEMI (Fig. 37-1). As the number of patients receiving primary PCI has increased, mortality has declined (Fig. 37-2). In-hospital and 1-year mortality rates are currently 4% to 6% and 7% to 18%, respectively.1-4 Few other interventions in clinical medicine require the complex organization of health care delivery systems and the high level of technical expertise to achieve optimum outcomes. In this chapter, we review the evidence for PCI in STEMI, including management of patients presenting to non–PCI-capable centers as well as selected technical aspects of PCI including adjunctive pharmacotherapy.
FIGURE 37-1 Reperfusion strategy for patients with ST-segment elevation myocardial infarction (STEMI). Bold arrows and boxes are the preferred strategies. *Patients with cardiogenic shock or severe heart failure initially seen at a non-percutaneous coronary intervention (PCI)-capable hospital should be transferred for cardiac catheterization and revascularization as soon as possible, irrespective of time delay from myocardial infarction (MI) onset. †Angiography and revascularization should not be performed within the first 2 to 3 hours after administration of fibrinolytic therapy. ### REPERFUSION STRATEGY

**PCI Versus Fibrinolysis Therapy**

PCI has been shown to be superior to fibrinolytic therapy in numerous large, randomized clinical trials in not only PCI-capable hospitals but also non–PCI-capable centers⁵⁻¹⁴ (Fig. 37-3). In the 2 largest trials, DANAMI-2 (Danish Acute Myocardial Infarction 2) and PRAGUE-2 (Primary Angioplasty After Transport of Patients from General Community Hospitals to Catheterization Units With/Without Emergency Thrombolysis Infusion), most of the patients presented to hospitals without PCI facilities.⁸⁻¹² A large 2009 meta-analysis of randomized controlled trials (RCT) and observational studies, comparing primary PCI (with balloon angioplasty or stenting) to
fibrinolysis, found that PCI was associated with significant reductions in short-term (≤6 weeks) mortality of 34% in RCTs and 23% in observational studies with significant reductions in long-term (>1 year) mortality (24%) and reinfarction (51%).

PCI has also been demonstrated to be superior to fibrinolysis in specific high-risk patient subgroups. There is substantial evidence of benefit for patients with anterior MI in subgroup analyses from randomized trials. For example, in the PAMI (Primary Angioplasty in Myocardial Infarction) trial, the benefit of primary percutaneous transluminal coronary angioplasty (PTCA) compared to fibrinolysis was limited to patients with anterior wall STEMI. Efficacy in anterior MI was directly addressed in a study in which 220 such patients were randomly assigned to primary PCI or alteplase. Primary PCI was associated with significant reductions in in-hospital mortality (2.8% vs 10.8%), postinfarction angina or positive exercise test (11.9% vs 25.2%), repeat revascularization (22% vs 47.7%), and, at 6 months, mortality (4.6% vs 11.7%) and revascularization (31.2% vs 55.9%). For patients with cardiogenic shock, a population in which fibrinolysis is generally not effective, observational data from the GUSTO-I (Global Utilization of Streptokinase and Tissue Plasminogen Activator for Occluded
Coronary Arteries) trial and the randomized SHOCK (Should We Emergently Revascularize Occluded Coronaries for Cardiogenic Shock?) trial demonstrated benefit with an early invasive strategy with revascularization by either PCI or coronary artery bypass grafting (CABG).\textsuperscript{17-19}

**Management at Non–PCI-Capable Centers**

**Transfer for Primary PCI**

The results from randomized trials indicate that outcomes are better when patients with STEMI who present to non-PCI hospitals are transferred to a PCI facility for primary PCI compared with being given fibrinolytic therapy at the local hospital\textsuperscript{5,6,8-12} (Fig. 37-4). The additional treatment delay of primary PCI compared with fibrinolytic therapy (door-to-balloon [D2B] time minus door-to-needle [D2N] time) in these trials ranged from 55 to 103 minutes. There are currently many statewide and nationwide efforts to improve D2B times (Fig. 37-5), including transfer from noninterventional hospitals.\textsuperscript{20-25} It has been shown that with well-defined goals, commitment from administrative and clinical leaders, standardized protocols, integrated systems of transfer, and data feedback to monitor progress, D2B times can be improved not only at PCI centers but also for patients presenting to noninterventional hospitals.\textsuperscript{5,6} In 2013, a study of 96,738 STEMI patients undergoing PCI at 515 hospitals enrolled in the ACCCathPCI Registry showed that median D2B times decreased from 83 minutes from July 2005 to June 2006, to 67 minutes from July 2008 to June 2009 (\(P < .001\)). The percentage of patients who met the guideline recommendation of ≤90 minutes increased from 59.7% to 83.1% (\(P < .001\)).\textsuperscript{26} In contrast to PCI centers, recent evidence indicates that 40% to 75% of patients transferred from non-PCI facilities continue to have a total D2B >120 minutes\textsuperscript{27-29} (Fig. 37-6).

Recommendations regarding triage of STEMI patients with an expected delay ≥120 minutes for fibrinolytic therapy versus transfer for primary PCI remains an area of some controversy. Propensity-matched data from the National Registry of Myocardial Infarction found no mortality benefit from primary PCI when the PCI-related delay (D2B-D2N time) exceeded 120 minutes (Fig. 37-7). The meta-analysis by Boersma of randomized trials comparing fibrinolytic therapy versus primary PCI also suggested that
primary PCI has a mortality advantage, with PCI-related delays of up to 2 hours.\textsuperscript{32} Data evaluating the impact of treatment delay with primary PCI on mortality suggest that patients presenting early after the onset of symptoms have much more impact than patients presenting late after the onset of symptoms.\textsuperscript{33,34} Currently, guidelines recommend that patients with cardiogenic shock, patients who are ineligible for fibrinolytic therapy, and patients who can be treated within 120 minutes should be transferred for primary PCI.\textsuperscript{5,6}

**Facilitated or Pharmacoinvasive PCI**

Most patients with acute MI (AMI) present to hospitals without interventional facilities, and the time delay required to transfer patients for
primary PCI has led to a great deal of interest in pharmacologic reperfusion combined with mechanical reperfusion (facilitated PCI). Facilitated PCI is the use of pharmacologic therapy to establish reperfusion as rapidly as possible followed by immediate PCI to maximize Thrombolysis in Myocardial Infarction (TIMI) grade 3 flow rates and to stabilize the ruptured plaque\textsuperscript{34,35} (Fig. 37-8). Primary PCI has the advantage of >97% successful reperfusion, but the challenges of availability and time delay. Fibrinolysis has the advantage of availability and rapid treatment, but the disadvantage of incomplete reperfusion (50%-70%) and the increased risk of bleeding. Patients undergoing primary PCI for AMI who arrive at the catheterization laboratory with an open versus closed infarct-related artery have higher procedural success rates, better recovery of left ventricular function, and lower early and late mortality.\textsuperscript{36} These factors led to a series of trials to examine the benefit of facilitated PCI, which has now evolved to “pharmacoinvasive” PCI.\textsuperscript{30}
FIGURE 37-8  Effect of timing of reperfusion on myocardial salvage and mortality. Mortality reduction as a benefit of reperfusion therapy is greatest in the first 2 to 3 hours after the onset of symptoms of acute myocardial infarction (MI), most likely a
consequence of myocardial salvage. The exact duration of this critical early period may be modified by several factors, including the presence of functioning collateral coronary arteries, ischemic preconditioning, myocardial oxygen demands, and duration of sustained ischemia. After this early period, the magnitude of the mortality benefit is much reduced, and as the mortality reduction curve flattens, time to reperfusion therapy is less critical. If a treatment strategy, such as facilitated percutaneous coronary intervention (PCI), is able to move patients back up the curve, a benefit would be expected. The magnitude of the benefit will depend on how far up the curve the patient can be shifted. The benefit of a shift from points A or B to point C would be substantial, but the benefit of a shift from point A to point B would be small. A treatment strategy that delays therapy during the early critical period, such as patient transfer for PCI, would be harmful (shift from point D to point C or point B). Between 6 and 12 hours after the onset of symptoms, opening the infarct-related artery is the primary goal of reperfusion therapy, and primary PCI is preferred over fibrinolytic therapy. The possible contribution to mortality reduction of opening the infarct-related artery, independent of myocardial salvage, is not shown. (Reproduced from Gersh BJ, Stone GW, White HD, Holmes DR Jr. Pharmacological facilitation of primary percutaneous coronary intervention for acute myocardial infarction: is the slope of the curve the shape of the future? JAMA. 2005;293(8):979-986. Copyright © American Heart Association, Inc. All rights reserved.)

The ASSENT-4 PCI (Assessment of the Safety and Efficacy of a New Treatment Strategy With Percutaneous Coronary Intervention) trial, which randomized patients to tenecteplase-facilitated PCI versus PCI alone found a higher incidence of death, reinfarction, and stroke with facilitated PCI.\(^{37}\) In a meta-analysis, facilitated PCI using a fibrinolytic or glycoprotein IIb/IIIa inhibitors in combination with PCI also was associated with higher rates of death, reinfarction, stroke, and bleeding compared with primary PCI alone.\(^{38}\) The major limitations of the meta-analysis were the heterogeneity of the treatment regiments, the lack of P2Y\(_{12}\) inhibitors, and the fact that most patients were treated at PCI centers. In addition, the meta-analysis included few patients with an expected delay >120 minutes, which is the specific patient population most likely to benefit from facilitated PCI.\(^{39}\) The FINESSE (Facilitated Intervention With Enhanced Reperfusion Speed to Stop Events) trial randomized patients to facilitated PCI with half-dose

### B. Theoretical advantages of pharmacoinvasive reperfusions. STEMI, ST-segment elevation myocardial infarction; TIMI, Thrombolysis in Myocardial Infarction. (Reproduced from Dauerman HL, Sobel BE. Synergistic treatment of ST-segment elevation myocardial infarction with pharmacoinvasive recanalization. J Am Coll Cardiol. 2003;42(4):646-51, Copyright © 2003, with permission from the American College of Cardiology Foundation.)
reteplase plus abciximab or abciximab alone versus primary PCI alone. Although the trial was underpowered due to slow enrollment, the 1-year mortality rates were 6.3%, 7.4%, and 7.0%, respectively ($P$ = not significant). However, there was a significant increase in TIMI major and minor bleeding in the group that received early administration of abciximab compared to the group that received abciximab at the time of primary PCI (10.1% vs 6.9%; $P$ = .008). A subsequent reanalysis of the 2452-patient FINESSE trial found a significant improvement in the 90-day composite end point (death, ventricular fibrillation after 48 hours, cardiogenic shock, and congestive heart failure) as well as mortality at 1 year with facilitated PCI in patients at high risk who presented early after the onset of symptoms.

Since that time, a number of large randomized trials have demonstrated the clinical benefit of a pharmacoinvasive strategy with fibrinolysis followed by routine coronary angiography with PCI compared with fibrinolysis alone. A meta-analysis of early routine PCI after fibrinolysis compared with fibrinolysis alone demonstrated a significant reduction in reinfarction and recurrent ischemia at 30 days with no significant increase in bleeding events. These benefits were maintained out to 12 months (Fig. 37-9).
Most recently, the STREAM (Strategic Reperfusion Early After Myocardial Infarction) trial compared a pharmacoinvasive strategy to primary PCI and found a trend in the primary end point (a composite of death, shock, heart failure, and reinfarction at 30 days), which was 12.4% versus 14.3%, but the pharmacoinvasive strategy was superior when delays were prolonged (≤55 minutes: 10.6% vs 10.3%; 55-97 minutes: 13.9% vs 17.9%; >97 minutes: 13.5% vs 16.2%). Therefore, the data currently support a pharmacoinvasive approach for the patient who cannot be treated with primary PCI within 120 minutes.

