The definition of small vessel has been based on angiography; nevertheless, results of intravascular ultrasound (IVUS) have demonstrated that many angiographically small vessels are in fact “pseudosmall” as a result of angiographically undetected disease in the reference segment and positive remodeling at the lesion site.\(^{17}\) Briguori and colleagues\(^{18}\) compared 344 consecutive patients having 419 lesions in small vessels (angiographic reference vessel ≤2.75 mm) with 953 patients having 1161 lesions in large vessels (>2.75 mm); all underwent concomitant IVUS. The difference in angiographic and IVUS reference vessel dimension delta (IVUS-angiography) was calculated for all lesions.\(^{18}\) The tendency to underestimate vessel size was significantly greater for small vessels (difference between IVUS and angiography, 1.3 ± 0.5 mm vs 1.0 ± 0.6 mm; \(P < .001\)). Angiography underestimated vessel size by more than 1.0 mm in 71% of small vessels and in only 49% of large vessels (\(P < .001\)). There was a
stronger correlation between plaque burden and the delta (IVUS-angiography) in small vessels ($r = 0.80; P < .001$) than in large vessels ($r = 0.59; P < .001$). Predictors of delta (IVUS-angiography) were proximal or middle lesion location and female gender.\textsuperscript{19} Extending these observations, Moussa et al\textsuperscript{19} examined the predictors of large discrepancies between IVUS and angiography. Independent predictors of a delta (IVUS-angiography) greater than 1.0 mm were small vessel size ($<3.0$ mm), location of the lesion in the proximal vessel, and diabetes (Fig. 39-1). The authors suggested that IVUS might be particularly helpful in small vessel intervention when the lesion was proximally located or the patient had diabetes.

**FIGURE 39-1** Predictors of large discrepancies between intravascular ultrasound (IVUS) and angiography (angio) as reported in 1 study. Independent predictors of a delta $>1.0$ mm were small vessel size ($<3.0$ mm), location of the lesion in the proximal vessel, and diabetes mellitus (DM). (Reprinted from Moussa I, Kobayashi Y, Adamian M, et al. Characteristics of patients with a large discrepancy in coronary artery diameter between quantitative angiography and intravascular ultrasound. *Am J Cardiol*. 2001;88:294-302, Copyright © 2001, with permission from Elsevier.)

**NONSTENT INTERVENTION**

Early studies of percutaneous transluminal coronary angioplasty (PTCA) demonstrated higher risks associated with small vessel intervention.\textsuperscript{20} Overall procedural success with plain old balloon angioplasty (POBA) was significantly less for small vessels compared to interventions on larger
vessels. Additionally, major adverse cardiac events occurred more frequently in small vessel cohorts. Hypotheses explaining the higher event rates include the association of small vessels with other high-risk comorbidities, greater lesion complexity, and the higher incidence of diffuse plaquing. The combination of small vessel size and diffuse disease is particularly difficult, with a much higher incidence of abrupt closure compared to focal lesions. Strategies that have been shown to be beneficial in reducing these complications and improving restenosis rates include utilization of longer balloons, gradual and prolonged balloon angioplasty, and cutting balloon (CB) angioplasty. Data from the REDUCE (Restenosis Reduction by Cutting Balloon Evaluation) and CAPAS (Cutting Balloon Angioplasty Versus Plain Old Balloon Angioplasty Study) trials collectively suggested that CB angioplasty may be a superior technique to POBA, with fewer coronary dissections, improved binary restenosis rates, and reduced target lesion revascularization.

Because the results of POBA had been demonstrated to be suboptimal, interventional therapies using ablative techniques, particularly rotational atherectomy and laser angioplasty, have also been evaluated. Several studies done in the early 2000s, including a meta-analysis of trials examining PTCA versus atherectomy, CB angioplasty, or laser angioplasty, demonstrated higher acute complication rates without restenosis benefits in patients who underwent these procedures. Despite limited data to suggest plaque ablative techniques should be used routinely to treat small, diffuse disease, it continues to have a niche role in heavily calcified vessels, facilitating more complete dilation and delivery of stents.

**BARE METAL STENTS**

Early reports of stenting in small vessels suggested higher rates of complications and no improvement in restenosis. Diffuse disease treated with multiple or long stents was also associated with a higher risk of stent thrombosis as well. A meta-analysis of the Belgian-Netherlands Stent (BENESTENT) study and the Stent Restenosis Study (STRESS) suggested no improvement in restenosis in small vessels when elective stenting was compared with balloon angioplasty. These reports led to initial American College of Cardiology/American Heart Association recommendations that
small vessels should not be routinely stented.\textsuperscript{30}

Despite these mediocre results, subsequent reports of bailout stenting in
the setting of abrupt or threatened closure in small vessels were
encouraging.\textsuperscript{31,32} An analysis of small vessel lesions enrolled in the STRESS
I and II trials suggested that in vessels less than 3.0 mm, elective stenting was
beneficial.\textsuperscript{10} Angiographic restenosis was significantly less in those receiving
elective stenting (34\% vs 55\% restenosis for stent vs balloon; \(P < .0001\)), and
there was no difference in abrupt closure between the POBA and stent group
(3.6\% in both groups). Many other elective registries also suggested
favorable outcomes with stenting when compared to historical controls.\textsuperscript{33-42}

Following these early reports, there have subsequently been a large
number of randomized trials comparing bare metal stenting to PTCA.\textsuperscript{9,13,42-50} There has been considerable variability in the results of these studies. In
2004, a meta-analysis of these randomized trials was performed and included
3541 patients; 1672 patients were allocated to balloon angioplasty, and 1869
were allocated to bare metal stenting.\textsuperscript{51} Of these, 84\% had angiographic
follow-up. The pooled restenosis rate was 25.8\% in patients assigned to
stenting and 34.2\% in patients allocated to balloon angioplasty (relative risk,
0.75; 95\% confidence interval [CI], 0.67-0.84; \(P < .001\)). A smaller reference
vessel diameter at baseline was associated with higher risk reduction of
restenosis in the stent group (\(P = .012\)). In summary, these studies suggested
that stenting improves restenosis in small vessels, particularly when PTCA
outcomes are not optimal and possibly when reference vessel size is smaller.

\textbf{Stent Strategies}

Initially, the treatment of diffuse disease, particularly in small vessels, was
discouraging because of higher rates of stent thrombosis and restenosis.
Subsequent studies suggested more favorable results. In long lesions, Serruys
et al\textsuperscript{52} showed the superiority of IVUS-guided stenting compared to optimal
balloon angioplasty in the Additional Value of NIR Stents for Treatment of
Long Coronary Lesions (ADVANCE) trial.\textsuperscript{52} In this study, 437 patients with
lesions 20 to 50 mm in length were angioplastied with long balloons; 149 of
the patients (34\%) required bailout stenting for flow-limiting dissections. The
remaining 288 patients who achieved an optimal PTCA result were
randomized to IVUS-directed stenting or no further therapy. The restenosis
rate in the stent group was significantly lower than in the PTCA-only group (27% vs 42%; \( P = .022 \)), with no difference in early complications. Using IVUS guidance, Colombo et al\(^5\) described a technique whereby the vessel was aggressively dilated and segments within the lesion with minimal lumen areas less than 5.5 mm received spot stenting. Compared to usual stenting, spot stenting was associated with no difference in 30-day major adverse cardiac events (MACE) but with significantly less restenosis (25% vs 39%; \( P < .05 \)). Although single-center reports of spot stenting have been encouraging, the time-consuming and operator-dependent technique has not been embraced as a mainstream strategy.

Another strategy examined in the setting of small vessel intervention has been direct stenting.\(^5\) Garcia and colleagues\(^5\) randomized 350 patients with reference vessel sizes between 2.2 and 2.7 mm to either direct stenting or predilation followed by stenting using the Pixel stent (Abbott Vascular, Santa Clara, CA). Of those assigned to direct stenting, 83% were successfully stented without predilation. Binary angiographic restenosis at 180-day follow-up was 16% for direct stenting versus 25% for the control (\( P = \text{not significant} \ [\text{NS}] \)). Target lesion revascularization was low in both groups (3.4% vs 4.3% for direct stent vs control; \( P = \text{NS} \)).

Finally, the use of glycoprotein IIb/IIIa inhibitors as a routine strategy in small vessel intervention has not been shown to reduce restenosis. Hausleiter and colleagues\(^4\) randomized 502 patients in a 2 × 2 factorial design to stent (phosphochlorine-coated) versus PTCA and abciximab versus control. There was no difference in 30-day MACE, restenosis, or target vessel revascularization (TVR) between the abciximab and control groups.

**First-Generation Drug-Eluting Stents**

The fundamental problem with stenting in small arteries is that the amount of neointimal hyperplasia is independent of vessel size, with small arteries suffering on average the same amount of late loss (0.8 mm) as larger vessels.\(^8\) Because of lower postprocedure stent area, small vessels are less able to accommodate neointimal accumulation than larger arteries. Lesion length independently exacerbates the negative impact of smaller vessel size.\(^8\) Even when in-stent minimal vessel areas are large, small vessels have higher rates of TVR than larger vessels with similar postprocedural minimal in-stent
lumen areas (Fig. 39-2).  

FIGURE 39-2 Results of a study demonstrating that even when the in-stent minimal vessel areas are large, small vessels have higher rates of target vessel revascularization than larger vessels with similar postprocedural minimal in-stent lumen areas. (Based on data from Moussa I, Kobayashi Y, Adamian M, et al. Characteristics of patients with a large discrepancy in coronary artery diameter between quantitative angiography and intravascular ultrasound. Am J Cardiol. 2001;88:294-302.)

The solution to improving long-term outcomes in small and diffuse coronary artery stenting is to reduce neointimal proliferation, thereby attenuating late lumen loss. The site-specific application of antiproliferative agents such as sirolimus, paclitaxel, everolimus, and zotarolimus dramatically and unequivocally reduces restenosis in larger vessels. Subset analysis from randomized trials and subsequent small vessel–specific studies have demonstrated remarkable effectiveness in the setting of small vessel disease as well. Their impact on diffuse disease has been equally favorable.