**Rescue PCI**

Rescue PCI is the mechanical reopening of an infarct artery after unsuccessful fibrinolytic therapy. Rescue PCI is differentiated from facilitated PCI in that rescue PCI is generally not planned. With current fibrinolytic therapy, successful reperfusion (TIMI grade 3 flow) is achieved in only 50% to 70% of patients. Consequently, almost half of patients who undergo fibrinolytic therapy may be candidates for rescue PCI.

In the initial experience with rescue PCI, procedural outcomes were often suboptimal, but with the introduction of stents and P2Y$_{12}$ inhibitors, procedural outcomes have improved, and several randomized trials documented improved outcomes with rescue PCI. The RESCUE (Randomized Evaluation of Salvage Angioplasty With Combined Utilization of Endpoints) trial investigators randomized 151 patients with anterior wall MI treated with fibrinolytic therapy who had an occluded infarct artery within 8 hours of symptom onset to rescue PCI versus conservative care. The rescue PCI group had a lower composite event rate of death or congestive heart failure and better exercise left ventricular ejection fraction (43% vs 38%; $P = .04$). These benefits occurred despite the fact that stents were not yet available and despite, what the authors felt, was a strong investigator bias not to randomize patients presenting very early after MI. The MERLIN (Middlesbrough Early Revascularization to Limit Infarction) trial investigators randomized patients with STEMI and failed thrombolysis (<50% ST-segment resolution at 60 minutes) to rescue PCI versus conservative care. There was no difference in 30-day mortality (the primary end point), but event-free survival was better with rescue PCI ($P = .02$). The REACT (Rescue Angioplasty Versus Conservative Treatment or Repeat Thrombolysis) trial randomized patients with STEMI and failed fibrinolysis (<50% ST-segment resolution at 90 minutes) to rescue PCI, repeat fibrinolysis, or conservative care. Patients treated with rescue PCI had a lower incidence of the composite end point (death, reinfarction, stroke, or heart failure) than patients treated with either repeat fibrinolytic therapy or conservative care. The problem with a rescue strategy is that it is frequently challenging to determine which patient has successful reperfusion, and this leads to inherent delay. Unfortunately, in real life, only 11% to 35% of patients in need of rescue PCI actually receive it.
DETECTION OF FAILED THROMBOLYSIS

A major limitation of the rescue PCI approach is the lack of a reliable noninvasive method to detect reperfusion after thrombolytic therapy. The electrocardiogram is very specific in predicting patency of the infarct artery when there is complete (>70%) resolution of ST-segment elevation, but this occurs in only a minority of patients. In most patients, there is partial or no resolution of ST-segment elevation, and the patency status of the infarct artery is uncertain. Consequently, acute angiography is often required to determine infarct artery patency.

In summary, we have made remarkable progress in the treatment of STEMI by improving timely access to PCI. In 2016, patients who present to a PCI center should undergo PCI with a D2B time of ≤90 minutes, and patients from a non-PCI hospital should be transferred to a PCI hospital if they can be treated in ≤120 minutes.\textsuperscript{5,6} For patients beyond 120 minutes, it now appears that a pharmacoinvasive approach (fibrinolysis followed by PCI within 24 hours) is the best strategy, but the ideal regimen and timing of revascularization remain areas of controversy.\textsuperscript{30,39,48}

MANAGEMENT PATHWAY

Before Procedure

The electrocardiogram (ECG) is critical to establishing a diagnosis of STEMI and triggering a management cascade. Transmission of an ECG taken in the field by emergency medical services to a PCI-capable hospital can facilitate rapid mobilization of the catheterization laboratory, thereby reducing transit time through the emergency department and thereby overall D2B time. When primary PCI is planned for patients with known or suspected AMI, a limited history and physical examination should be performed to avoid delays in initiating the catheterization procedure. Patients are given 325 mg of soluble chewable aspirin, intravenous unfractionated heparin, and sublingual nitroglycerin and are transported promptly from the emergency department to
the catheterization laboratory. A P2Y<sub>12</sub> inhibitor should be given as soon as possible based on evidence from multiple trials, discussed later, since the rate of emergent CABG following primary PCI for STEMI is low.

**Procedural Considerations**

**Radial Versus Femoral Access**

Bleeding portends a worse prognosis in STEMI. Access site–related bleeding can be reduced via a radial approach. Evidence supporting better outcomes with radial catheterization comes from a 2015 meta-analysis of 4 large, contemporary, multicenter trials and trials of patients (n = 17,133) with acute coronary syndromes<sup>53-57</sup> (Fig. 37-10). Comparing radial with femoral access, the risk was lower in terms of major bleeding (relative risk [RR], 0.57; 95% confidence interval [CI], 0.37-0.88), death (RR, 0.73; 95% CI, 0.59-0.90), and major adverse cardiac events (MACE; RR, 0.86; 95% CI, 0.75-0.98). However, in certain clinical situations, such as a patient with cardiogenic shock or cardiac arrest, a transfemoral approach may be preferable to facilitate use of larger guide catheters and peripheral hemodynamic support devices that are not able to be delivered radially.

Radial versus femoral access for primary percutaneous interventions in ST-segment elevation myocardial infarction patients: a meta-analysis of...
Aspiration Thrombectomy

Intracoronary thrombus is found in a significant proportion of patients with STEMI. Thrombus may obstruct distal blood flow and increases subsequent myocardial ischemia. Although aspiration thrombectomy may reduce thrombus burden, there is a lack of evidence to demonstrate a significant clinical benefit from routine use. The TOTAL (Randomized Trial of Routine Aspiration Thrombectomy With PCI Versus PCI Alone in Patients With STEMI Undergoing Primary PCI), TASTE (Thrombus Aspiration in ST-Elevation Myocardial Infarction in Scandinavia), and TAPAS (Thrombus Aspiration During Percutaneous Coronary Intervention in Acute Myocardial Infarction Study) trials are the largest studies of manual thrombectomy in STEMI.  

In the TAPAS trial (n = 1071), the primary end point of a myocardial blush grade of 0 or 1 (defined as absent or minimal myocardial reperfusion, respectively) occurred in 17.1% of the patients in the thrombus-aspiration group and in 26.3% of those in the conventional PCI group (P < .001). TAPAS showed a significant reduction in the rate of death from any cause at 1 year with thrombus aspiration, but this finding must be interpreted in the context of the trial being underpowered for hard clinical end points. In a 2013 meta-analysis of trials that included TAPAS but not TASTE or TOTAL (n = 3936), the risks of all-cause mortality (the primary end point) and MACE (a composite of death, MI, and target vessel revascularization) were lower with aspiration thrombectomy (risk ratio, 0.71; 95% CI, 0.51-0.99 vs 0.76; 95% CI, 0.63-0.92). However, limitations of the meta-analysis include the lack of inclusion of patient-level data and the inclusion of non-peer-reviewed trials. Subsequently, 2 much larger contemporary trials have shown no benefit.

In the TASTE trial (n = 7244), the primary end point of death from any cause at 30 days was similar in both groups (2.8% vs 3.0%, respectively; hazard ratio [HR], 0.61; 95% CI, 0.34-1.07). Similarly, there was no difference in mortality at 1 year (5.3% vs 5.6%, respectively; HR, 0.94; 95% CI, 0.78-1.15). Most recently, in the largest trial, TOTAL (n = 10,732), the primary outcome (a composite of cardiovascular death, recurrent MI,
cardiogenic shock, or New York Heart Association class IV heart failure within 180 days) occurred with similar frequency in both groups (347 vs 351 events, respectively; HR, 0.9; 95% CI, 0.85-1.15) among the 10,063 patients who underwent PCI. Stroke rates were higher at 30 days (33 vs 16 events; HR, 2.06; 95% CI, 1.13-3.75) and at 180 days in patients who received thrombectomy (52 vs 25 events; HR, 2.08; 95% CI, 1.29-3.35). The 2015 American College of Cardiology Foundation/American Heart Association/Society for Cardiac Angiography and Interventions focused update on primary PCI for patients with STEMI recommends against performing routine manual aspiration thrombectomy due to disparities in clinical data.

**Drug-Eluting Stents Versus Bare Metal Stents**

Drug-eluting stents (DESs) are generally preferred to bare metal stents (BMSs) for the majority of PCI procedures, due to reduced rates of restenosis and target vessel revascularization. In the era of first-generation DESs, rates of stent thrombosis were higher than with BMSs, and there was concern that this difference could be translated to patients with STEMI, in whom the risk of stent thrombosis is higher than in patients with stable disease due to higher platelet reactivity and a generalized proinflammatory state. However, the introduction of second-generation DESs has resulted in improved clinical outcomes and excellent clinical evidence to support the preferential use of DESs in STEMI. A 2013 comprehensive network meta-analysis of STEMI patients found that when comparing cobalt chromium everolimus-eluting stents (CoCr-EES) or phosphorylcholine polymer–based zotarolimus-eluting stents (PC-ZES) to BMS, the 1-year risk of cardiac death or MI was reduced (odds ratio [OR], 0.63; 95% CI, 0.42-0.92 vs 0.86; 95% CI, 0.50-1.49), the 1-year risk of target vessel revascularization was reduced (OR, 0.45; 95% CI, 0.29-0.66 vs 0.60; 95% CI, 0.34-1.05), and the 1-year risk of definite stent thrombosis was reduced (OR, 0.32; 95% CI, 0.11-0.78 vs 0.44; 95% CI, 0.12-1.79). There were trends toward lower 1-year rates of cardiac death or MI, definite stent thrombosis, and target vessel revascularization with CoCr-EES compared to PC-ZES (OR, 0.73; 95% CI, 0.40-1.30; OR, 0.72; 95% CI, 0.17-3.16; and OR, 0.74; 95% CI, 0.38-1.42, respectively; Fig. 37-11). Current evidence suggests the majority of patients with STEMI will benefit from a newer generation DES.

Treatment of Nonculprit Lesions

Approximately 40% to 60% of patients presenting with STEMI have multivessel coronary artery disease with other nonculprit lesions that may be angiographically or physiologically significant. These patients are at greater risk of mortality and reinfarction than those with single-vessel disease. Observational studies, performed prior to the randomized trials and their meta-analyses, concluded that culprit-only PCI, as opposed to multivessel PCI, at the time of initial reperfusion led to better outcomes. However, when patients who were treated with staged PCI during the hospitalization were analyzed separately, short- and long-term outcomes favored multivessel revascularization compared with culprit-only strategy.

Eight published randomized trials of patients with multivessel disease, with DANAMI-3–PRIMULTI (Primary PCI in Multivessel Disease), PRAMI (Preventive Angioplasty in Acute Myocardial Infarction), and CvLPRIT (Complete Versus Lesion-Only Primary PCI Trial) being the 3 largest, have compared culprit-only with complete revascularization. A 2015 meta-analysis of 7 randomized trials with 1303 patients (excluding DANAMI-3–PRIMULTI) reported that, at a median follow-up of 12 months, complete revascularization at the time of primary PCI reduced the odds of MACE (death, recurrent MI, and repeat revascularization; OR, 0.59; 95% CI, 0.36-0.97), driven principally by a reduction in recurrent MI (OR, 0.48) and repeat revascularization (OR, 0.51; Fig. 37-12). Furthermore, complete revascularization was associated with a nonsignificant trend toward reduced cardiovascular mortality (OR, 0.54; 95% CI, 0.26-1.10). However, questions remain as to the optimal timing of complete revascularization, value of fractional flow reserve (FFR) in the acute setting, and approach to chronic
total occlusions. In the absence of compelling evidence, a reasonable approach would involve complete revascularization in the same hospital admission, FFR of any intermediate lesions at a separate time from the index procedure, and intervention on chronic total occlusions where the occluded vessel subtends a large area of viable myocardium.

**Complications**
No Reflow

No reflow (TIMI grade 0-1 flow) or slow reflow (TIMI grade 2 flow) may occur transiently or may persist after primary PCI for AMI in 10% to 25% of patients. This is generally due to microvascular dysfunction from spasm, distal embolization, or endothelial injury and is associated with poorer recovery of left ventricular function and a higher incidence of post-MI complications\(^\text{75}\) (Fig. 37-13). When slow reflow or no reflow occurs, TIMI grade 3 flow usually can be reestablished with the use of intracoronary verapamil (100-200 μg boluses), adenosine (10-20 μg boluses), nicardipine (200 μg boluses), or nitroprusside (50-100 μg boluses) given through the guiding catheter, an infusion catheter, or the distal lumen of the balloon catheter (for no reflow).\(^\text{76}\) The no-reflow phenomenon may sometimes be prevented by early administration of antiplatelet agents or by preadministration of adenosine or verapamil.\(^\text{77}\) Caution should be used in stenting lesions with no reflow, because poor run-off may increase the likelihood of stent thrombosis.
Cardiogenic Shock

The mortality of patients with STEMI complicated by cardiogenic shock approaches 50%. In addition to standard care measures for routine STEMI, prompt treatment of hypotension and resulting hypoperfusion is essential. Pharmacologic and mechanical means of circulatory support are available to maintain coronary perfusion and ultimately vital organ perfusion. Although the question of the optimal inotropic agent is controversial, in most cases, a vasopressor agent such as norepinephrine is the preferred first-line agent. Mechanical support options in the acute setting include intra-aortic balloon pump and percutaneous left ventricular assist devices (Impella, Abiomed, Danvers, MA; Tandem Heart, CardiacAssist, Pittsburg, PA). In the
subacute setting, percutaneous cardiopulmonary bypass with extracorporeal membranous oxygenation or surgically implanted left ventricular/biventricular assist devices may provide a bridge to recovery or further therapy.\textsuperscript{78}

**ADJUNCTIVE PHARMACOLOGIC THERAPY**

**Antiplatelets**

**Dual Antiplatelet Therapy**

Aspirin should be given immediately with a loading dose of 162 to 325 mg. Ideally, the first tablet should be chewed or crushed to rapidly establish an effective plasma concentration.

A platelet P2Y\textsubscript{12} receptor blocker (clopidogrel, prasugrel, or ticagrelor) should be given to all patients with STEMI, irrespective of treatment strategy. Benefits of P2Y\textsubscript{12} inhibitor therapy were first shown in the CURE (Clopidogrel in Unstable Angina to Prevent Recurrent Events) trial\textsuperscript{79} in patients treated with a clopidogrel. Prasugrel and ticagrelor are newer oral antiplatelet agents that inhibit platelet aggregation more rapidly with greater potency than clopidogrel.\textsuperscript{79} Prasugrel was compared to clopidogrel in the TRITON (Trial to Assess Improvement in Therapeutic Outcomes by Optimizing Platelet Inhibition with Prasugrel)–TIMI-38 trial of 13,608 moderate- to high-risk acute coronary syndrome patients undergoing PCI, including 3534 with STEMI.\textsuperscript{80} Prasugrel was given with a loading dose of 60 mg and maintenance dose of 10 mg/d, whereas clopidogrel was given with a 300-mg loading dose and a 75-mg/d maintenance dose (current guideline recommendations are for a clopidogrel loading dose of 600 mg). The primary efficacy end point of cardiovascular death, nonfatal MI, or nonfatal stroke occurred significantly less often in patients treated with prasugrel at 15-month follow-up (10% vs 12.4%; HR, 0.79; 95% CI, 0.65-0.97), driven primarily by a significant reduction in nonfatal MI (7.4% vs 9.7%). In the STEMI subgroup, there was no significant difference in the rate of major
bleeding (TIMI) unrelated to CABG at 30 days (HR, 1.11; 95% CI, 0.70-1.77), although the overall trial population did have a significantly increased risk of bleeding and transfusion requirements. In addition, the rate of definite or probable stent thrombosis was significantly reduced in the prasugrel group (1.6% vs 2.8%; \( P < .001 \)).

Ticagrelor was compared to clopidogrel in over 18,000 ACS patients in the PLATO (Platelet Inhibition and Patient Outcomes) trial, 38% of whom had STEMI with intended PCI. Patients were randomly assigned to ticagrelor 180 mg loading dose followed by 90 mg twice daily or clopidogrel 300 mg loading dose followed by 75 mg daily. As in the entire cohort of acute coronary syndrome patients, the primary end point (MI, stroke, or cardiovascular death) occurred less often with ticagrelor (9.4% vs 10.8%). There was no significant difference in the rate of non–CABG-related TIMI major bleeding between ticagrelor and clopidogrel in the subgroup of patients with STEMI (HR, 1.09; 95% CI, 0.80-1.48), although the overall trial population did experience a modest increase in non–CABG-related bleeding (HR, 1.25; \( P = .03 \)). Unfortunately, there are limited data that directly compare P2Y\(_{12}\) inhibitors in STEMI patients. A recent network meta-analysis of 37 studies including 88,402 patients indicates the strongest data are with prasugrel, but the presence of a black box warning regarding use in patients with previous cerebrovascular accident is a limitation (Fig. 37-14).
FIGURE 37-14 Meta-analysis results of major adverse cardiac events (MACE) between prasugrel with other P2Y$_{12}$ inhibitors stratifying studies by (A) randomized
trials only, (B) transradial (TR) access used ≥50%, (C) bivalirudin use ≥50%, (D) bivalirudin use <50%, (E) glycoprotein IIb/IIIa inhibitors (GPI) use ≥50%, (F) GPI use <50%, (G) drug-eluting stent (DES) use ≥50%, and (H) bare metal stent (BMS) use ≥50% patients. Optimal P2Y12 inhibitor in patients with ST-segment elevation myocardial infarction undergoing primary percutaneous coronary intervention: a network meta-analysis. *JACC Cardiovasc Interv*. 2016;9(10):1036-1046.)

Finally, cangrelor, an intravenous P2Y₁₂ inhibitor, has been recently approved based on the reduction of the primary end point of a composite of MI, ischemia-driven revascularization, and death at 48 hours in the CHAMPION-PHOENIX (Clinical Trial Comparing Cangrelor to Clopidogrel Standard Therapy in Subjects Who Require Percutaneous Coronary Intervention) trial.⁸⁴,⁸⁵ Cangrelor has the advantage of immediate onset with a very short half-life and consistent pharmacokinetics and may be particularly useful in patients with STEMI.

### Glycoprotein IIB/IIIa Inhibitors

The majority of trials favoring glycoprotein IIb/IIIa inhibitors to placebo were performed prior to the routine use of P2Y₁₂ inhibitors, particularly the more novel and effective platelet inhibitors such as prasugrel and ticagrelor. Evidence supporting the use of abciximab in patients with STEMI undergoing primary PCI with either balloon angioplasty or stenting who are not pretreated with a P2Y₁₂ inhibitor comes from a meta-analysis of over 27,000 patients in 11 trials that found that abciximab, compared to placebo, significantly lowered the rate of death at 30 days (2.4% vs 3.4%; OR, 0.68; 95% CI, 0.47-0.99).⁸⁶ There is less evidence of benefit from either tirofiban or eptifibatide.⁸⁷,⁸⁸ In the HORIZONS-AMI (Harmonizing Outcomes With Revascularization and Stents in Acute Myocardial Infarction) and EUROMAX (European Ambulance Acute Coronary Syndrome Angiography) trials with P2Y₁₂ inhibitor loading, bivalirudin was generally superior to heparin plus glycoprotein IIb/IIIa inhibition.⁸⁹,⁹⁰ The BRIGHT (Bivalirudin in Acute Myocardial Infarction Versus Glycoprotein IIb/IIIa and Heparin Trial) study showed no benefit of adding glycoprotein inhibition to unfractionated heparin.⁹¹

However, some patients, such as those with significant thrombus burden
or persistent no reflow at time of PCI, may benefit from glycoprotein IIb/IIIa inhibitor.

Although there are no head-to-head trials for direct comparison, data from small randomized trials with surrogate end points and from observational studies suggest equivalent efficacy among abciximab, tirofiban, and eptifibatide.\textsuperscript{92}

\textbf{Anticoagulation}

\textbf{Heparin}

Intravenous unfractionated heparin is given immediately prior to and during the procedure to prevent acute vessel closure due to thrombosis. Dose adjustment and monitoring are usually performed via serial checks of the activated clotting time (ACT). Careful monitoring of the ACT is important because some patients have persistent thrombin activity despite heparin therapy.

\textbf{Bivalirudin}

A number of large trials (HORIZONS-AMI, EUROMAX, HEAT PPCI [How Effective Are Antithrombotic Therapies in Primary PCI], BRIGHT, and MATRIX) have examined the effectiveness of bivalirudin in the AMI setting, usually compared to heparin alone or, in some cases, heparin plus a glycoprotein IIb/IIIa inhibitor.\textsuperscript{89-91,93-96} A 2014 meta-analysis (published before MATRIX) of 16 trials involving nearly 34,000 patients (the majority with an acute coronary syndrome)\textsuperscript{90} found that when compared to heparin, bivalirudin was associated with an increase in the risk of the primary composite outcome of death, MI, ischemia-driven revascularization, and stent thrombosis at 30 days (risk ratio, 1.09; 95\% CI, 1.01-1.17). All components of the composite were increased except death. Bivalirudin was associated with an increase in the risk of stent thrombosis (risk ratio, 1.38; 95\% CI, 1.09-1.74), with most events being acute. Favoring bivalirudin was a decrease in the overall risk of major bleeding (risk ratio, 0.53; 95\% CI, 0.47-0.61; \(P < .0001\)), although this was compared to heparin plus glycoprotein IIb/IIIa inhibitor. However, when considering studies in which glycoprotein
IIb/IIIa inhibitor use was planned in both arms, there was no difference (risk ratio, 1.07; 95% CI, 0.87-1.31). In contrast, a recent comprehensive analysis of all the available data suggests a significant reduction in bleeding with or without glycoprotein IIb/IIIa inhibitors (Fig. 37-15A). Overall event rates are similar, but there was a significant reduction in mortality in both HORIZONS-AMI and MATRIX-STEMI with bivalirudin (Fig. 37-15B). The HEAT trial was an outlier in that it was a single-center trial with only a brief infusion of bivalirudin and no pretreatment with a P2Y$_{12}$ inhibitor. In summary, the optimal antithrombin regimen will continue to be an area of controversy. Although overall the data appear to support the use of bivalirudin, the significantly higher cost compared to heparin also impacts the decision.
FIGURE 37-15 A. **CONCLUSION**

In summary, over the past 2 decades, we have made remarkable progress in the treatment of STEMI through improvements in adjunctive pharmacology and stent technology but primarily by producing timely access to PCI. Still, there are opportunities to improve outcomes even further, in particular with transfer from non-PCI centers and treatment of multivessel disease as well as improvements in the care of patients with cardiogenic shock and out-of-hospital cardiac arrest.