An early analysis compared the use of sirolimus-eluting stent (SES) versus balloon angioplasty. In vessels with a reference size less than 3.0 mm, the effectiveness of the SES in the SIRIUS (Sirolimus) trial was compared to the results of balloon angioplasty in patients treated in BENESTENT I and II and STRESS. Subacute occlusion was 0.4% versus 1.4% (SES vs POBA), and the SES reduced target lesion revascularization (TLR) from 24% to 5.1% (difference, –18.9%; 95% CI, –23.5% to –14.3%), suggesting that the drug-
eluting stent was far more effective than balloon angioplasty.

In the evaluation of first-generation drug-eluting stents (DESs) on small vessel disease, the SIRIUS trial demonstrated that the Bx-VELOCITY SES (Cordis, Hialeah, FL) dramatically reduced in-stent late loss in smaller vessels with some attenuation of the effect over the analysis segment due to proximal edge restenosis (Fig. 39-3).\textsuperscript{58} TVR was reduced in a similar fashion, although the relative reduction was somewhat less for smaller vessels. Likewise, the results from the e-SIRIUS and c-SIRIUS trials, looking at the benefits of CYPHER stents (Cordis) in small vessels compared to the Bx-VELOCITY bare metal stents,\textsuperscript{61} demonstrated decreased late lumen loss across all vessel sizes, particularly small vessels (~2.2 mm), of 0.12 mm. The lack of edge restenosis shown in these studies suggests that avoiding geographic miss and stenting “normal to normal” is particularly important in small vessels.

Like the SES, the paclitaxel-eluting stent (PES) has been shown to be
Results from the TAXUS IV (Treatment of De Novo Coronary Disease Using a Single Paclitaxel-Eluting Stent) trial demonstrated substantial reductions in in-segment restenosis, with no edge restenosis and with concomitant reductions in TVR and TLR (Fig. 39-4). However, older trials comparing PES with SES in small vessel and diffuse coronary disease were inconsistent. The REALITY trial randomized patients having a mean vessel diameter of 2.4 mm and a lesion length of 17 mm to either the TAXUS (Boston Scientific, Marlborough, MA) or CYPHER SES stent. Although the in-stent late loss was significantly less in the CYPHER group, there was no overall significant difference in binary angiographic restenosis and TLR; in particular, neither stent was superior in the subgroups of “long lesions” and “small vessel.” In contradistinction, the SIRTAX (Sirolimus-Eluting Versus Paclitaxel-Eluting Stents for Coronary Revascularization) trial exhibited that the angiographic restenosis and TLR associated with CYPHER was significantly lower overall in small vessels and long lesions compared to the PES.

**FIGURE 39-4** Results from TAXUS IV, which demonstrate significant reductions in in-segment restenosis. Although the relative reductions in restenosis were similar between vessel sizes, the absolute difference was greater with smaller vessel size. QCA, quantitative coronary angiography. (Based on data from Grube E, Silber S, Hauptmann KE, et al. TAXUS I: six- and twelve-month results from a randomized, double-blind trial on a slow-release paclitaxel-eluting stent for de novo coronary lesions. *Circulation*. 2003;107:38-42.)
**Newer Generation Drug-Eluting Stents**

The benefits of newer generation DESs in treating coronary stenosis by percutaneous transcatheter intervention compared to older therapies extend to the treatment of small vessel coronary disease, as well. The newer generation everolimus-eluting stents (EESs) have particularly been demonstrated to be effective in reducing clinical and angiographic events in diffuse, small vessel disease. The XIENCE V USA study was a “condition of approval” postmarket study involving 5054 patients to evaluate the safety of XIENCE V (Abbott Vascular), everolimus-eluting platform in a real-world setting. Two cohorts were identified; a small vessel cohort comprising 1869 patients who received at least one 2.5-mm XIENCE V stent and a non–small vessel cohort comprising 2905 patients who received XIENCE V stents larger than 2.5 mm. Baseline characteristics were similar between both patient populations, with the exception that small vessel patients were more likely to be women; had a higher prevalence of diabetes, hypertension, and anemia; and were more likely to have had a prior myocardial infarction, multivessel disease, and prior coronary artery bypass graft. Despite these differences in baseline characteristics and clinical risk factors, 1-year clinical outcomes were similar in both the small vessel and non–small vessel groups, which included stent thrombosis rates, and composite rates of cardiac death or Academic Research Consortium–defined myocardial infarction. TLR was higher in the small vessel group (4.9% vs 3.8%).

More consistent differences between drug-eluting platforms were demonstrated between EES and PES in a subset in a post hoc analysis of the SPIRIT (Clinical Evaluation of the XIENCE V Everolimus Eluting Coronary Stent System in the Treatment of Patients with de novo Native Coronary Artery Lesions) III trial, which sought to compare clinical and angiographic outcomes in patients treated with 2.5-mm XIENCE V (EES) or TAXUS stents; lower rates of late loss were observed in vessels treated with EES. The subgroup of patients in the original trial who received at least one 2.5-mm stent consisted of 160 patients (total of 190 stents implanted) in the XIENCE V arm and 59 (total of 67 stents) in the TAXUS arm, with a mean vessel diameter of 2.36 ± 0.3 mm and 2.34 ± 0.33 mm in the XIENCE V and TAXUS arms, respectively. In-hospital and 30-day event rates for MACE and target vessel failure (TVF) were low and similar in both groups. Through 9 months of follow-up, however, TVF and MACE were significantly lower in
the group receiving EES compared to PES. The difference in MACE was driven mainly by a reduction in TLR (1.3% vs 12.5%; \( P = .0016 \)). Follow-up angiography also demonstrated a significant difference in in-stent and in-segment late loss between the stents, and binary in-segment angiographic restenosis was significantly lower for the EES group (4.1% vs 20.8%; \( P = .02 \); Fig. 39-5).

Another pooled analysis from both the SPIRIT III and SPIRIT IV trials also demonstrated reduced clinical adverse events in patients with small vessel disease treated with EES compared to PES. In this patient-level meta-analysis, which included 4689 patients, randomized 2:1 to EES versus PES, patients with small vessel intervention (n = 1019) were pooled, and the performance of these stents in single-lesion intervention was evaluated at 1 year. The use of EES was associated with a significant reduction in target lesion failure (4.4% vs 7.9%; \( P = .03 \)) in favor of EES. Target lesion revascularization was also significantly reduced by 56% in small vessels with EES compared to PES (2.4% vs 5.5%; \( P = .02 \)). It was concluded then that in
high-risk patients requiring percutaneous coronary intervention in small coronary arteries, EES results in significantly improved 1-year rates of event-free survival compared to PES, with evidence present for both enhanced safety and efficacy.

Similar data are available for the zotarolimus-eluting stents (ZES) and the treatment of small vessel disease. The ENDEAVOR IV and RESOLUTE trials looking at first- and second-generation ZES, respectively, demonstrated good outcomes and at least noninferiority when compared to PES, SES, or EES. However, the mean reference vessel diameter was 2.73 mm for ZES and 2.70 mm for PES in the ENDEAVOR IV trial and 2.59 mm for ZES in the RESOLUTE trial. The results of a small trial looking at the second-generation ZES RESOLUTE (R-ZES) in small vessel coronary artery disease were recently published. This study sought to examine the angiographic results of R-ZES in de novo coronary lesions of ≥50% diameter stenosis in target vessels ≤2.5 mm. The results on follow-up angiography performed on 143 lesions in 127 patients demonstrated an angiographic restenosis rate of 6.3%, with late lumen loss of 0.26 ± 0.34 mm. At 1-year follow-up, the MACE event rate was only 8.5%, which included 4 cardiovascular deaths, 2 nonfatal myocardial infarctions, and 6 repeated revascularizations. The results of a small trial looking at the second-generation R-ZES for treatment of small vessels compared to larger vessel intervention. Looking at 2-year clinical outcomes from 5 previously performed R-ZES studies comparing small vessel (reference vessel diameter [RVD] ≤2.5 mm; n = 1956) with larger vessel disease (RVD >2.5 mm; n = 3174), baseline characteristics revealed a higher incidence of comorbidities in the small vessel group. There was no significant difference in target lesion failure (TLF) (10.1% vs 8.7%; P = .54) at 2 years. When the subgroup of patients with diabetes was examined (n = 1553), there was no significant difference in 2-year TLF in small compared to large vessels (11.2% vs 11.1%; P = 0.17). Similarly, within the small vessel cohort, no significant difference was seen regarding TLF at 2 years between people with and without diabetes (11.2% vs 9.6%; P = .28).

The evidence supporting the use of second-generation DES, both EES and ZES, in treating small vessel coronary artery disease is encouraging. The use of these newer antiproliferative agents in the platforms of currently available DES appears superior to earlier generation DES as a treatment modality for
small vessel disease and certainly overcomes the inherent problems with balloon angioplasty alone in treating this difficult subset of patients.

**DRUG-ELUTING BALLOONS**

The success of drug-eluting stents in the treatment of coronary artery disease, mainly in the attenuation of cellularity and consequent neointimal hyperplasia, and thus reduction of restenosis and revascularization, is clear. Limitations to DES include the issue of late and very late stent thrombosis, as well as the difficulty in delivery and expandability of stents to tortuous, long calcified, and small vessels. Although treatment of small vessel disease has improved with the aforementioned newer generation agents, limitations of DES still exist.

Drug-eluting balloons (DEBs) have developed as a potential alternative that is intuitively attractive, especially for the treatment of in-stent restenosis of bare metal stents or DES. The use of DEB allows for the delivery of an antiproliferative agent, while potentially eliminating the nidus for late and very late stent thrombosis. For these reasons, as well as a relatively higher restenosis rate of small vessel coronary artery disease treated with DES, the use of DEB was thought to be an attractive alternative in this patient cohort.