MULTIPLE CHOICE QUESTIONS

1. Which of the following is the most appropriate management strategy for a patient presenting 180 minutes following the onset of symptoms to a non–percutaneous coronary intervention (PCI)–capable hospital located 60 minutes away from a PCI-capable hospital?
   A. Immediate transfer to a PCI-capable hospital
   B. Fibrinolysis
   C. Facilitated PCI
   D. Fibrinolysis with rescue PCI as indicated

2. Which of the following has not been demonstrated to be an advantage of a radial compared to a femoral approach in STEMI?
   A. Reduced rate of stroke
   B. Reduced rate of death
   C. Reduced rate of major adverse cardiac events (MACE)
   D. Reduced rate of bleeding

3. Which of the following drugs has not been shown to be effective for treatment of no-reflow phenomenon?
   A. Adenosine
B. Verapamil  
C. Nitroprusside  
D. Lignocaine

4. Which of the following antiplatelet agents is least appropriate for a patient with a prior history of stroke?  
   A. Clopidogrel  
   B. Ticagrelor  
   C. Prasugrel  
   D. Aspirin

5. Which of the following P2Y$_{12}$ inhibitors can be administered intravenously?  
   A. Prasugrel  
   B. Clopidogrel  
   C. Ticagrelor  
   D. Cangrelor

**ANSWERS**

1. A

   The results from randomized trials indicate that outcomes are better when patients with ST-segment elevation myocardial infarction (STEMI) who present to non-PCI hospitals are transferred to a PCI facility for primary PCI compared with being given fibrinolytic therapy at the local hospital. Current guidelines recommend the door-to-balloon (D2B) time be ≤90 minutes for patients presenting to a PCI facility and ≤120 minutes for patients transferred from a non-PCI facility. Currently, guidelines recommend that patients with cardiogenic shock, patients who are ineligible for fibrinolytic therapy, and patients who can be treated within 120 minutes be transferred for primary PCI.

2. A

   Evidence supporting better outcomes with radial catheterization comes from a 2015 meta-analysis of 4 large, contemporary, multicenter trials and trials of
patients. Comparing radial with femoral access, the risk was lower in terms of major bleeding (relative risk [RR], 0.57; 95% confidence interval [CI], 0.37-0.88), death (RR, 0.73; 95% CI, 0.59-0.90), and MACE (RR, 0.86; 95% CI, 0.75-0.98).

3. D

No reflow is generally due to microvascular dysfunction from spasm, distal embolization, or endothelial injury. No reflow usually can be reestablished with the use of intracoronary verapamil, adenosine, nicardipine, or nitroprusside given through the guiding catheter or an infusion catheter or the distal lumen of the balloon catheter.

4. C

Unfortunately, there are limited data that directly compare P2Y₁₂ inhibitors in STEMI patients. However, a recent network meta-analysis of 37 studies including 88,402 patients indicates the strongest data are with prasugrel, but the presence of a black box warning regarding use in patients with previous cerebrovascular accident is a limitation.

5. D

Cangrelor, an intravenous P2Y₁₂ inhibitor, has been recently approved based on the reduction of the primary end point of a composite of myocardial infarction, ischemia-driven revascularization, and death at 48 hours in the CHAMPION-PHOENIX trial. Cangrelor has the advantage of immediate onset with a very short half-life and consistent pharmacokinetics and may be particularly useful in patients with STEMI.
INTERVENTION FOR BIFURCATION LESIONS

Bifurcation lesions have been reported to constitute 15% to 20% of all percutaneous coronary interventions (PCI). Since they are associated with an increased risk of procedure-related complication, especially side branch (SB) occlusion after stent implantation, treating these distinct lesion subsets has been a significant challenge for interventional cardiologists. Rapid advancements in novel techniques, devices, and adjunctive pharmacotherapies have considerably reduced the risk of acute complications, restenosis, and stent thrombosis (ST), and ultimately have led to the extension of PCI’s clinical application for various complex bifurcation lesions. Moreover, interventional cardiologists have learned lessons from extensive clinical experiences in that many important anatomic features, including relative plaque distribution to the bifurcation, degree of SB angulation, and severity or length of SB lesion, should be taken into account.
for technical success and favorable clinical outcome.\(^2\) Considering that currently there are no clear guidelines to address the use of particular interventional techniques with regard to the specific anatomy of a given bifurcation lesion, every effort should be made to obtain understanding of the technical, clinical, and fundamental aspects of the management of bifurcation disease.

**Definition and Classification of Bifurcation Lesions**

According to the consensus of the European Bifurcation Club, bifurcation coronary lesion can be defined as “a coronary artery narrowing occurring at, or adjacent to, a significant division of a major epicardial coronary artery.” A “significant SB” is a branch that the operator does not want to lose in a global context of a particular patient (e.g., symptoms, comorbidity, diameter and length of SB, size of the myocardial mass supplied by the SB, location of ischemia, viability of the supplied myocardium, collateralizing vessel, left ventricular function, results of functional tests).\(^3\)

Although several classification systems of bifurcation lesions have been proposed to facilitate PCI, planning the treatment approach according to the angulation of the bifurcation and the degree of plaque burden seems to be most practical (Fig. 38-1). The Y-shaped lesion is defined when the SB and the main vessel (MV) angulation is less than 70%, while that of the T-shaped lesion is greater than 70%. In general, the risk of atheromatous plaque shifting (snow-plow effect) and deterioration of SB flow during stent implantation is higher in Y-shaped lesions. Furthermore, it is technically difficult to achieve the whole coverage of the SB ostium using popular T-stenting in these lesions. Although the risk of SB occlusion is relatively low in T-shaped lesions, wire access can be problematic when large plaque burden is present at a significant SB ostium. The location of stenosis in each of the 3 segments that constitute the bifurcation is also crucial for the treatment strategy, and 7 lesion types, with each type assumed to be associated with a specific treatment technique, have been described in the Medina classification, the simplest and most widely used classification system\(^4\) (Fig. 38-2).
FIGURE 38-1 Lesion description according to the angle between the main vessel and side branch (SB).

- T-shape
  - Difficult SB access
  - Less plaque shifting
  - T-stenting better

- Y-shape
  - Easier SB access
  - More plaque shifting
  - Culotte or crush better
The Medina classification for bifurcation lesions. The designation “1” indicates the presence of stenosis (diameter stenosis ≥50% by visual estimation), and “0” indicates the absence of stenosis. MV, main vessel; SB, side branch.

**One-Stent Simple Crossover Technique**

The most frequently used approach to treat a bifurcation lesion is to place a stent in the MV while covering the ostium of the SB with the stent (Fig. 38-3). Although this treatment strategy may be very useful in lesions involving a normal SB ostium, it can be used after the predilation in lesions with SB ostial stenosis. In case of significant flow limitation to the SB after MV stenting, further treatment of the SB with a balloon or additional stent (provisional stenting) may be performed. In contrast, even if the diameter stenosis of the SB is up to 70% to 80% after MV stenting, the long-term patency and clinical outcome are usually excellent if the stenosis is confined
to the ostium and the flow is not impaired. Therefore, treating such lesions with stent implantation is not recommended.

FIGURE 38-3 Single-stent implantation covering the side branch. Stent implantation in the main vessel (B) is performed with double-wire technique (A). After retrieval of the wire from the side branch, a new wire is inserted into the side branch through the stent strut. Thereafter, optional kissing balloon dilation can be performed (C and D).

Since SB compromise occurs to some extent unpredictably, a decision to protect the SB by placing a wire to be left in until the procedure on the MV has been completed, including high-pressure postdilation, should be made carefully. In general, an SB <2.0 mm in diameter and supplying a small amount of viable myocardium is rarely considered for protection, whereas relatively large SBs (≥2.5 mm in diameter) with an ostial diameter stenosis ≥50% need to be considered for protection in case of further specific treatment. The jailed wire in the SB can act as a marker of the occluded SB and straighten the angle between the SB and the MV to facilitate further access. In the provisional technique, rewiring through the distal strut (close to the carina) following the MV stenting is strongly recommended since it creates better SB scaffolding compared with the proximal wire crossing.

One- and Two-Stent Techniques: Clinical Trials in the Drug-Eluting Stent Era

The sirolimus-eluting stent bifurcation study was the first randomized trial that was conducted to assess the feasibility and safety of drug-eluting stent
(DES) implantation for bifurcation lesions. In this study, 22 of the 43 patients who were randomly assigned to the strategy of single stent implantation in the MV with balloon angioplasty for the SB (group B) were crossed over to the strategy of T-stenting in both branches with 2 stents (group A) due to flow impairment or >50% residual diameter stenosis in the SB after stent implantation into the MV. Overall, 63 patients were treated with 2 stents, and 22 patients were treated with 1 stent. Although the high crossover rate (51.2%) made it difficult to directly compare the 2 groups, the in-segment restenosis rate at 6 months did not differ significantly between the 2 treatment groups (28.0% in group A vs 18.7% in group B; \( P = .53 \)). The researchers in this study postulated that the relatively high restenosis rate at the SB in the 2-stent technique group was caused by the incomplete coverage of the ostium of the SB since T-stenting may leave a gap between the 2 stents at the bifurcation. To address this problem, other bifurcation stenting techniques have been introduced. In the Nordic Bifurcation Trial (NORDIC), the investigators randomized 413 patients with complex lesions to MV-only stenting (n = 207) versus MV and SB stenting using crush, culotte, Y, or other techniques (n = 206) with sirolimus-coated stents. In the MV-only treatment arm, the threshold for crossover to SB stenting was high and was allowed only if the Thrombolysis in Myocardial Infarction (TIMI) flow grade was 0 following SB dilation. Overall, only 4.4% of the patients in the MV-only stenting group received a stent in the SB. The combined rate of MV restenosis (stenosis >50% in diameter) and SB occlusion after 8 months was low and similar in both the provisional and routine 2-stented groups (5.3% vs 5.1%; \( P = \text{not significant} \)). Long-term results of the Nordic Bifurcation Study were recently published and showed comparable incidences of all-cause mortality (5.9% vs 10.4%; \( P = .16 \)), non–procedure-related myocardial infarction (MI; 4% vs 7.9%; \( P = .09 \)), target vessel revascularization (TVR; 13.4% vs 18.3%; \( P = .14 \)), and definite ST (3% vs 1.5%; \( P = .32 \)) over 5 years between the 1-stent (n = 202) and 2-stent (n = 202) approaches. The investigators therefore concluded that excellent clinical and angiographic results appeared to be obtained with the percutaneous treatment of de novo coronary artery bifurcation lesions, independent of the stenting strategy that was used. However, the 1-stent strategy was associated with reduced procedure and fluoroscopy times and lower rates of procedure-related biomarker elevation.

The BBC ONE (British Bifurcation Coronary Study: Old, New, and
Evolving Strategies) study further provided evidence for the preference of 1-stent technique for bifurcations. A total of 500 patients were randomized either to a simple or a complex stenting strategy (crush or culotte) using paclitaxel-eluting stents. At 9 months of clinical follow-up, there was a significant difference between the 2 groups in terms of the primary end point (a composite of death, MI, and target vessel failure; 8.0% in the simple group vs 15.2% in the complex group; hazard ratio [HR], 2.02; 95% confidence interval [CI], 1.17-3.47; \( P = .009 \)), MI (3.6% vs 11.2%; \( P = .001 \)), and inhospital major adverse cardiovascular events (MACE; 2.0% vs 8.0%; \( P = .002 \)). A meta-analysis of previous randomized studies demonstrated that a provisional 1-stent approach was comparable to a 2-stent approach in terms of mortality, repeat revascularization, and quality of life. However, the 1-stent technique was superior in regard to the risk of periprocedural MI and ST. Based on these studies, the 1-stent technique with provisional SB stenting is currently recommended as the primary approach for most bifurcation coronary lesions. However, it should be noted that the results of the randomized studies are limited in generalizability due to selective inclusion criteria. Because the aforementioned randomized studies could not include all patients with bifurcations, patients with complex anatomies who may have potentially benefited from the 2-stent approach might have been excluded in enrollment. Moreover, a lack of enough experience in 2-stent techniques across operators might have inflated the risk of adverse events for patients.

The 2-stent approach in provisional or planned situations is still a viable option for a minority of patients who have complex true bifurcations. In 1170 true bifurcation lesions from the Coronary Bifurcation Stenting (COBIS) registry, 17.3% of lesions were treated with 2-stent approaches. The types of 2-stent approaches were T-stenting (47.8%), crush technique (34.1%), V-stenting (14.7%), and culotte stenting (3.4%). There were no differences in the rates of death, MI, target lesion revascularization (TLR), and their composite of MACE. Even in the randomized studies, for patients assigned to a 1-stent approach, a 2-stent technique was eventually performed in 3.5% of patients from the NORDIC and BBC ONE studies and 31% from the CACTUS (Coronary Bifurcations: Application of the Crushing Technique Using Sirolimus-Eluting Stents) study by the operators’ decision. In the recently updated randomized Optimal Stenting Strategy for True Bifurcation Lesions (PERFECT) trial, 28.2% of patients with true bifurcation lesions who
were randomized to 1-stent approach eventually received SB stenting. The 2-stent approach can be attempted for bifurcation lesions if the operator is concerned about the acute complications, including hemodynamic compromise or periprocedural MI in the circumstances of SB loss. In the COBIS registry, SB occlusion occurred in 8.4% of 2227 bifurcation lesions after MV stenting during 1-stent treatment. Preprocedural percent diameter stenosis of the SB (≥50%) and SB lesion length were independent predictors of SB occlusion, with odds ratios of 2.34 and 1.03, respectively. Moreover, SB occlusion was associated with an increase in the adjusted HR of 2.34 (95% CI, 1.15-4.77; \( P = .02 \)) for the composite of cardiac death or MI and 6.19 (95% CI, 2.00-19.13; \( P = .002 \)) for ST. In the PERFECT randomized trial, patients treated with provisional SB stenting experienced greater procedural time and contrast amount than the planned 2-stent approach. These findings indicate that bifurcations with complex SB stenosis, which are expected to be compromised or occluded during the 1-stent approach based on angiography with or without intravascular ultrasound (IVUS), may be an indication for a planned 2-stent approach. In general, if the SB is large enough (reference diameter ≥2.5 mm), has significant stenosis extending beyond the ostium (10-20 mm or more), supplies sufficient size of the territory to justify stent implantation, and/or has an unfavorable angle for recrossing after MV stenting, the 2-stent technique can be considered.

Two-Stent Techniques

Current 2-stent techniques using DES include culotte, crush and its variants, T-stenting, and V-stenting or simultaneous kissing stent (SKS) techniques. Classic crush is now rarely performed, and variants of the crush technique, such as mini-crush, step crush, and double kissing (DK) crush techniques, are preferred. The potential advantages and disadvantages of each technique are summarized in Table 38-1. Because of lack of studies on the comparative outcomes of diverse 2-stent techniques, selection of proper stenting technique should be dependent on the patient’s clinical manifestation, bifurcation morphology, and operator’s preference. In the same context, since the favorable outcome is more related to the successful procedure itself, not with the type of 2-stent technique, a careful angiographic evaluation is required to identify disease severity, vessel size, and the angle of both branches before the treatment of bifurcation lesions with 2-stent technique.
### T-Stenting Technique

The technique of T-stenting is better suited to treat the SBs that originate with an angle close to 90°. The deployment of 2 stents in the SB and the MV can be performed in different steps. Since this method is most frequently used for provisional SB stenting, the majority of T-stenting is performed with MV stenting first. However, with the intention to treat with a 2-stent technique at the beginning, initial deployment of the SB stent is preferred to avoid re-crossing the stent strut in the MV (Fig. 38-4). The technique is safe and eliminates the difficulty of advancing the second stent. However, this strategy may carry the risk of incomplete coverage of the SB ostium. This small gap between the stent implanted in the MV and the one implanted in the SB may result in an uneven distribution of the drug, which leads to late restenosis at the SB ostium (Fig. 38-5).
technique is a modification of the T-stenting technique to overcome this limitation and is based on an intentional minimal protrusion (1-2 mm) of the SB stent within the MV.\textsuperscript{21}

**FIGURE 38-4** T-stenting technique. The first stent is advanced into the side branch, and a second stent is advanced into the main vessel covering the ostium of the side branch (A). The first stent is carefully positioned right at the ostium of the side branch or slightly within the main vessel and dilated (B). The balloon and wire are removed from the side branch, and then the stent in the main vessel is deployed (C). The side branch is rewired, and kissing balloon dilation of both branches can be performed (D).

**FIGURE 38-5** Limitation of T-stenting technique. A. Restenosis was most frequent at the junction between the 2 implanted stent (from SIRIUS bifurcation study). B. To prevent the potential gap at the ostial side branch, the first stent should cover the
The culotte technique can be a suitable approach when there is small discrepancy in vessel size between the proximal MV segment and SB (Fig. 38-6). This technique provides full coverage of the bifurcation at the expense of an excess of metal component in the proximal MV. The culotte technique is very useful for all angles of bifurcation lesions and can be applied either in the provisional SB stenting strategy or planned 2-stent technique. The more angulated branch is usually stented first. However, if predilation results in a dissection or occlusion in 1 branch, this branch should be stented first in case of the difficulty of rewiring through the stent struts. It is advisable to make minimal overlap of stents in proximal MV segment whenever possible.

**FIGURE 38-6** Culotte technique. After predilation (A), the wire is removed from the straighter branch and the more angulated branch is stented (B). After removing the wire from the stented branch, a wire is recrossed through the stent strut. The stent strut should be dilated toward the nonstented branch. A second stent is advanced and expanded into the nonstented branch (C). Finally, the first stented branch is rewired, and final kissing balloon inflation is performed (D).

**Crush Technique**

Crush technique is the most widely used 2-stent technique. Despite the complex procedural steps, this technique can be applied to any true
bifurcations requiring a 2-stent technique with complete lesion coverage for SB ostium (Figs. 38-7 and 38-8). Because of some limitations of the classic crush technique, its variants, such as mini-crush, step crush, or DK crush, are preferred. The mini-crush technique is recommended over classic crush to avoid the large area of 3 strut layers in the proximal MV. Using the step crush technique, in which the SB stent strut is crushed by MV balloon instead of stent, separate manipulation of 2 stents is possible and allows precise placement of each stent using 6-Fr guiding catheter (Fig. 38-9). The DK crush technique may aid rewiring into the SB after MV stenting and also increases the expanded stent cell area in front of the SB detectable at follow-up. In any crush techniques, final kissing balloon inflation (FKI) is mandatory because it allows better strut contact against the ostium of the SB and better drug delivery. FKI may also correct the stent deformation and ensure optimal stent scaffolding. As compared with the culotte technique, the mini-crush technique showed similar incidence of MACE (composite of death, MI, TVR, or ST) at 6 months (4.3% for crush vs 3.7% for culotte; \( P = .87 \)) in the NORDIC II randomized study. However, a recent DKCRUSH-III randomized study showed that DK crush (n = 210) was superior to the culotte technique (n = 209) in terms of 1-year MACE including death, MI, and TVR for unprotected distal left main (LM) bifurcation stenosis (6.2% vs 16.3%; \( P = .001 \)).

**FIGURE 38-7** Crush technique. A first stent is advanced into the side branch but not expanded, and a second stent is advanced into the main branch to fully cover the bifurcation (A). At this time, the proximal marker of the main vessel stent should be more proximal in the coronary tree than the proximal marker of the side branch stent. Assuring the appropriate position of the side branch stent, the balloon is
inflated and the stent is deployed (B). After stent implantation in the side branch, the delivery balloon and the wire are removed from the side branch. Then, the stent in the main branch is expanded, and the protruding struts from the side branch are crushed against the wall of the main vessel (C). (D) Final result after kissing balloon inflation.

FIGURE 38-8 Example of the crush technique. A and B. Baseline angiogram of a bifurcation lesion involving the left anterior descending artery (LAD) and a large diagonal branch. C and D. Predilation for each branch. E and F. Two stents are placed, with the stent in the LAD positioned more proximally than the stent in the diagonal branch. A side branch stent is deployed first following the main vessel stent implantation. G and H. Adjunctive poststenting balloon dilatation for each stent. I. Final kissing balloon inflation. J. Optimal final result.
FIGURE 38-9 Step crush technique. Similar to the standard crush technique, the stent in the side branch is deployed (A). The stent strut in the side branch is crushed by the main vessel balloon instead of the stent (B). The second stent is advanced in the main vessel and deployed (C). (D) Final result after kissing balloon inflation.

V-Stenting and SKS Technique

The V-stenting or SKS technique can be preferred for bifurcations with a large proximal MV such as LM stenosis.\textsuperscript{31,32} V-stenting is preferable for selected bifurcation lesions where the lesions are limited to the distal portion of the bifurcation and have a narrow angle (Fig. 38-10). If there is a proximal stenosis in the MV, the SKS technique is preferred (Fig. 38-11). Since the SKS technique has advantages of fast procedural time and no need of strut reopening, it may have potential benefit for hemodynamically unstable patients with large LM bifurcation stenosis. However, the risk of restenosis or ST may be relatively high compared with other techniques due to the formation of long metal carina; hence, the SKS technique is not recommended for routine 2-stent treatment.
FIGURE 38-10 V-stenting. After predilation of both branches, the 2 stents are positioned into the branches, with usually a slight protrusion of both stents in the main proximal vessel (A). Each stent is deployed alternatively. Final kissing balloon inflation is performed using the same pressure for both balloons (B and C).

FIGURE 38-11 Kissing stenting technique. Both branches are wired and dilated (A). The 2 unexpanded stents are positioned in bifurcation with parallel proximal stent edges (B). The stents are deployed alternately followed by the final kissing balloon inflation (C).

INTERVENTION FOR LEFT MAIN CORONARY ARTERY LESIONS

As a result of the long-term benefit of coronary artery bypass graft (CABG) surgery compared with medical therapy, CABG has been regarded as the standard therapy for unprotected left main coronary artery (LMCA)
However, because of easy anatomic accessibility and a relatively large vessel caliber, PCI for LMCA disease has become an attractive option for interventional cardiologists. In addition, technical advances in PCI and devices have emboldened physicians to test the feasibility of LMCA intervention and, coupled with the widespread availability of DESs, have led to a reevaluation of the role of PCI as a viable alternative treatment for unprotected LMCA disease. As a result, over the last decade, the prevalence of LMCA stenting has significantly increased worldwide. In addition, several recent large registries and randomized controlled trials have demonstrated that LMCA stenting yields comparable mortality and morbidity rates compared with CABG. This chapter will provide an overview of current techniques and contemporary outcomes of PCI with either bare metal stents (BMSs) or DESs.

**Assessment of Lesion Severity**

Clinically, significant LMCA disease has been found in 3% to 5% of all patients who undergo coronary angiography and in 10% to 30% of patients who undergo bypass surgery. Traditionally, angiographic diameter stenosis of 50% has been considered a cutoff for significant LMCA stenosis. However, conventional coronary angiogram is only a luminogram and has critical limitations in assessing lesion morphology and plaque characteristics. The LM trunk is often short in length and lacks a normal segment for comparison. In addition, contrast material in the aortic cusp sometimes obscures the ostium, and “streaming” of contrast may result in a false impression of luminal narrowing. As a result, marked discrepancy in interpretation of degree of stenosis of LMCA narrowing has been documented in several studies. Therefore, fractional flow reserve (FFR) and IVUS are often used to assess the severity of LMCA stenosis.