Small vessel disease treated with a paclitaxel DEB has been shown to be associated with less angiographic late loss and similar rates of restenosis and revascularization as compared to PES. In the BELLO (Balloon Elution and Late Loss Optimization) trial, 182 patients with lesions located in small vessels (reference diameter <2.8 mm) were randomized to treatment with paclitaxel DEB and provisional bare metal stenting (n = 90) or PES implantation (n = 92). The primary end point was no inferiority of angiographic in-stent (in-balloon) late loss with a delta of 0.25 mm. Secondary end points were angiographic restenosis, target lesion revascularization, and MACE (death, myocardial infarction, TVR) at 6 months. Although the DEB group had smaller vessel sizes overall, the groups were otherwise well matched, and the majority of the treated lesions (89%) were <2.5 mm in diameter. The primary end point of in-device late loss was significantly less with DEB compared to PES ($P_{\text{noninferiority}} < .001$; $P_{\text{superiority}} = .001$). At 6-month follow-up, the angiographic restenosis, TLR, and MACE rates were similar between DEB and PES. 73
The results of this trial, although encouraging for the use of DEB in the treatment of small vessel disease, contradict data from the earlier PICCOLETO trial. In the PICCOLETO trial, the Dior (Eurocor, Bonn, Germany) paclitaxel-covered balloon (PCB) failed to show no inferiority to paclitaxel DES regarding angiographic end points during percutaneous coronary intervention (PCI) of small coronary arteries. The trial was a small randomized study including patients with stable or unstable angina undergoing PCI of small coronary vessels (≤2.75 mm) who were randomized to Dior PCB (n = 28) or paclitaxel DES (n = 29). The primary study end point was stenosis diameter percentage at 6-month angiographic follow-up (noninferiority), with secondary end points being angiographic binary restenosis and occurrence of MACE (death, myocardial infarction, or TLR) at 9-month follow-up. The study was terminated early, after clear superiority in stenosis percentage of PES was observed (43.6% vs 24.3%; \( P = .029 \)) in two-thirds of enrolled patients. Angiographic restenosis and MACE were also significantly higher in the PCB group compared to the PES group\(^7\) (Fig. 39-6).

![The piccoleto trial](image)

**FIGURE 39-6** In the PICCOLETO trial, the Dior paclitaxel-eluting balloon (PEB) failed to show noninferiority to paclitaxel-eluting stent (PES) regarding angiographic end points during percutaneous coronary intervention of small coronary arteries. PES was superior to PEB in stenosis percentage (24.3% vs 43.6%; \( P = .029 \)). Angiographic restenosis and major adverse cardiac events were also significantly higher in the PEB group compared to the PES group. (Reproduced from Cortese B,

Although the widespread use of these devices may have a future niche role in treating in-stent restenosis, based on these 2 small trials, the data are certainly lacking to suggest a clear role for drug-eluting/drug-coated balloons in the treatment of small vessel coronary disease.

**BIOREABSORABLE POLYMERS AND STENTS**

The use of biodegradable polymers, as opposed to durable polymers, which serve as the vehicle for the elution of antiproliferative agents, has garnered interest in recent years as a way of minimizing the limitations of DES in the treatment of de novo coronary lesions. It is hypothesized that the eventual reabsorption of polymer not only removes a trigger of inflammation, but also decreases the risk of late and very late stent thrombosis, because endothelialization occurs sooner. Although DESs that are not permanent are intuitively attractive, good data are lacking regarding this technology as it relates to small vessel disease.

Finally, the use of bioabsorbable stent scaffolding represents a groundbreaking advance in the field of PCI. Long-term follow-up from the ABSORB I and II studies of bioresorbable vascular scaffold (BVS) suggested late plaque regression and favorable remodeling, which are attributes that would be particularly beneficial in the setting of small vessel disease. ABSORB III randomized 2008 patients 2:1 to the ABSORB BVS (Abbott Vascular) versus XIENCE in patients with uncomplicated lesions. The strut thickness of the ABSORB BVS is 150 μm. Although the overall trial suggested noninferiority of the bioresorbable stent compared to the XIENCE metallic platform, patients with small vessels (particularly <2.5 mm in diameter) had a higher stent thrombosis rate. This may have been due to the relatively high ratio of stent thickness to vessel lumen diameter in these small vessels, particularly when coupled with suboptimal stent dilatation. There are no trials to date specifically looking at bioresorbable scaffolding in the treatment of small vessel disease. As the strut thickness of these
bioresorbable scaffolds decreases and implantation techniques are optimized, we will have to see how these devices compare to the best metallic platforms. If their early safety is comparable, they may have an advantage if the promise of their long-term benefits is demonstrated (Fig. 39-7).

**FIGURE 39-7** ABSORB III 1-year events based on the reference vessel diameters (RVDs) of less than or greater than 2.25 mm. $P_{\text{int diff}}$, $P$ value for interaction difference; QCA, quantitative coronary angiography; ST, stent thrombosis; TLF, target lesion failure. **WHAT PCI THERAPY IS BEST FOR SMALL VESSELS?**

To evaluate the most appropriate PCI in the treatment of small vessel coronary disease, Siontis and colleagues\(^76\) performed a pairwise meta-analysis followed by a network meta-analysis of small vessel PCI studies. Nineteen trials were included with over 5000 patients.\(^76\) The 5 identified interventions included and compared were (1) first-generation SES, (2) first-generation PES, (3) DCB, (4) bare metal stents, and (5) balloon angioplasty (BA). No dedicated trial was identified evaluating new-generation DESs.
Both angiographic and clinical outcomes were assessed. Early-generation SES yielded the best angiographic results according to percent diameter stenosis. For percent diameter stenosis, SES was ranked as the most effective treatment followed by PES and DCB. In terms of absolute differences, SES yielded a significant reduction of 18% in diameter stenosis compared to DCB. SES significantly reduced the risk of TLR versus PES, DCB, bare metal stent, and BA (Fig. 39-8).

**FIGURE 39-8** Network meta-analysis demonstrating superiority of sirolimus-eluting stent (SES) over other percutaneous coronary intervention PCI modalities. A. Ranking plots for all the outcomes of with respect to diameter stenosis. Interventions have been ranked according to the surface under the cumulative ranking curve (SUCRA) values. SES was superior to all other modalities; balloon angioplasty (BA) was least effective. B. Estimated odds ratios (95% confidence intervals [CIs]) for the secondary outcomes of the network meta-analysis (binary restenosis, target lesion revascularization, myocardial infarction, and overall mortality) of different percutaneous interventions compared to BA. BMS, bare-metal stent; DCB, drug-coated balloon; PES, paclitaxel-eluting stent; PrI, prediction interval; SMD, standardized mean difference. (Reprinted from Siontis G, Piccolo R, Praz F, et al. Percutaneous coronary interventions for the treatment of stenoses in small coronary arteries: a network meta-analysis. *JACC Cardiovasc Interv*. 2016;9(13):1324-1334, Copyright © 2016, with permission from American College of Cardiology Foundation.)

**SUMMARY**
Small vessel and diffuse coronary disease continue to be challenging subsets even in the era of advanced transcatheater therapies. Frequently, what is thought to be a small vessel by angiographic criterion is often incorrect, because unsuspected disease in the reference areas and positive remodeling at the lesion promote the underestimation of vessel size, particularly in the proximal coronary segments and in patients with diabetes. The acute risks and technical problems associated with percutaneous intervention of these lesions can be higher, although advances in stent design and the use of newer antiproliferative agents have attenuated these challenges. DESs have revolutionized the treatment of small and diffuse disease. Although the restenosis rates with DES in small vessels may be incrementally higher than in larger vessels, DESs dramatically improve angiographic outcomes and reduce repeat revascularization in small and diffuse vessel coronary intervention, particularly limus-eluting stents. Newer technologies, such as the use of biodegradable polymers or bioabsorbable stents, may play a significant role in the future of treating these lesions. Nonetheless, the use of DES has truly become the dominant technology used for these lesions and has broadened the indication for transcatheter therapy in many untreatable patients who suffer from the difficult problem of small and diffuse coronary disease.

MULTIPLE CHOICE QUESTIONS

1. Independent predictors of underestimating the true coronary vessel size based on a disparity between intravascular ultrasound (IVUS)–determined reference lumen diameter and coronary angiography include all of the following except:
   A. Diabetes
   B. Proximal left anterior descending artery (LAD) lesion location
   C. Coronary calcification
   D. Diffuse disease

2. True or false? Small vessel size has been associated with higher restenosis rates. However, equally expanded stents (equal minimum stent area) in different-sized arteries have equivalent restenosis risk.

3. True or false? For calcified small coronary lesions, prestent atherectomy has been associated with lower restenosis rate.

4. True or false? Compared to bare metal stents, percutaneous transluminal coronary angioplasty has a higher rate of target lesion revascularization.

5. True or false? Compared to drug-eluting stents, bare metal stents in small vessels have a lower incidence of negative remodeling over the first year.

6. The use of bioresorbable scaffolds in small vessels has been associated with higher stent thrombosis compared to metallic second-generation drug-eluting stents in vessels smaller than which size?
   A. 2.5 mm
   B. 2.75 mm
   C. 3.0 mm
   D. 3.25 mm

PREVALENCE OF DIABETES MELLITUS

Diabetes mellitus affects a significant portion of the population; 1 in 10 adults in the United States has diabetes, with 90% to 95% of patients having type 2 diabetes.\(^1\) In 2012, nearly 20.1 million Americans ≥20 years of age were diagnosed with diabetes mellitus, 8.1 million Americans had undiagnosed diabetes mellitus, and an estimated 80.8 million (35.3%) had prediabetes (ie, fasting blood glucose of 100 to <126 mg/dL).\(^1\) The prevalence of diabetes mellitus is rapidly increasing and is attributed to the increased frequency of obesity, suboptimal nutritional habits, and aging of the population (Fig. 40-1).\(^2\) The total prevalence of diabetes mellitus in the United States is expected to more than double from 2005 to 2050 (from 5.6% to 12.0%) in all age, sex, and race/ethnicity groups, with minorities disproportionately affected.\(^1\) This increase, however, is not limited to the United States. The global prevalence of diabetes mellitus for all age groups is also increasing. In 2010, the prevalence of diabetes mellitus worldwide was estimated to be 6.4% and is projected to increase to 7.7% in 2030; the total
number of people with diabetes mellitus is projected to increase from 285 million in 2010 to 439 million in 2030.\textsuperscript{1,3}

Global and societal implications of the diabetes epidemic. *Nature*. 2001;414:782-787, Copyright © 2001.)