An FFR value of 0.75 to 0.80 or greater has been suggested to be a strong predictor of excellent survival and low event rates in patients with intermediate LMCA disease, making it a useful cutoff value to determine significant LMCA stenosis. In a study involving 213 patients with intermediate LMCA stenosis, 5-year survival rates of 138 patients treated medically with an FFR ≥0.80 and 75 patients treated surgically with an FFR <0.80 were 89.8% and 85.4%, respectively (\(P = .48\)). Several other studies...
using FFR cutoff values of 0.75 to 0.80 as a surrogate for revascularization showed similar outcomes, and as a result, FFR-guided decision making for the treatment of LMCA stenosis is generally accepted.\textsuperscript{55-58} Practically, the FFR of LMCA stenosis should be interpreted with caution because isolated LMCA disease is rare, with most stenosis associated with disease in the left anterior descending artery (LAD) and/or left circumflex artery (LCX), both of which tend to increase the FFR value measured across the LMCA stenosis. Therefore, in these situations, the functional significance of intermediate LMCA stenosis should be reassessed after the correction of distal coronary artery stenosis.\textsuperscript{59}

The IVUS-derived minimal lumen area (MLA) has frequently been used to determine the functional significance of intermediate LMCA stenosis, and traditionally, an MLA cutoff value of 6.0 mm$^2$ has been considered to represent functionally significant LMCA stenosis. This value was derived primarily from the Murray law, with an MLA of 4.0 mm$^2$ considered to represent the ischemic threshold of the LAD or LCX, and was supported by a clinical study conducted by Jasti et al.\textsuperscript{58} However, recent studies reported that the IVUS MLA value corresponding to ischemia-producing lesions of non-LM epicardial coronary arteries to be $<3$ mm$^2$, and application of the Murray law to these values suggests that the IVUS MLA of a stenotic LMCA should be $<5.0$ mm$^2$.\textsuperscript{60-62} Park et al\textsuperscript{63} attempted to determine the IVUS-derived MLA criteria corresponding to an FFR $<0.80$ in 112 patients with isolated intermediate LMCA stenosis who underwent preinterventional IVUS and FFR measurements. They found that the IVUS-derived MLA value within the LMCA that best predicted FFR $<0.80$ was $<4.5$ mm$^2$ (77% sensitivity, 82% specificity, 84% positive predictive value, and 75% negative predictive value; area under the curve, 0.83; 95% CI, 0.76-0.6; $P < .001$), which was similar to the theoretical cutoff of $<5.0$ mm$^2$. It is interesting to note that the positive predictive value of IVUS-measured MLA $<4.5$ mm$^2$ was acceptably high and the anatomic parameter provided by IVUS appeared to correlate well with functional significance of LMCA stenosis. Thus, in cases when FFR measurement is not feasible, IVUS-derived MLA criteria could possibly be used as a surrogate of functional significance of LMCA disease.

\textbf{Outcomes of Unprotected Left Main Intervention}
LMCA stenosis might be considered to be an attractive target for percutaneous intervention because of its large vessel size, short lesion length, and lack of tortuosity. Consequentially, LMCA intervention has been shown to be feasible and to have acceptable short- and mid-term outcomes in the BMS era. The ULTIMA registry enrolled 279 patients with unprotected LMCA stenosis who were treated with BMSs; 46% of the patients were inoperable or at high surgical risk. The in-hospital mortality rate was 13.7%, and the 1-year incidence of all-cause mortality was 24.2%. However, among the 32% of patients at relatively low risk (age <65 years, left ventricular ejection fraction >30%, and no shock), there were no periprocedural deaths, with a 1-year mortality rate of only 3.4%. Park and colleagues found that elective BMS stenting for LMCA bifurcation (n = 63) in highly selected patients with normal left ventricular ejection fraction and a large reference vessel might be safe and effective. In this report, the procedure was successful in all patients, and major in-hospital events did not occur in any patients. Moreover, no significant differences were noted in the rates of 2-year freedom from TLR among LMCA ostium, shaft, and bifurcation stenting (82%, 86%, and 85%, respectively). Several other studies also showed favorable short- or mid-term outcomes (in-hospital mortality, 0%-4.3%; mortality at 6-12 months, 2.5%-10.8%) in low-risk patients undergoing elective PCI using BMS for unprotected LMCA disease. However, considerable risk of restenosis (18%-31%) and repeat revascularization (7.3%-33.6%), which may lead to worst-case outcomes such as sudden death and acute MI, have limited the durability of LMCA stenting with BMSs. Therefore, LMCA stenting had to be reserved for selected patients who were not candidates for CABG or refused to receive CABG in the BMS era.

After the introduction of DESs, with a remarkable reduction of restenosis and repeat revascularization, PCI with DES has been widely performed for more complex clinical and anatomic subsets of LMCA disease. Although limited by their nonrandomized nature, small numbers of patients, and short follow-up periods, several early observational studies have shown promising outcomes after PCI using early-generation DES compared with BMS. Even after safety concerns regarding very late ST associated with early-generation DES, physicians’ threshold for performing PCI at the LMCA became less restrictive, and the worldwide frequency of LMCA stenting started to sharply increase. In a subsequent meta-analysis comparing
outcomes for DES and BMS after LMCA stenting, a total of 44 studies including 10,342 patients who received a DES or BMS were analyzed. The respective (DES vs BMS) cumulative event rates at 3 years were 8.8% and 12.7% for death, 4.0% and 3.4% for MI, 8.0% and 16.4% for TVR/TLR, and 21.4% and 31.6% for MACE. Adjusted outcomes at 3 years favored DES, including the reduction of mortality.

Regarding the differential benefit of DES for the prevention of restenosis, the 2 most widely applicable first-generation DESs (sirolimus- and paclitaxel-eluting stents) were evaluated in previous studies. An early study comparing the 2 DESs from a RESEARCH registry showed a comparable incidence of MACE, with a rate of 25% for sirolimus-eluting stents (n = 55) and 29% for paclitaxel-eluting stents (n = 55). The ISAR-LEFT MAIN (Intracoronary Stenting and Angiographic Results: Drug-Eluting Stents for Unprotected Coronary Left Main Lesions) study compared 305 patients receiving sirolimus-eluting stents and 302 patients receiving paclitaxel-eluting stents using a prospective randomized design. The study enrolled patients with relatively high-risk clinical (mean age of 69 years, 30% with diabetes, 40% with acute coronary syndrome, and 50% with prior PCI) and angiographic (63% with distal bifurcation stenosis and 70% with multivessel disease) characteristics. At 12-month follow-up, the rates of death (6.6% vs 5.0%), MI (4.6% vs 5.0%), stroke (1.0% vs 1.7%), and major cardiac events (death, MI, or revascularization; 15.8% vs 13.6%) were similar in the sirolimus- and paclitaxel-eluting stent groups, respectively, as were the angiographic restenosis rates at 6 to 9 months (19.4% vs 16.0%) and 2-year revascularization rates (7.8% vs 6.5%). The rates of definite (0.3% vs 0.7%) and probable (0% vs 0.3%) ST at 2 years were also similar in the 2 study arms.

Thereafter, several refined versions of DESs sharing common features of thinner struts and biocompatible polymers have been rapidly adopted in clinical practice, and newer generation DESs further decreased the risk of ST and restenosis compared to the previous stents. Although no randomized trial has specifically compared the outcomes of first-generation and second-generation DESs for LMCA disease, several observational studies have suggested better outcomes with newer versions of DESs for LMCA PCI. The multicenter randomized ISAR-LEFT MAIN 2 study compared the safety and efficacy of the zotarolimus-eluting stent (ZES) with the everolimus-
eluting stent (EES) for LMCA intervention. At 1 year, the cumulative incidence of death, MI, or TLR was 17.5% in the ZES group and 14.3% in the EES group (relative risk, 1.26; 95% CI, 0.85-1.85; \( P = .25 \)). All-cause mortality (5.6%; relative risk, 1.00; 95% CI, 0.52-1.93; \( P = .98 \)) and angiographic restenosis (21.5% vs 16.8%; relative risk, 1.28; 95% CI, 0.86-1.92; \( P = .24 \)) was comparable between the 2 groups at 1-year follow-up.

**Comparison Between PCI and Bypass Surgery**

Table 38-2 summarizes the key observational studies and randomized trials that compare PCI with DES and CABG. The representative study to assess the feasibility of PCI as an alternative to CABG came from the MAIN-COMPARE registry, which included 2240 patients with unprotected LMCA disease who underwent intervention (BMS, \( n = 318 \); DES, \( n = 784 \)) or CABG (\( n = 1138 \)) at 12 major cardiac centers in South Korea. The first 3-year outcome report after propensity score matching and the second 5-year report using the inverse probability of treatment weighting method showed that the risk of death and the combined risk of death, Q-wave MI, or stroke were not significantly different for patients undergoing PCI versus CABG. A similar pattern was observed in patients treated with either DES or BMS. However, the risk of repeat revascularization was significantly higher in the PCI group than in the CABG group, with HRs varying by the type of implanted stent, in that DES recipients were almost 6-fold more likely to require repeated revascularization and BMS recipients almost 10-fold more likely to require repeated revascularization compared to patients who underwent surgery. An interesting finding in this study was that the majority of PCI patients who needed repeat revascularization were treated with repeat PCI instead of CABG. Given the fact that the recommendation for CABG for unprotected LMCA disease has been based mostly on survival benefit compared with medical therapy, the lack of a statistically significant difference in mortality may support PCI as an alternative option to bypass surgery.

Table 38-2 **Comparative Studies of PCI With DES and CABG for Left Main Disease**
Four consecutive randomized clinical trials comparing early-generation DES and CABG reported similar results. The first randomized study comparing PCI (n = 52) with CABG (n = 53) for treatment of unprotected LMCA stenosis was conducted by Buszman and colleagues.\(^{50,88}\) PCI was performed using either BMS (65%) or DES (35%), and left internal mammary artery grafts were used in 72% of CABG patients. At 1 year, the primary end point of absolute change in left ventricular ejection fraction was significantly greater in the PCI group than in the CABG group (3.3% ± 6.7% vs 0.5% ± 0.8%; \(P = .047\)), whereas the secondary end points of survival and major adverse cardiac or cerebrovascular events (MACCE) were comparable between the 2 groups. These outcome findings were maintained at up to 10 years of follow-up. Although it provides valuable information, this trial only included patients with low to medium complexity of coexisting coronary artery disease and was underpowered by the small number of patients and the inconclusive primary end point chosen to evaluate comparative treatment effects. The SYNTAX (Synergy Between PCI with Taxus and Cardiac Surgery) trial compared the outcomes of PCI using paclitaxel-eluting stents versus CABG for unprotected LMCA stenosis in a subgroup analysis from the randomized study cohort.\(^{40}\) In the subset of LMCA disease comprising 348 patients receiving CABG and 357 patients receiving PCI, PCI...
demonstrated an equivalent 12-month rate of MACCE compared with CABG (15.8% vs 13.7%). Of note, the higher rate of repeat revascularization with the use of PCI (11.8% vs 6.5%; \( P = .01 \)) was offset by a higher incidence of stroke with the use of CABG (2.7% vs 0.3%; \( P = .01 \)). Even when the follow-up was extended to 5 years, there were no significant differences in the rates of death (12.8% vs 14.6%; \( P = .94 \)), MI (8.2% vs 4.8%; \( P = .2 \)), and MACCE (36.9% vs 31.0%; \( P = .14 \)) between patients who received PCI and CABG. The incidence of stroke was lower (1.5% vs 4.3%; \( P = .03 \)), whereas the incidence of repeat revascularization was higher (26.7% vs 15.5%; \( P = .003 \)) in the PCI arm. When patients were stratified according to the SYNTAX score tertiles, the incidence of MACCE did not differ between the PCI and CABG groups in patients with low (0-22) and intermediate (23-32) scores, but significantly increased in PCI patients with high scores (≥33). These findings suggest that both treatment modalities are valid options for patients with LMCA disease and that the anatomic complexity should be considered when choosing PCI or CABG.

In the PRECOMBAT trial, 600 patients with unprotected LMCA disease were randomized to undergo either CABG or PCI with a sirolimus-eluting stent. The primary end point was MACCE, defined as a composite of all-cause death, MI, stroke, or ischemia-driven TVR. PCI was noninferior to CABG for the incidence of MACCE at 1 year (absolute risk difference, 2%; upper margin of 95% CI, 5.6%; HR, 1.56; \( P = .011 \) for noninferiority). At 5 years, the primary end point occurred in 52 patients in the PCI group and 42 patients in the CABG group (17.5% vs 14.3%, respectively; HR, 1.27; 95% CI, 0.84-1.90; \( P = .26 \)). The 2 groups did not significantly differ in terms of the composite of death from any cause, MI, or stroke. Ischemia-driven TVR occurred more frequently in the PCI group than in the CABG group (11.4% vs 5.5%, respectively; HR, 2.11; 95% CI, 1.16-3.84; \( P = .012 \)). Another small randomized trial by Boudriot et al compared sirolimus-eluting stenting (n = 100) with CABG (n = 101) for patients with unprotected LMCA disease. The primary end point was noninferiority in freedom from the composite of cardiac death, MI, and the need for TVR at 12 months. The incidence of the primary end point was 13.9% in the CABG group and 19.0% in the PCI group (\( P = .19 \) for noninferiority). The combined rates for death and MI were comparable (7.9% in CABG vs 5.0% in PCI), but PCI was inferior to CABG for repeat revascularization (5.9% vs 14.0%; noninferiority \( P = .35 \)).

Based on these registries and randomized studies showing PCI with DES
to be feasible and effective in the treatment of unprotected LMCA disease, the updated guidelines for the treatment of LMCA stenosis upgraded PCI as a reasonable or considerable treatment (Level of Evidence B) in prespecified patients to improve survival\textsuperscript{91,92} (Table 38-3). In summary, PCI using DES is currently considered an effective alternative option in anatomically suitable patients with significant LMCA disease. Two randomized trials comparing PCI with newer generation DES and CABG (the Nordic-Baltic-British Left Main Revascularization [NOBLE] and Evaluation of Xience Prime vs Coronary Artery Bypass Surgery for Effectiveness of Left Main Revascularization [EXCEL] trials) are ongoing and will hopefully provide more information on the differential treatment effect of both strategies.

**Technical Considerations**

During unprotected LMCA intervention, a femoral approach and use of guiding catheters with relatively large lumen (7 or 8 Fr) are preferred. The end of a thin guiding catheter may suddenly advance into the lesion, resulting in plaque dissection. In addition, multiple devices for complex procedures are
easily delivered through catheters with large lumens.

Patients with normal left ventricular function are usually tolerant of brief global ischemia during the balloon occlusion. Although an intra-aortic balloon pump is not routinely recommended during the procedure, prophylactic use should be considered to prevent hemodynamic collapse in patients with severe left ventricular dysfunction, critical right coronary artery disease, complex LMCA anatomy, or unstable presentations. In general, for provisional use, another femoral routine with small sheath for the rapid insertion of intra-aortic balloon pump is recommended before PCI for high-risk patients (low left ventricular ejection fraction, heavy calcified stenosis, or thrombus containing LMCA stenosis). New supporting devices, such as the TandemHeart PTVA system (CardiacAssist Inc., Pittsburgh, PA) or the Impella Recover System (Abiomed, Danvers, MA), can provide active circulatory support and may improve the feasibility of unprotected LMCA intervention.

Stenting of ostial or shaft LMCA lesions can be performed safely using careful hemodynamic monitoring and meticulous guiding technique. Coaxial alignment of the guiding catheter is important to minimize vessel injury and to ensure proper positioning of the stent. Once the balloon or stent is properly positioned, the guiding catheter can be retracted 1 to 2 cm into the aorta with gentle forward pressure on the balloon catheter. A brief (<30 seconds) and multiple (>3) balloon inflation is required to avoid ischemic complications. In ostial LMCA lesions, the stent is generally deployed to protrude 1 to 2 mm into the aorta for full lesion coverage. Further dilatation using a high-pressure balloon may be needed to achieve optimal stent cross-sectional area. Aorto-ostial coverage is not mandatory for treatment of disease limited to the shaft of the LMCA.

Stenting for LMCA bifurcation lesions is technically demanding and should be restricted to highly skilled interventional cardiologists. For LMCA bifurcation disease, the 1-stent strategy showed more favorable long-term clinical outcomes compared with the 2-stent strategy. Therefore, in real practice, the 1-stent crossover technique has been used more frequently, in approximately 60% of all LMCA bifurcation treatments. However, a notable rate of SB occlusion has been reported (187 of 2227 patients, 8.4%) from a real-world registry, the majority of which occurred in the true bifurcation lesion, and considering the possibility of circulatory collapse after SB occlusion in LM bifurcation lesions, the elective 2-stent technique is still
advocated as a viable option for this lesion subset. The selection of a 1- or 2-stent technique should be based on disease involvement of the LCX ostium because SB compromise after stent crossover is frequent in the setting of significant ostial disease of the SB (Table 38-4). Thus, to determine the appropriate stenting strategy, IVUS use is strongly recommended because it provides more accurate information of the disease status of the MV and SB as well as the degree of vascular remodeling compared with conventional angiogram. If possible, direct imaging from LCX is necessary because IVUS evaluation of an SB ostium from the MV is only moderately reliable.94

**IVUS-Guided Optimization of LMCA Stenting**

Optimal stent expansion was considered one of the most important factors in preventing restenosis or adverse clinical outcomes after PCI.95,96 However,
there were no data suggesting the optimal minimal stent area (MSA) cutoff for prediction of restenosis and long-term clinical outcome after DES implantation for LMCA stenosis until the recent report from Kang et al. After analyzing 403 patients undergoing sirolimus-eluting stent implantation for LMCA disease, the best IVUS-MSA criteria that predicted angiographic in-stent restenosis (ISR) on a segmental basis were found to be 5.0 mm$^2$ for the LCX ostium, 6.3 mm$^2$ for the LAD ostium, 7.2 mm$^2$ for the polygon of confluence (POC), and 8.2 mm$^2$ for the proximal LMCA above the POC (Fig. 38-12). Stent underexpansion was more frequent in the 2-stent group than in the 1-stent group (54% vs 27%, respectively; $P = .001$). In addition, in the 2-stent group, the LCX ostium was the most common site of underexpansion (37%), which may explain the greater risk of ISR when LMCA bifurcation lesions are treated with a 2-stent strategy. Overall, angiographic ISR was more frequent in lesions with underexpansion than in lesions without underexpansion (24.1% vs 5.4%, respectively; $P = .001$). Even in the 2-stent group, lesions with complete expansion at all sites showed only 6% of the ISR rate, which was similar to that of the single-stent group (6.3%) and in nonbifurcation LMCA lesions (4.5%).
FIGURE 38-12 A. Minimal stent area (MSA) cutoff values for the prediction of angiographic in-stent restenosis (ISR) on a segmental basis. B. Frequency of underexpansion in 2-stent group (n = 104). Left circumflex artery (LCX) ostium was the most common site of underexpansion (37%); ISR developed in 55% of the underexpanded LCX ostia. C. Frequency of underexpansion in the single-stent group (n = 289, including 67 nonbifurcation stents and 222 bifurcation lesions treated with a 1-stent crossover technique). The rate of underexpansion at the left anterior descending artery (LAD) ostium and polygon of confluence (POC) was significantly lower in the single-stent group compared with the 2-stent group (*P <.05). LM, left main artery.

Although there are some controversies regarding the clinical impact of IVUS-guided stenting for unprotected LMCA along with some cost-benefit issues, this adjuvant method recently gained support from many interventional cardiologists after associated publications. A subgroup analysis from the MAIN-COMPARE registry including 201 propensity-score matched pairs demonstrated that there was a strong tendency for lower risk of 3-year mortality with IVUS guidance compared with angiography guidance (6.3% vs 13.6%; log-rank P = .063; HR, 0.54; 95% CI, 0.28-1.03). In particular, for 145 matched pairs of patients receiving DES, the 3-year rate of mortality was significantly lower for IVUS guidance compared with angiography guidance (4.7% vs 16.0%; log-rank P = .048; HR, 0.39; 95% CI, 0.15-1.02). Of note, mortality started to diverge beyond 1 year after the procedure. Given that IVUS guidance did not reduce the risk of mortality in 47 matched pairs of patients receiving BMS (8.6% vs 10.8%; log-rank P = .35; HR, 0.59), this study indicates that IVUS guidance may play a role in reducing very late ST and subsequent long-term mortality. A recent IVUS-TRONCO-ICP Spanish study also demonstrated the importance of IVUS surveillance during LMCA stenting. The IVUS-guided group had a lower incidence of the composite of cardiac death, MI, and TLR and also ST at 3 years.

INTERVENTION FOR OSTIAL LESIONS

Ostial lesions have a reputation of being fibrotic, calcified, and relatively rigid. Because these unique characteristics contribute to resistant to dilatation and propensity for recoil, treatment of ostial lesions was associated with lower angiographic success and frequent procedural complications, such
as dissections and acute vessel closure, in the balloon angioplasty era. Although, significant progress in clinical outcomes has been made with the use of stents and adjunctive devices such as cutting balloons or IVUS, percutaneous intervention in ostial lesions still poses unique challenges as a result of technique considerations in catheter manipulation, lesion preparation, and stent positioning.

**Types of Ostial Lesions**

Traditionally, ostial disease is defined as a lesion arising within 3 to 5 mm of the vessel origin. Coronary ostial lesions can be classified by location as aorto-ostial and branch ostial lesions. Aorto-ostial lesions involve the junction between the aorta and the orifice of the right coronary artery, LMCA, or bypass grafts and histologically resemble the aortic wall, being rich in smooth muscle cells and elastic fibers. Isolated aorto-ostial disease is more frequently encountered in women and is more common at the right coronary artery than at the LMCA. Branch ostial lesions involve the junction between a large epicardial vessel and the orifice of a major branch and are frequently accompanied by various bifurcation lesions.

**Technical Tips for Branch Ostial Stenting**

Precise stent positioning to obtain full lesion coverage is of the utmost importance in branch ostial intervention. Unnecessary proximal extension may result in obstruction of major vessels. For example, in ostial LAD stenting, the stent should be deployed to cover the most proximal part of the LAD ostium without protrusion of the stent into the LMCA. Using multiple angiographic views to minimize foreshortening or overlap is necessary. In ostial LAD stenting, super-zooming angiography (magnification ×8) in the right or left anterior oblique and caudal views may be useful to facilitate the exact stent positioning. Proper positioning can be confirmed by a small amount of contrast injection in multiple projections. Occasionally, the stent becomes subject to an oscillating or rocking motion in time with the cardiac cycle, which makes accurate stent positioning impossible. Pharmacologic methods (such as esmolol, adenosine, and atropine) and rapid ventricular pacing to reduce or slow cardiac motion have been described. However, these methods have a short time window and can potentially distress the patient,
which can be counterproductive. Use of a large guiding catheter, deeper intubation of the guiding catheter, and use of a stiffer guide wire might allow the entire apparatus for angioplasty to swing with cardiac motion. The partial inflation technique is another option to overcome the cardiac cycle–related motion. Slight inflation of the stent balloon at 2 atm can increase the stent profile and reduce oscillation while allowing positional adjustment before full deployment. However, abrasion of the normal vessel intima by the stent or possible stent loss can be problematic.