**DIABETES AND CARDIOVASCULAR DISEASE: GENERAL CONSIDERATIONS**

The interventional cardiologist often encounters patients with diabetes mellitus in more advanced stages, when vascular complications have already occurred. The pathophysiology of vascular disease involves derangements in endothelial, vascular smooth muscle cell, and platelet function.\textsuperscript{4} The hyperglycemia, increased availability of free fatty acids, and insulin resistance in the diabetic patient collectively decrease nitric oxide availability, increase oxidative stress, disrupt intracellular signal transduction,
and activate receptors for free radical–producing advanced glycation end products. In addition, several deregulatory factors play a part in the derangements of coagulation and platelet activity seen in patients with diabetes, mostly mediated by enhancement of the prothrombotic state due to insulin resistance and hyperglycemia. Subsequently, atherosclerosis ensues, and as such, the risk for adverse cardiovascular events increases.

The concept of diabetes as a coronary artery disease (CAD) risk equivalent has its roots in a landmark Finnish-based study that demonstrated that the presence of diabetes alone increased the 7-year risk of fatal and nonfatal myocardial infarction (MI). These results laid the foundation for the recommendation that patients with diabetes receive secondary level prevention per the Adult Treatment Panel III of the National Cholesterol Education Program.

Indeed, CAD is prevalent in the patient with diabetes even when asymptomatic. Occult CAD was discovered in asymptomatic patients with diabetes who underwent coronary computed tomography angiography despite having a normal stress test (using single-photon emission computed tomography pharmacologic stress testing), a normal electrocardiogram, a lack of symptoms, and a lack of peripheral arterial disease. A separate study of an autopsy cohort from Olmstead County, Minnesota, examined patients with diabetes without prior evidence of clinical CAD and found that they were more likely than their nondiabetic counterparts to have high-grade atherosclerosis (68% vs 46%; \( P < .001 \)) and more likely to have multivessel CAD (50% vs 31%; \( P < .001 \)).

Moreover, the presence of angina was not found to be predictive of future mortality or cardiac events. In a post hoc analysis of the Bypass Angioplasty Revascularization Investigation in Patients With Diabetes (BARI 2D) trial, the prognostic significance of angina or its equivalents was examined, and it was determined that the presence of angina did not significantly affect the 5-year risk of cardiovascular events or all-cause mortality.

The patient with diabetes and underlying ischemic heart disease is more likely to be female and have a higher prevalence of hypertension, hypercholesterolemia, renal insufficiency, peripheral vascular disease, and congestive heart failure. There is an excess mortality associated with CAD in patients with diabetes, particularly in patients with acute coronary syndromes (ACS), and females have a relative risk for fatal CAD that is
50% higher than males.  

**MEDICAL THERAPY**

It is well established that patients with CAD across the spectrum of stable ischemic heart disease, ACS, and ST-segment elevation MI (STEMI) should be treated with guideline-directed medical therapy (GDMT). However, in patients with diabetes, with more rapid progression of atherosclerosis and a higher incidence of adverse events, special considerations exist. It has been shown that diabetes is a clinical predictor of nonresponse to aspirin and clopidogrel therapy, suggesting that patients with diabetes may require more aggressive antiplatelet regimens. Using aggregation-based testing in a prospective evaluation of 635 patients with non-STEMI to evaluate the clinical predictors of nonresponse to aspirin and clopidogrel therapy, diabetes was associated with an attenuated response to these antiplatelet agents.

In addition, subgroup analysis of patients with diabetes in the Trial to Assess Improvement in Therapeutic Outcomes by Optimizing Platelet Inhibition With Prasugrel–Thrombolysis in Myocardial Infarction 38 (TRITON-TIMI 38) examined the net effect of diabetes on the efficacy and safety profiles of prasugrel as compared with clopidogrel. For patients with diabetes treated with prasugrel for high-risk ACS, the rate of cardiovascular death, nonfatal MI, and nonfatal stroke was significantly reduced as compared with clopidogrel (Fig. 40-2).
FIGURE 40-2 Kaplan-Meier curves for prasugrel versus clopidogrel stratified by diabetes status. A. Primary efficacy end point (cardiovascular death, nonfatal myocardial infarction [MI], or nonfatal stroke) stratified by diabetic status. B. MI (fatal or nonfatal). DM, diabetes mellitus; HR, hazard ratio. (Reproduced with permission Wiviott SD, Braunwald E, Angiolillo DJ, et al. Greater clinical benefit of more intensive oral antiplatelet therapy with prasugrel in patients with diabetes mellitus in the trial to assess improvement in therapeutic outcomes by optimizing platelet inhibition with prasugrel-Thrombolysis in Myocardial I. Circulation. 2008;118:1626-1636.)

The BARI 2D trial compared GDMT with and without coronary revascularization in a relatively low-risk population and revealed that an initial strategy of percutaneous coronary intervention (PCI; n = 1605) or coronary artery bypass graft (CABG; n = 763) plus GDMT did not improve
outcomes compared with GDMT alone (freedom from death, MI, or stroke: 77.2% vs 75.9%). However, in the CABG-stratified group (more advanced CAD and class C lesions), freedom from death, MI, or stroke was significantly lower in patients treated with CABG plus GDMT compared with GDMT alone (77.6% vs 69.5%), suggesting that patients with advanced CAD may benefit from CABG.\textsuperscript{20}

**CORONARY REVASCULARIZATION: SPECIAL CONSIDERATIONS**

Nearly 25\% of all revascularization procedures are performed in patients with diabetes\textsuperscript{1}; in the National Cardiovascular Data Registry, 36.2\% of patients undergoing PCI between 2010 and 2011 had diabetes.\textsuperscript{21} Although acute procedural success and complications are similar in patients with and without diabetes undergoing PCI,\textsuperscript{11,22} patients with diabetes are more likely to have advanced CAD, with more multivessel disease, total occlusions, and diffuse disease.\textsuperscript{11,23} This finding may translate to higher in-hospital mortality rates. In an analysis of the National Heart, Lung, and Blood Institute (NHLBI) Dynamic Registry, a significantly higher in-hospital mortality in patients with diabetes compared to patients without diabetes (diabetes 2.3\% vs no diabetes 1.3\%; $P = .02$) undergoing PCI was observed.\textsuperscript{11} Patients with diabetes who undergo PCI are at increased risk not only for death and MI during subsequent follow-up, but also for repeat revascularization and angiographic restenosis.\textsuperscript{11,24,25} Patients with diabetes, in particular type 1 diabetes with poor glycemic control, who underwent CABG had increased long-term risk of major adverse coronary events and all-cause mortality.\textsuperscript{26} In addition, patients with type 1 diabetes who underwent CABG were found to have a more than 2-fold increased risk of death at 6 years compared with the general population, whereas patients with type 2 diabetes had only a slightly worse prognosis after CABG.\textsuperscript{27}

Revascularization considerations for patients with diabetes across the spectrum of CAD have been noted earlier for patients with stable ischemic heart disease where CABG may play a role in patients with advanced disease. Although the last 2 decades have witnessed an innovative expansion of catheter-based therapy for CAD, for the patient with stable ischemic heart
disease, this expansion has not resulted in a survival improvement but rather a decrease in restenosis. A meta-analysis comparing these methods to medical therapy in stable CAD did not improve the rates of death or MI.²⁸

In patients with ACS, in whom 30-day mortality is higher in patients with diabetes compared to without diabetes, the benefit seen overall in terms of a decrease in major adverse cardiac events is similar in patients with and without diabetes. However, patients with diabetes experienced a reduction in nonfatal MI (relative risk [RR], 0.71; 95% confidence interval [CI], 0.55-0.92) not seen in patients without diabetes.²⁹ It is noteworthy that the American College of Cardiology/American Heart Association guidelines suggest that the invasive strategy is preferred in patients with diabetes and ACS.³⁰ For patients with STEMI and diabetes, management should be similar to that for patients without diabetes, where primary PCI is the preferred strategy if accomplished within guideline-recommended time to reperfusion.

**RESTENOSIS**

There is evidence that the metabolic abnormalities associated with the diabetic state (hyperglycemia and hyperinsulinemia) can lead to enhanced platelet adhesion, activation, and aggregation, in addition to thrombus formation, endothelial cell dysfunction, and alterations in local growth factor production.³¹ Smooth muscle cell proliferation and extracellular matrix deposition, crucial elements in the cellular response to vessel injury and subsequent development of restenosis following PCI, are also enhanced in diabetic patients.³¹ It has been observed that the mechanism of increased restenosis in patients with compared to without diabetes following coronary stent placement was due to increased late loss of minimal lumen diameter, suggesting more aggressive neointimal hyperplasia with diabetes.³²

The presence of diabetes is an independent risk factor for restenosis after PCI. Among patients with diabetes who underwent standard balloon angioplasty in the first report from the NHLBI Percutaneous Transluminal Coronary Angioplasty Registry in the early 1980s, restenosis occurred in 47%, compared with 32% in patients without diabetes.³³ This finding is not limited to patients undergoing balloon angioplasty, but extends to those who are treated with stents. In a study that included over 12,000 patients with
diabetes undergoing stent implantation (bare metal and first- and second-generation drug-eluting stents), diabetes was an independent risk factor for restenosis (odds ratio, 1.32; 95% CI, 1.19-1.46). Although drug-eluting stents have been shown to have significantly lower rates of restenosis as compared to bare metal stents, restenosis still occurs and may be related to longer stent length and small vessel size in patients with diabetes.

**DRUG-ELUTING STENTS**

In 2010, approximately 75% of stents used during PCI were drug-eluting stents and 25% were bare metal stents. As compared with bare metal stents, drug-eluting stents reduce cardiac events in a broad selection of patients with angina or ACS, a finding driven by a reduction in restenosis. In the patient with diabetes, the advantages of drug-eluting stents have also been observed. In all patients with diabetes who underwent PCI with stents between April 1, 2003, and September 30, 2004, in the state of Massachusetts, drug-eluting stents reduced mortality, MI, and revascularization compared with bare metal stents (Fig. 40-3).
FIGURE 40-3 Clinical outcomes after stenting in patients with diabetes mellitus. Cumulative incidence of mortality (A), myocardial infarction (B), and target vessel revascularization (C) at 3 years in the matched cohort of patients with diabetes. Solid lines indicate drug-eluting stents (DES); dashed lines indicate bare metal stents (BMS). Error bars are 95% confidence intervals. (Reproduced with permission from Garg P, Normand S-LT, Silbaugh TS, et al. Drug-eluting or bare-metal stenting in patients with diabetes mellitus: results from the Massachusetts Data Analysis Center Registry. Circulation. 2008;118:2277-2285.)