**Technical Tips for Aorto-Ostial Stenting**

Because engagement of catheters at aorto-ostial sites can often provoke spasm and give a false impression of severe ostial disease, every effort should be made to confirm the true stenosis severity before intervention. Intracoronary nitroglycerin should be administered unless contraindicated; nonselective coronary injection into the aortic sinus or IVUS evaluation can be performed for this purpose.

Selection of an adequate guiding catheter is particularly important in aorto-ostial intervention. Generally, less aggressive catheters with a short tip are preferred to avoid deep engagement and wedging of the catheter within the lesion and to facilitate disengagement during stent deployment. Most native aorto-ostial lesions can be successfully approached with the Judkins catheter, whereas multipurpose right coronary bypass, left coronary bypass, or Amplatz left catheters are often used for aortocoronary bypass graft lesions. Pressure damping, which indicates wedging of the catheter within the lesion, can be a sign of flow occlusion, and catheters with side hole should be used for intervention. In general, coaxial alignment of the guides minimizes ostial injury, permits proper positioning of devices, and facilitates accurate assessment of the ostium. Once the balloon or stent is properly positioned, the guiding catheter can be gently retracted into the aorta. The balloon should not be fully inflated inside the catheter due to the possible risk of balloon rupture and air embolism (Fig. 38-13). After balloon angioplasty, stent implantation is strongly recommended in almost all cases of significant aorto-ostial lesions because of the specific characteristics of lesion rigidity and high elastic recoil. Guiding catheter disengagement can result in poor contrast opacification, which can hinder accurate stent positioning. Frequent and intense test injections of contrast in multiple angiographic views are required.
to verify proper stent positioning. The proximal 1 to 2 mm of the stent should extend into the aorta to ensure complete coverage of the ostial lesion (Fig. 38-14). Excessive stent protrusion into the aorta can cause difficulty in repeat catheterization or increase the risk for thromboembolic complications. IVUS evaluation to identify the correct reference vessel size and to confirm stent optimization can be very useful for favorable outcomes, especially for aorto-ostial intervention. However, operators should bear in mind that the need for catheter disengagement during IVUS pullback risks non-coaxial imaging of the ostium and overestimation of the luminal area (Fig. 38-15).

**FIGURE 38-13** Proper balloon dilation technique for aorto-ostial lesions. The catheter is gently retracted 1 to 2 cm into the aorta prior to the balloon inflation.

**FIGURE 38-14** Proper stenting technique in aorto-ostial lesions. A. The proximal 1 to 2 mm of the stent should extend into the aorta. The guiding catheter should be retracted 1 to 2 cm before stent implantation. B. After stent deployment, the delivery balloon is removed while maintaining backward tension of the guide to prevent it
from advancing into the ostium and damaging the stent. C. Perform adjunctive balloon dilation with a high pressure balloon. D. Final result.

**FIGURE 38-15** Example of aorto-ostial right coronary artery (RCA) stenting. (A) Baseline RCA angiogram showing significant stenosis at mid-portion and ostium. Preprocedural intravascular ultrasound examination for RCA revealed diffuse concentric plaque resulting in a minimal lumen area of 2.37 mm$^2$ and 1.69 mm$^2$ for mid-portion (B) and ostium (C), respectively. (D) Several predilations were done from mid to ostial RCA. (E) Distal stent was deployed first. (F) Proximal stent was deployed while securing both the full ostial coverage and overlap with the distal stent. (G) Optimal final result.
PCI Results for Coronary Ostial Lesions

The use of BMSs to treat ostial stenosis has been reported to have a high procedural success rate but also associated with a high rate of restenosis.\textsuperscript{105,106} To overcome this limitation, several studies were designed to evaluate the role of plaque modification and debulking strategy with use of adjunctive devices including excimer laser, directional coronary atherectomy, and rotational atherectomy. However, these devices increase procedural complexity and the risk of device-related complication, and the studies could not find consistent superiority of combining these devices over stenting alone.\textsuperscript{105,107-109}

The use of DES can reduce the rates of restenosis in a broad range of coronary lesions. Indeed, several studies reported improved outcomes of PCI with DES in ostial lesions compared with BMS, especially in terms of the rates of restenosis and repeat revascularization.\textsuperscript{110-113} In addition, despite the lack of adequate evidence, procedural and long-term outcomes of coronary ostial stenting in the DES era seem to be comparable to other coronary lesions so far.

**MULTIPLE CHOICE QUESTIONS**

1. Which bifurcation stenting technique has a risk of incomplete side branch coverage?
   A. Culotte technique
   B. T-stenting technique
   C. Crush technique
   D. Simultaneous kissing stent technique
   E. Double kissing crush technique

2. Which anatomic feature of distal left main bifurcation would be favorable for a 2-stent strategy rather than single stenting?
   A. Wide angle with left anterior descending artery
B. Left circumflex artery <2.5 mm in diameter  
C. Medina classification 1,0,1  
D. Right dominant coronary artery system  

3. What site is most common for restenosis after distal left main stenting, and what is the intravascular ultrasound minimal stent area criterion to predict restenosis at that site?  
   A. Left circumflex artery ostium, 5.0 mm\(^2\)  
   B. Left circumflex artery ostium, 6.0 mm\(^2\)  
   C. Left anterior descending artery ostium, 6.0 mm\(^2\)  
   D. Left anterior descending artery ostium, 7.0 mm\(^2\)  
   E. Polygon of confluence, 7.0 mm\(^2\)  

4. Which circumstance is least reliable for additional side branch intervention in a provisional 1-stent approach for a distal left main bifurcation lesion?  
   A. Chest pain  
   B. New ST-segment depression on lead I  
   C. Side branch diameter stenosis of 70%  
   D. Fractional flow reserve (FFR) of 0.70  

5. For a stable patient with significant left main coronary artery disease, which outcome measure is most affected by different revascularization methods (ie, coronary artery bypass grafting [CABG] and PCI)?  
   A. All-cause death  
   B. Repeated revascularization  
   C. Myocardial infarction  
   D. Composite of death, myocardial infarction, and stroke  

**ANSWERS**  

1. B  

T-stenting technique is the most commonly used approach in the provisional stenting strategy, in which a single main vessel stent is deployed, with side branch stenting only used in cases of suboptimal angiographic results. A
technical consideration with T-stenting is the angulation of the side branch relative to the main vessel. Lesions that more closely resemble a true “T” configuration with a side branch angulation >70° will enable better coverage of the entire side branch than lesions with less angulation, which may carry a risk of incomplete side branch ostium coverage. The side branch ostium is the most common site for angiographic restenosis following stenting of bifurcation lesions, which is why adequate coverage of this region is important.

2. C

For distal left main bifurcation disease, the possibility of circulatory collapse after main vessel, attributable to the large myocardial volume supplied by the left circumflex artery in many patients, is always a concern. This is why 2-stent techniques are chosen relatively more frequently for left main bifurcation lesions than for non–left main lesions. In general, the provisional 1-stent approach would be preferred for left main bifurcations with insignificant stenosis at the ostial left circumflex artery or a nondominant left coronary system, whereas the elective 2-stent technique is preferred in patients with significant ostial stenosis of the left circumflex artery with a dominant left coronary arterial system. Medina class of 1,0,1 refers to a presence of significant stenosis at the side branch, a situation in which a 2-stent strategy should be considered.

3. A

Either after a single-stent crossover strategy or an elective 2-stent strategy, the most frequent site of restenosis is the ostium of the left circumflex artery. Based on our research results, stent underexpansion after percutaneous coronary intervention (PCI) was most common at that site and was more frequent in the 2-stent group than in the 1-stent group. This explains why the 1-stent strategy shows more favorable long-term clinical outcomes compared with the 2-stent strategy in relevant studies. The rule of “5-6-7-8” is a best intravascular ultrasound minimal stent area criterion after PCI that predicts angiographic in-stent restenosis on a segmental basis for left circumflex artery ostium (5 mm$^2$), left anterior descending artery ostium (6 mm$^2$), polygon of confluence (7 mm$^2$), and the left main coronary artery above the polygon of confluence, respectively.
Additional treatment for “functionally significant” side branch lesion would be the reasonable approach in this situation. If a patient develops ischemic symptoms or signs after left main stenting that are attributable to the compromise of the left circumflex artery, further intervention should definitely be performed. Currently, there are small observational studies suggesting the benefit of FFR-guided decision making for further left circumflex artery intervention after main vessel stenting. In these reports, considerable discrepancy between angiographic stenosis and FFR value was demonstrated in that only less than one-third of angiographically jailed left circumflex artery ostia were revealed to be functionally significant (FFR <0.80). In left main or non–left main bifurcations, even if the diameter stenosis of the side branch is up to 70% to 80% after main vessel stenting, the long-term patency and clinical outcome are usually excellent if the stenosis is confined to the ostium and the flow is not impaired.

There are robust data indicating the inherent weakness of stent-related treatment in left main coronary artery disease in that PCI, compared with CABG, consistently displayed a disadvantage for the risk of repeated revascularization. Accordingly, left main coronary artery disease patients with a high degree of anatomic complexity (eg, SYNTAX score >32) are recommended to undergo CABG rather than PCI by community guidelines, mainly because of the differential future outcome of repeated revascularization. However, this drawback for PCI did not translate into an increase in hard clinical end points in most comparative effectiveness studies.
Special Considerations: Small Vessel and Diffuse Disease

James B. Hermiller
Evan T. Russell

Small vessel disease and diffuse coronary artery disease represent particularly challenging subsets for treatment with transcatheter coronary interventional therapies. This pathology is associated with higher risk comorbidities, such as diabetes, and is more frequently associated with female gender and diffuse coronary involvement. Small and diffusely diseased vessels are frequently noncompliant, calcified, tortuous, and distal in location, making these targets more technically challenging for intervention. Consequently, a higher incidence of acute complications, including significant vessel dissection, acute vessel closure, myocardial infarction, and emergent coronary bypass grafting, has historically complicated intervention in small and diffusely diseased vessels. Along with poorer acute outcomes, these subsets are plagued by high restenosis and thrombosis rates, often necessitating repeat intervention or bypass surgery. Despite the challenges and complexities inherent to small vessel intervention, the problem is common. Between 30% and 67% of all percutaneous coronary interventions involve small vessels, depending on the definition of a small vessel.

This chapter will review the definition and diagnostic approach to small and diffuse coronary artery disease. Acute and long-term outcomes associated with percutaneous interventional therapies, particularly the favorable impact of drug-eluting stents, will be reviewed. Finally, the future
role in the treatment of these subsets with drug-eluting balloons and bioabsorbable stents will be examined.

**DEFINITION OF SMALL VESSEL DISEASE**

The definition of what constitutes a small vessel in the context of coronary interventional therapy has been quite variable. A number of studies examining small vessel intervention have defined vessels less than 3.0 mm in reference size as being small, and this criterion is in part derived from early stent trials in which patients with vessels less than 3.0 mm were excluded from enrollment.\(^{10,11}\) Other studies have defined small vessels as those less than 2.5 to 2.8 mm in diameter.\(^{9,12-14}\) Certainly, less than 3.0 mm is the most sensitive descriptor, although necessarily less specific. Despite whatever arbitrary cutoff is used, the relationship between vessel size and outcome is not a step function; instead, a continuous inverse relationship exists between outcomes and size.\(^{8,15}\) Consequently, differences in the definition and enrollment criterion frequently help explain apparently conflicting results from various studies of small vessel intervention. Like the small vessel, diffuse disease has had various definitions; however, the most consistent definition is lesion length greater than 20 mm.\(^{16}\)