In a collaborative network meta-analysis of 35 trials, sirolimus- and paclitaxel-eluting stents were found to be safe and effective in both patients with and without diabetes when combined with greater than 6 months of dual antiplatelet therapy. In another analysis, the outcomes of various commercially available drug-eluting stents (including sirolimus-, paclitaxel-, zotarolimus-, and everolimus-eluting stents) were examined. In this mixed treatment comparative meta-analysis of 42 trials with over 10,000 patients...
with diabetes, all of the drug-eluting stents showed a reduction in target vessel revascularization compared with bare metal stents. The efficacy varied between stents, with everolimus-eluting stents having the lowest rate of target vessel revascularization compared to zotarolimus, sirolimus, and paclitaxel stents.³⁹

**PCI VERSUS CABG**

The optimal method of revascularization, percutaneous or surgical, has been debated for nearly 2 decades. Complicating the interpretation of the initial studies, which compared the outcomes of surgical versus percutaneous modalities of revascularization in the patient with diabetes, are the recent advances in both surgical and percutaneous techniques and materials. Table 40-1 presents an overview of the major trials comparing PCI with CABG in patients with diabetes and multivessel CAD.⁴⁰

Abbreviations: BMS, bare-metal stent; CABG, coronary artery bypass graft; CAD, coronary artery disease; significant multivessel CAD defined as >70% stenosis in ≥2 major epicardial coronary arteries; DES, drug-eluting stent; MACCE, major adverse cardiac and cerebrovascular events (defined as all-cause mortality, myocardial infarction, stroke, or repeat revascularization); NR, not reported; PCI, percutaneous coronary interventions; RCT, randomized clinical trials.

*Composites pertaining to the diabetic cohort reported.
*Subset of patients with treated diabetes.
*Only percentage was reported.
*Initially started with BMS and switched to sirolimus-eluting stents when they became available.
*All outcomes are defined at 1 year in this FREEDOM trial.
*Choice of any US Food and Drug Administration-approved DES.

The first major trial comparing the outcomes of the 2 revascularization strategies was a subset analysis of the initial BARI trial.⁴¹ In this landmark study, 1829 patients with symptomatic multivessel CAD were randomized to
either multivessel balloon angioplasty (percutaneous transluminal coronary angioplasty [PTCA]) or CABG. Although the overall trial results showed no difference in mortality between the 2 revascularization strategies, analysis of the 353 patients with diabetes revealed a significantly lower 5-year survival in the group treated with PTCA compared with CABG (65.5% vs 80.6%).\textsuperscript{42} In a 10-year follow-up analysis, this survival disadvantage persisted in individuals managed with PTCA (PTCA 45.5% vs CABG 57.8%; \( P < .025 \)).\textsuperscript{43}

Additional findings from this study revealed that the benefit of surgery was greater in patients with diabetes treated with insulin compared to those treated with oral hypoglycemic agents and appeared to be limited to patients receiving a left internal mammary artery (LIMA) graft and to those with more diffuse disease defined by 4 or more lesions.\textsuperscript{42,44}

One possible explanation for the improved survival seen in patients with diabetes undergoing CABG may be related to progression of disease in patients undergoing PTCA. A retrospective analysis of 248 patients referred for diagnostic angiography >1 month after successful PTCA found a significantly higher rate of new lesions on the follow-up angiogram in patients with compared to without diabetes (22% vs 12%; \( P < .004 \)).\textsuperscript{45} PTCA appeared to increase the risk of new lesions distant from the treatment site, and the risk was additive in patients with diabetes. This may, in part, account for the possible survival advantage of CABG, especially when using the LIMA.

The Coronary Angioplasty Versus Bypass Revascularization Investigation (CABRI) and Emory Angioplasty versus Surgery Trial (EAST) trials were similar trials of PTCA versus CABG in patients with multivessel CAD.\textsuperscript{46,47} Although both trials showed a trend toward improved survival with CABG in the diabetes subset, the number of patients with diabetes in these trials was small, and the differences did not reach statistical significance.

Moreover, in a collaborative analysis of patient data from 10 randomized trials of PCI compared with CABG in patients with multivessel CAD, including 4 trials using bare metal stents in 7821 patients of whom 1233 were patients with diabetes, mortality was similar at a median follow-up of 5.9 years. However, in patients with diabetes, CABG was associated with significantly lower mortality (23% vs 29%; hazard ratio [HR], 0.7; 95% CI, 0.56-0.87) in comparison to PCI. While overall mortality was 50% lower in
the trial using bare metal stents, the relative advantage of CABG persisted overall and in patients with diabetes.\textsuperscript{48}

The majority of these early trials preceded the modern era of coronary stents and technical improvements in PCI and surgical revascularization. In the Arterial Revascularization Therapies (ART) Part-I and Part-II studies, bare metal stents, sirolimus-eluting stents, and surgical revascularization were compared. These studies included a total of 367 patients with diabetes, in whom there were 112 patients who received bare metal stents, 159 patients who received sirolimus-eluting stents, and 96 CABG patients.\textsuperscript{49} The rate of major adverse cardiovascular and cerebrovascular events favored the surgical revascularization group (bare metal stents 53.6\% vs CABG 23.4\% vs sirolimus-eluting stents 40.5\%; \( P < .01 \) for sirolimus-eluting stents vs bare metal stents and sirolimus-eluting stents vs CABG). Repeat revascularization was highest with the bare metal stent group at 43.5\%, compared with 33.2\% in the sirolimus-eluting stent group and 10.7\% in the CABG group (sirolimus-eluting stent vs bare metal stent, \( P < .02 \); sirolimus-eluting stent vs CABG, \( P < .01 \)). Of note, mortality was not significantly different between all 3 groups.

The CARDia (Coronary Artery Revascularization in Diabetes) trial was the first to enroll an all-diabetic cohort with CAD and randomize patients to CABG versus PCI plus stenting (with bare metal stents or sirolimus-eluting stents). Although 1-year results revealed all-cause mortality rates of 3.2\% for both groups, this study failed to show that PCI was noninferior to CABG. When repeat revascularization was added to the composite of death, MI, or stroke, there was a significant difference favoring CABG (11.3\% vs 19.3\% in the CABG and PCI groups, respectively; HR, 1.77; 95\% CI, 1.11-2.82; \( P = .02 \)).\textsuperscript{50}

In the Synergy Between PCI With Taxus and Cardiac Surgery (SYNTAX) trial, investigators compared PCI (with paclitaxel-eluting stents) with CABG in 1800 patients with de novo left main or 3-vessel CAD.\textsuperscript{51} After a follow-up of 5 years, the subset of patients with medically treated diabetes (\( n = 452, 26\% \)) had significantly higher rates of major adverse cardiac and cerebrovascular events when treated with PCI compared with CABG (PCI 46.5\% vs CABG 29.0\%; \( P = .001 \))\textsuperscript{52} driven by repeat revascularization. However, there remained no significant difference in all-cause mortality in this subgroup with diabetes (PCI 23.9\% vs CABG 19.1\%; \( P < .26 \)).
An interesting subgroup analysis of SYNTAX compared patients with and without diabetes with low (<22) SYNTAX scores. In this subgroup, management with PCI resulted in comparable major adverse cardiac and cerebral event rates (30.5% vs 29.8%; \( P < .98 \)), with no difference in repeat revascularization (Fig. 40-4).\textsuperscript{53} This suggests that PCI is a reasonable alternative to CABG in patients with diabetes with less complex 3-vessel or left main disease. However, these findings must be interpreted with caution in view of a small subset of patients with diabetes, use of first-generation drug-eluting stents, and an overall trial that did not meet its primary end point.
FIGURE 40-4 Three-year outcomes for patients with and without diabetes according to anatomic lesion complexity, as measured by the SYNTAX score: (A, D) major adverse cardiac and cerebrovascular events (MACCE); (B, E) composite of death, cerebrovascular accident (CVA), and myocardial infarction (MI); and (C, F) revascularization in patients with medically treated diabetes (A-C) and without medically treated diabetes (D-F). Rates are separated by SYNTAX scores, indicating low (≤22), intermediate (23–32), and high (≥33) anatomic lesion complexity. CABG, coronary artery bypass grafting (Blue); PCI, paclitaxel-eluting stent (Red).

(Reproduced with permission from Mack MJ, Banning AP, Serruys PW, et al. Bypass versus drug-eluting stents at three years in SYNTAX patients with diabetes mellitus or...

The Future Revascularization Evaluation in Patients With Diabetes Mellitus: Optimal Management of Multivessel Disease (FREEDOM) trial, the largest randomized trial investigating revascularization strategies in patients with diabetes, consisted of 1900 patients with diabetes and multivessel CAD who were randomized to either PCI with drug-eluting stents (primarily sirolimus-eluting and paclitaxel-eluting stents) or CABG. This study concluded that CABG was the superior modality of revascularization in this specific patient population. The majority of the patients (83%) had 3-vessel disease, mean SYNTAX score was 26.2 with a symmetric distribution, nearly all had hypertension and/or dyslipidemia, 26% had a prior MI, 29% had a low-density lipoprotein level <70 mg/dL, and 95% of patients received a LIMA conduit. During a median follow-up of 3.8 years, the primary end point of death from any cause, nonfatal MI, or nonfatal stroke occurred more frequently in the PCI group compared with the CABG group (P = .005). The 5-year rate of all-cause mortality, MI, and stroke was 26.6% in the PCI arm and 18.7% in the CABG arm. Of note, the rate of stroke was higher in the CABG arm compared with the PCI arm (5.2% vs 2.4%; P = .03), mostly driven by the excess of stroke event rate (87% ischemic, 13% hemorrhagic) within the first 30 days after surgery. The superiority of CABG was not affected by the SYNTAX score. Moreover, the individual end points of mortality and MI were significantly lower in the CABG group.

Finally, a meta-analysis of 4 randomized trials of PCI using drug-eluting stents and CABG in >3000 patients with diabetes revealed that the major adverse coronary event rate (death, MI, or stroke) was higher in the PCI group (22.5% vs 16.8%; RR, 1.34; 95% CI, 1.16-1.54; P < .0001). The superiority of CABG compared with PCI was most evident with high SYNTAX scores.

In aggregate, these data suggest that in patients with diabetes and multivessel disease, CABG is the preferred strategy, particularly in patients at low or moderate risk for surgery with complex anatomy and 3-vessel disease and in patients who will receive a LIMA graft.

**PRACTICAL CONSIDERATIONS**
As described earlier, patients with diabetes undergoing PCI are at risk for periprocedural and long-term complications. Careful peri- and intraprocedural management can often mitigate some of the acute risk, and here we discuss strategies that we believe are helpful to consider.

Patients with diabetes should be in a euvolemic state prior to and following use of iodinated contrast agents. Volume depletion increases the risk for contrast-mediated renal insufficiency, which is a concern in patients with diabetes, particularly in those with chronic kidney disease. We recommend that diuretics be held the morning of the scheduled procedure, and if there is any baseline renal impairment, we consider withholding angiotensin-converting enzyme inhibitors. Our practice is to withhold metformin at least 24 hours prior to the procedure, if possible, and to withhold it for a minimum of 72 hours after the procedure. In addition, we routinely hold oral hypoglycemic agents and short-acting insulin preparations. Long-acting insulin can be administered at a reduced (half) dose. Our patients also routinely receive 0.9% isotonic saline (with dextrose added if insulin is administered), at a rate of 1 mL/kg/h prior to the start of the procedure. After the procedure, we administer a high volume of hydration with saline infusion (minimum 1-2 L), maintaining euvolemia with furosemide as needed (with positive or negative fluid balance at 12-24 hours after procedure determined by filling pressures). Serum electrolytes and creatinine are routinely measured on the day after the procedure.

Transradial catheterization is associated with a lower incidence of bleeding and vascular complications when compared with the transfemoral route, and this is preferred, especially in the patient with diabetes and peripheral arterial disease. Since diabetic patients are at increased risk for repeat revascularization, drug-eluting stents are our preferred revascularization strategy.

**RECOMMENDATIONS**

We prefer PCI in patients with diabetes with single- or selected double-vessel CAD, if the anatomy is suitable, and especially if they are candidates for treatment with drug-eluting stents. However, deciding on a revascularization strategy in a patient with diabetes with triple-vessel (and multilesion) CAD is more of a challenge. We strongly consider CABG for patients with diabetes
with multivessel diffuse disease, especially if there is involvement of the proximal left anterior descending artery, which would allow grafting with an internal mammary artery. We also prefer CABG for patients with complex multivessel disease and reduced left ventricular function.

The Fractional Flow Reserve Versus Angiography in Multivessel Evaluation 2 (FAME 2) trial revealed similar results in patients with and without diabetes and improvements in stent technology including bioabsorbable stents, new platforms, and new polymers, and newer and more effective thienopyridines are on the horizon. Notwithstanding these advancements, since the mechanism responsible for the advantage of CABG compared with PCI in patients with diabetes and multivessel disease is most likely protection of the myocardium against subsequent events, it is expected that CABG will continue to be associated with more favorable outcomes.

**MULTIPLE CHOICE QUESTIONS**

1. In comparison with percutaneous coronary intervention (PCI), which of the following best explains the benefit of coronary artery bypass grafting (CABG) in patients with diabetes mellitus and multivessel coronary artery disease (CAD)?
   A. Fewer procedural complications with CABG
   B. Progression of disease following PCI
   C. Superior long-term patency of saphenous vein conduits compared with drug-eluting stents
   D. Higher periprocedural mortality with PCI compared with CABG

2. Compared with bare metal stents, drug-eluting stents reduce the incidence of which of the following in patients with diabetes?
   A. Stent thrombosis
   B. Periprocedural myocardial infarction
   C. Restenosis
   D. Periprocedural bleeding complications
3. CABG surgery is preferred to PCI in which of the following clinical scenarios in patients with diabetes?
   A. A 45-year-old man with unstable angina and a 90% stenosis in the mid right coronary artery
   B. A 60-year-old woman with rheumatoid arthritis on steroids, unstable angina, and a 70% discrete stenosis in the proximal circumflex artery and 90% ulcerated stenosis in the proximal right coronary artery
   C. A 55-year-old man with stable angina and an 80% stenosis in the proximal left anterior descending artery, a 100% stenosis in the proximal right coronary artery, and a 70% stenosis in the proximal left circumflex artery
   D. An 80-year-old man with stable class III angina and a 100% chronic occlusion of the proximal right coronary artery

4. The Bypass Angioplasty Revascularization Investigation (BARI) study demonstrated which of the following outcomes in patients with diabetes treated with balloon angioplasty (percutaneous transluminal coronary angioplasty [PTCA]) compared with CABG at 5-year follow-up?
   A. Decreased survival with PTCA
   B. Improved survival with PTCA
   C. Decreased rate of myocardial infarction (MI) with PTCA
   D. Decreased rate of MI with CABG

5. In the FREEDOM trial, which of the following was responsible for the benefit of CABG compared with PCI in patients with diabetes and multivessel CAD?
   A. Higher rate of death, MI, and stroke with PCI
   B. Lower rate of stroke with CABG
   C. Higher rate of stroke with PCI
   D. Lower rate of cardiovascular death with CABG

**ANSWERS**

1. B

Patients with diabetes mellitus treated with PCI are at increased risk for
progression of disease in nontreated segments of the coronary artery, which often leads to recurrent ischemic events and the need for subsequent repeat revascularization.

2. C

Bare metal stents were developed to reduce the incidence of restenosis following balloon angioplasty. Neointimal proliferation within the stent became an important limitation, leading to restenosis and need for subsequent revascularization, particularly in diabetic patients. Drug-eluting stents were developed to decrease the incidence neointimal proliferation and restenosis.

3. C

The 2011 American College of Cardiology Foundation/American Heart Association guidelines for CABG recommends CABG in preference to PCI to improve survival in patients with multivessel coronary artery disease and diabetes, particularly in patients in whom a left internal mammary arterial graft can be anastomosed to the left anterior descending artery (Class IIa, Level of Evidence B).

4. A

Although the overall BARI trial results showed no difference in mortality between the two revascularization strategies, subsequent post hoc analysis of the 353 diabetic patients revealed a significantly lower 5-year survival in the group treated with PTCA compared with CABG (65.5% vs 80.6%). In a 10-year follow-up analysis, this disadvantage persisted in those individuals managed with PTCA (PTCA 45.5% vs CABG 57.8%; P < .025).

5. A

The FREEDOM trial randomized patients with diabetes and multivessel CAD to either PCI with drug-eluting stents or CABG. During a median follow-up of 3.8 years, the primary end point of death from any cause, nonfatal MI, or nonfatal stroke occurred more frequently in the PCI group compared with the CABG group. The benefit of CABG was mostly driven by decreases in death and MI. The rate of stroke was higher in the CABG arm compared with the PCI arm, mostly driven by the excess of stroke event rate within the first 30
days after surgery.
The introduction of percutaneous balloon mitral valvuloplasty (BMV) by Inoue et al\textsuperscript{1} in 1982 has opened a new dimension in the treatment of patients with mitral stenosis. The body of data accrued to date has clearly established this invasive, nonsurgical procedure as the treatment of choice in symptomatic patients with moderate to severe mitral stenosis (mitral valve area $<1.5\text{ cm}^2$) and favorable valve morphology (noncalcified, pliable valve with minimal subvalvular disease and no or mild mitral regurgitation).\textsuperscript{2-5} The presence of either severe (grade $\geq 3$) angiographic mitral regurgitation or left atrial thrombus is considered to be a contraindication for BMV. However, several controversial issues in the use of this procedure exist, because the selection of patients for BMV in clinical practice continues to be a complex decision involving consideration of multiple variables, including clinical profile, operator skill, valve morphology, and severity of associated mitral regurgitation.

Among the multiple variables, valve morphology and severity of associated mitral regurgitation have, to a large extent, remained the principal determinants in patient selection. In patients with favorable valve morphology (pliable, noncalcified valve with minimal subvalvular disease) and no or mild mitral regurgitation, BMV predictably yields excellent results and a low risk of resultant severe mitral regurgitation. With successful balloon valve enlargement, there is generally a 2-fold increase in the mitral
valve area and an associated dramatic fall in transmitral valve gradient, left atrial pressure, and pulmonary artery pressure.\textsuperscript{2-5} These hemodynamic benefits are mirrored in clinical improvements in the patients’ symptoms and exercise tolerance.

This is not entirely surprising, considering the fact that BMV enlarges the stenosed mitral valve in the same manner as that afforded by surgical commissurotomy—namely that of commissural split. Several randomized trials\textsuperscript{6-11} comparing BMV and closed and/or open surgical commissurotomy in patients with favorable valve morphology have demonstrated that BMV is as efficacious, if not more so, than surgical mitral commissurotomy in acutely relieving the obstructed valve and achieving favorable clinical outcome. The long-term results of BMV are excellent, especially when the acute results are optimal and valve morphology is good. Long-term data in BMV have also indicated that after optimal mitral valve dilation, the restenosis rate is low and the acute symptomatic benefits are sustained.\textsuperscript{12-16} When restenosis is defined as mitral valve area less than 1.5 cm\textsuperscript{2}, the restenosis rate in patients with favorable valve morphology at 7-year follow-up in the randomized trial by Farhat et al\textsuperscript{11} was 6.6\% in patients who underwent BMV; this rate was similar in those who underwent open surgical commissurotomy and was far superior to the restenosis rate of 37\% observed after closed surgical commissurotomy. Hernandez and associates\textsuperscript{16} found that survival free of major events (cardiac death, mitral surgery, repeat BMV, or functional impairment) was 69\% at 7 years, ranging from 88\% to 40\% in different subgroups of patients. Mitral area loss, although mild (0.13 ± 0.21 cm\textsuperscript{2}), increased with time and was greater than or equal to 0.3 cm\textsuperscript{2} in 12\%, 22\%, and 27\% of patients at 3, 5, and 7 years, respectively.

In contrast to the usually excellent results obtained with the procedure in patients with favorable valve anatomy, the results of BMV in those with adverse valve morphology (heavily calcified leaflets and commissures and extensive subvalvular disease) are less predictable.\textsuperscript{17-20} BMV in the latter compared with the former patient subset tends to produce inferior acute and long-term results. Therefore, patients with unfavorable mitral morphology are, in general, better served with mitral valve replacement (but not surgical commissurotomy). Having said that, there remains a significant minority of patients with adverse valve morphology in whom BMV may yield acceptable hemodynamic outcome and may continue to gain long-term symptomatic
improvement. It is thus reasonable to perform BMV in these patients if they refuse surgery as a bridge to surgery at a later stage, particularly if urgent noncardiac surgery is required or if the risk of cardiac surgery is deemed to be prohibitively high because of other major medical comorbidities (Table 41-1). In fact, BMV may occasionally be the only option for some of these patients.

Abbreviations: BMV, percutaneous balloon mitral valvuloplasty; MR, mitral regurgitation; MVR, mitral valve replacement; OSC, open surgical commissurotomy.
Many centers performing BMV exclude patients with moderate (angiographic grade 2+) mitral regurgitation from the procedure for fear of increasing the severity of the mitral regurgitation and the need for emergency mitral valve surgery. In our centers, these patients with moderate mitral regurgitation but with otherwise favorable valve characteristics are not excluded from BMV. In our experience, the risk of resultant severe mitral regurgitation is minimal with the use of cautionary balloon sizing approach and the controlled stepwise dilation technique.\textsuperscript{21-23} However, should the procedure fail to provide optimal clinical results, patients can still be subjected to elective surgery without exposing them to any additional risk. Recent work suggests that even patients with severe mitral regurgitation and mitral stenosis can benefit from BMV.\textsuperscript{24}

The presence of left atrial thrombus has traditionally been considered a contraindication to BMV because of the heightened risk of cardioembolism with the procedure. In patients with nonpedunculated thrombi in the left atrial cavity, one may elect to administer long-term (3-6 months) warfarin therapy (targeting an international normalized ratio between 2 and 2.5), if their clinical and hemodynamic status does not warrant immediate surgery and the mitral valves are deemed suitable for BMV. When the thrombus is observed to have resolved with transthoracic echocardiographic reassessments performed at 3-month intervals, BMV can then be performed safely after confirmation of the absence of thrombi in the left atrial cavity with transesophageal echocardiography.\textsuperscript{23,25} Patients with lytic-resistant or mobile thrombi should be considered for open surgical commissurotomy with direct visual clot removal. Despite our safe and successful experience in performing Inoue-BMV in patients with left atrial thrombi confined to the appendage,\textsuperscript{23,26} the subject has remained controversial even among experienced operators of Inoue-BMV. Therefore, the alternative approach is either to subject patients with appendage thrombi to mitral valve surgery or to defer BMV for stable patients until resolution of the thrombi under warfarin treatment.\textsuperscript{23,27} Another clinical concern is pulmonary hypertension; successful BMV usually decreases the pulmonary pressure, although early intervention is better.\textsuperscript{28}

The best choice of technique for BMV remains a contentious issue. Beside the original Inoue technique using size-adjustable, self-positioning balloon catheters, various other techniques for performing BMV have been developed
that use fixed-size balloon catheters. These include the antegrade (transvenous) approaches with 1 or 2 balloon catheters through 1 or 2 interatrial septal punctures \textsuperscript{29,30} or the retrograde (transarterial) approaches with transseptal wiring or without transseptal access. \textsuperscript{31} An overview of the various comparative studies, both randomized and nonrandomized, does not reliably indicate that either the double-balloon or the Inoue-balloon technique is superior to the other in achieving a larger final mitral valve area. There is, however, persuasive evidence that the Inoue-balloon approach is technically less demanding and clearly simpler to perform; hence, it has a shorter irradiation and procedural time and is safer than the double-balloon approach. \textsuperscript{32-34} These advantages are vital in pregnant patients in whom the hazards of irradiation to the fetus are of paramount importance and for patients with pulmonary edema in whom swift and expeditious BMV is clearly desirable. Therefore, the transvenous Inoue-balloon approach has obtained its current position as the principal BMV technique.

Subsequent sections of the present chapter are drawn largely from our incremental experience in Inoue-BMV techniques and evolving technical refinements in BMV techniques. These have resulted in a nearly 100% technical success rate and a significant diminution in complications despite the presence of a significant number of technically demanding scenarios and high-risk comorbid conditions. \textsuperscript{12,22,23} Mainly discussed are the technical aspects of Inoue-BMV, the pitfalls and tricks to facilitate a successful procedure, and how to minimize procedure-related complications.

**TRANSSEPTAL ACCESS**

Transseptal catheterization is a vital component of BMV. Transseptal puncture must not only be executed safely to avoid cardiac perforation but also made at an appropriate interatrial septal site to facilitate balloon crossing of the stenosed mitral valve. \textsuperscript{35} To avert cardiac perforation, some operators have resorted to routine intraprocedural transesophageal echocardiography to facilitate optimal transseptal needle placement; however, even with the echocardiographic guidance, cardiac perforation may still occur. \textsuperscript{36} Recently developed intracardiac echocardiography is useful, but it is not widely available and its use adds to more cost. Therefore, acquisition of basic transseptal skill is essential. To perform transseptal procedure, biplane
fluoroscopic equipment is preferable, but single-plane fluoroscopy is usually sufficient.

The instruments used for the procedure include a Brockenbrough needle and a 7- or 8-Fr transseptal catheter. The use of an outer sheath is optional, but its utility is recommended, especially for inexperienced operators, for 2 reasons: (1) to prevent inadvertent perforation of the dilator by the needle during its insertion, and (2) to prevent left atrial perforation during insertion of the catheter/needle into the left atrium; the sheath tip works as a safety stopper at the septum.

Landmarks for Optimal Puncture Site

The puncture target site is usually located at the cross point of (1) a horizontal line crossing the center of the mitral annulus (M-line) and (2) a vertical line, assumed to divide the interatrial septum into anterior and posterior halves (“midline”). However, in individual cases, the puncture site may have to be adjusted. For example, in patients with giant left atria, the operator is often forced to make the interatrial septal puncture more caudal to the horizontal M-line. In patients with a more vertically oriented left ventricle and a relatively small left atrium, the operator may need to make the puncture site slightly more cephalad to the M-line and lateral to the vertical midline.

Definition of Horizontal M-Line

The line is derived from a diastolic stop frame of diagnostic left ventriculography obtained in 30° right anterior oblique (RAO) view (Fig. 41-1). This horizontal line level is memorized in relation to the vertebral body. The angiogram is also used as a road map during transseptal puncture and balloon catheter manipulation.
Definition of Vertical Midline

Inoue devised a specific transseptal puncture technique designed for the Inoue balloon BMV, incorporating the concept of a vertical “midline,” a line assumed to divide the interatrial septum into anterior and posterior halves. The midline is a vertical line crossing the midpoint of a horizontal line spanning the anterior and posterior limits of the septum. The upper end of the tricuspid is assumed to be the anterior septal limit in Inoue’s angiographic method, corresponding to the aortic valve in our modified fluoroscopic method.

Because the septum lies within the superimposed area between the 2 atria in both methods, the medial atrial silhouette (usually the left atrium) is used as the posterior limit (not necessarily the posterior border) because there is no septum beyond this silhouette. Infrequently, such as in patients with giant left atria or distorted cardiac anatomy, the right atrial border is medial to that of the left atrium, and thus, the right atrial border is used as the posterior limit.

1. Angiographic method (Fig. 41-2A-B): The midline is defined based on the landmarks obtained from frontal plane right atrial angiography during normal respiration.
**FIGURE 41-2** Definition of “midline.” Angiographic method (A and B): the upper end of the tricuspid valve at systole (point T, marked as asterisk) is determined on a stop-frame frontal right atrial (RA) image (A) and translated to a stop-frame left atrial (LA) image (B). On the latter image, a horizontal line is drawn from point T until point L, where the line intersects the LA silhouette. The “midline” (broken line) is the vertical line crossing at the midpoint between T and L. Fluoroscopic method (C): a horizontal line is drawn from the tip of the pigtail catheter (point A) to L, the LA silhouette (black arrows), to define the “midline.” The dotted line indicates the right atrial silhouette. (Used with permission from www.ptmv.org.)

2. Fluoroscopic method (Fig. 41-2C): In this method, the aortic valve is used to substitute the upper end of the tricuspid valve as the anterior septal limit because the 2 structures are in close proximity to each other. Therefore, a pigtail catheter is placed with its tip in the noncoronary sinus of Valsalva, touching the aortic valve. The midline thus derived is usually identical to that from Inoue’s angiographic method.

Because in most cases of mitral stenosis the left and right atrial silhouettes are visible under fluoroscopy (see Fig. 41-2C), the angiographic method is infrequently used and is reserved for the following situations: (1) for operators inexperienced with the transseptal puncture technique, (2) in cases in which atrial silhouettes are not well visualized under fluoroscopy, and (3) in extremely difficult cases of transseptal puncture (eg, in the presence of a giant left atrium and kyphoscoliosis). In these cases, it may be necessary to perform biplane (frontal and lateral) right angiography to properly visualize the atrial septal orientation and relative anatomic relationships of the atria, the tricuspid valve, and the aorta.
Confirmation of Optimal Puncture Site

Frontal View

Under frontal view, the needle-fitted transseptal catheter placed in the superior cava inserted from the right femoral vein is slowly withdrawn to align the catheter/needle on the midline. Reshaping of the distal Brockenbrough needle to make it more curved may be necessary to align the catheter tip with the midline. The needle tip should be constantly kept concealed slightly (2-3 mm) within the catheter tip before needle puncture.

The catheter tip should not be set medial to the midline to avoid puncturing the aorta, tricuspid valve, or coronary sinus. More importantly, the puncture site thus made is too close to the mitral valve, and this makes balloon crossing of the mitral valve difficult or even impossible. Slight lateral deviation of the puncture site to the midline is permissible, especially in patients with relatively small left atria. It is important to note that there may not be septum in an area near the inferior (caudal) border of the left atrium because the atrium often bulges caudally beyond the true septal boundary.

Thirty-Degree Right Anterior Oblique View

The catheter tip site is further examined in this view to confirm its optimal position (see Fig. 41-1B), also using the left ventriculogram as a road map (see Fig. 41-1A). The tip position is usually in front of the spinal column, and the distance between the intended puncture site and the mitral orifice (P to M in Fig. 41-1C) should exceed 1.3 times the vertebra width for easy catheter balloon crossing of the mitral valve. Because the catheter tip is away from the aorta, tricuspid valve, coronary sinus, and left atrial posterior border, needle puncture at this point pierces only the septum unless the puncture is made too caudally near the caudal edge of the left atrium in frontal view.

Confirmation of Catheter Tip at Septum

When setting of the catheter/needle at the septum is in doubt, septal flush or stain method may be used to examine the catheter/needle tip position. This is done by injecting a small amount of pure contrast medium contained in a 5-mL syringe attached to the proximal needle end.
**Septal Flush Method**

The contrast medium flushing outlines the right atrial margin of the septum, and the optimal puncture site is at the curving segment of the septal outline (Fig. 41-3A, right panel).
**FIGURE 41-3** Septal flush/stain method in frontal (*left panel*) and lateral (*right panel*) views. (A) Flushing of contrast medium outlines the right atrial margin of the septum (*white arrows, lateral view*). The optimal puncture site (*P, arrowhead*) is at the curved segment of the septal outline (*right*). The *dotted line* shows the left atrial caudal border. (B) Needle puncture at higher septum results in septal dissection as evidenced by staining of the septum in a more vertical orientation (*arrow*), and the catheter direction is aligned with the septal outline (*lateral view*). (C) Contrast staining of the septum after needle puncture made at more caudal site shows obliquely directed staining (*arrow*), indicating that the puncture is made at an optimal site at the curved segment of the septum. (Used with permission from www.ptmv.org.)

**Septal Stain Method**

After needle puncture is made, the needle is aspirated and contrast medium is injected to confirm its entry into the left atrium. If no blood is aspirated, the needle either has dissected the higher septum or is caught in the thickened septum (usually, in the muscular septum). Staining of the septum with injection of contrast medium easily distinguishes these 2 possibilities (*Fig. 41-3B-C*). If the catheter/needle is caught in the septum, it should be carefully forced across the septum. With pressure monitoring, it is not possible to differentiate high septal dissection from needle entrapment in the thick septum. This is another reason why the authors perform the transseptal puncture without constant pressure monitoring.

**Confirmation of Left Atrial Entry**

After entry of the needle in the left atrium is confirmed, first by contrast medium injection followed by pressure recording, the needle direction is set toward 3 o’clock (left side of the patient). If there is no or little resistance, the catheter/needle is advanced forward slightly into the left atrium. Then, the catheter alone is advanced until the tip of the sheath meets a resistance at the septum, while the needle is being withdrawn.

On needle removal, heparin, 100 U/kg body weight, is given immediately through the catheter. After baseline hemodynamic studies, BMV is performed. If the patient has been on warfarin prior to BMV, the drug is discontinued 2 to 3 days before the procedure and substituted with intravenous unfractionated or subcutaneous low-molecular-weight heparin until before the procedure.
SELECTION OF BALLOON CATHETER

Selection of an appropriate-sized balloon catheter for the controlled stepwise dilation technique is extremely important in order to avoid creating severe mitral regurgitation during BMV. Our balloon catheter selection methods have evolved from our continuing efforts to minimize this complication.12,21-23

Catheter Selection

Selection guidelines are based on balloon reference size (RS) derived from patient height, transthoracic echocardiographic findings of the mitral valve, fluoroscopic presence of valvular calcification, and degree of angiographic mitral regurgitation before the procedure. The RS is calculated according to the following simple formula12,22: patient height (cm) is rounded to the nearest zero and divided by 10, and 10 is added to the ratio to yield the RS (mm). (For example, if the patient’s height is 167 cm, then RS = 170/10 + 10 = 27 mm [Table 41-2].) In patients with pliable and noncalcified valves and with mitral regurgitation less than or equal to 1+, a catheter with a nominal balloon size at least that of the RS (an RS-matched catheter) is used. In contrast, in patients at high risk for creating severe mitral regurgitation (valvular calcification and/or severe subvalvular lesions, baseline 2+ mitral regurgitation), a balloon catheter 1 size smaller than an RS match is selected. Therefore, in the above example with an RS of 27 mm, a PTMC-28 catheter would be selected for a pliable, noncalcified valve, and a PTMC-26 catheter would be selected for a calcified valve and/or a valve with severe subvalvular disease.

Table 41-2 Catheter Selection and Balloon Sizing Based on Patient Height and Valvular Status
Pretesting for Balloon-Syringe Mismatch

Although the volume predefined by red marks on the syringe and its corresponding balloon size at full inflation have been tested by the manufacturer, balloon-syringe mismatch may occur. Although this mismatch is usually mild, gross mismatch may take place when the catheter and the syringe are from different packages. The mismatch, if undetected, may result in either underinflation or overinflation of the balloon. Therefore, before inserting the balloon catheter into each patient, the diameters of balloon inflated by injection of diluted contrast medium should be confirmed using a test; the balloon diameter chosen for the first inflation and the nominal diameter of the balloon should be compared. If there is a mismatch, the difference should be noted and adjusted.

### CATHETER PLACEMENT

#### Balloon Catheter Advancement

**Resistance at Groin Access Site**
To avoid creating a long subcutaneous tunnel, which may pose some resistance during insertion of the balloon catheter, the puncture needle is angled more vertically than usual during the initial vascular access (at about 60° to the skin surface). After insertion of the coiled-tip guide wire into the left atrium, the shorter subcutaneous track is then well stretched with an artery forceps alongside the wire. This is followed by use of the 12-Fr dilator, which is also used to dilate the atrial septum. When inserting the stretched balloon catheter, the guide wire should be held taut by an assistant. Use of a 14-Fr intravascular sheath for balloon catheter insertion is optional. During insertion of the catheter into the femoral vein, the catheter should never be twisted or the metal stretching tube or the guide wire will bend, thereby requiring replacement.

**Septal Passage and Resistance**

After placement of the coiled-tip guide wire in the left atrium, there may be some difficulty at times in advancing the balloon catheter across the septum, particularly when the latter is markedly thickened at the puncture site. When this occurs, forceful action is to be avoided. Rather, the balloon catheter should be turned slightly, usually in a clockwise direction, as it is pushed forward to overcome septal resistance. In the rare instances when this method also fails, the septum is redilated with the dilator. After passage across the septum, it is also important not to push the catheter tip up against the left atrial roof, or the guide wire may be bent into an acute angle.

**Deep Catheter Placement in Left Atrium**

The balloon catheter is introduced under frontal fluoroscopic view into the atrium over the coiled-tip guide wire to form a large loop with the tip medial to the mitral valve (Fig. 41-4). This placement has the following advantages: (1) the catheter thus positioned is less likely to flip to the left atrial appendage area when the stylet is inserted to the catheter tip; (2) the catheter does not enter the pulmonary veins; and (3) in subsequent manipulations to cross the valve, the catheter has already been advanced deep into the atrium, and it will need only to be withdrawn. Thus, the mitral valve crossing is attempted first with the vertical method, and potential catheter entrapment by a tough septum is avoided.
FIGURE 41-4 Deep catheter placement in left atrium and mitral valve crossing. A balloon catheter is introduced under frontal view into the atrium over a coiled-tip guide wire to form a large loop with the tip medial to the mitral valve (MV), pointing downward to a 6 to 7 o’clock direction (A). The catheter thus positioned is less likely to flip to the left atrial appendage area (open arrowhead). Subsequent catheter manipulations are done in 30° right anterior oblique (RAO) view. (B) Mitral valve crossing is attempted in order of vertical, horizontal, direct and posterior loop method (C1 to C4). The broken line indicates mitral orifice to left ventricular apex orientation. (Used with permission from www.ptmv.org.)

MITRAL VALVE CROSSING

Catheter manipulation is done in the 30° RAO view using the left ventriculogram as a road map. In difficult cases, such as in patients with giant left atria, additional use of lateral fluoroscopic view may be needed to facilitate valve crossing.

With the stylet inserted to the catheter tip, the partially inflated distal balloon is directed toward the anteriorly located mitral orifice. The balloon is directed anteriorly by applying a counterclockwise twist (usually 180°) to the stylet with one hand (usually the right), thus controlling the axial movement
of the catheter balloon (see Fig. 41-4). The catheter is then withdrawn gradually, using the other hand, to control the vertical motion of the balloon. Mitral valve crossing is then attempted using 4 methods in the order that they are described below.

**Vertical Method**

On further slight retraction of the catheter, the balloon is observed to move in (during diastole) and out of the left ventricle even though the catheter is not aligned with the orifice-apex axis of the left ventricle (black broken line in Fig. 41-4). Coincident with diastole, only the stylet is withdrawn. This allows the distal segment of the catheter to take on a more horizontal orientation to cross the valve and enter deep in the left ventricle. Having replaced the originally used direct method, the vertical method is now the most frequently used successful crossing method.

**Direct Method**

When the vertical method fails, the balloon catheter is further withdrawn until the catheter balloon is near the valve and the catheter is well aligned with the orifice-apex axis. At this time, a “woodpecking” sign is observed as the balloon moves away from the mitral orifice in systole and toward it in diastole along the axis between the mitral orifice and the left ventricular apex (orifice-apex axis). Once this sign is evident, the operator jerks the stylet back slightly as the balloon approaches the orifice and simultaneously advances the catheter with the left hand to drive the balloon across the valve and deep into the left ventricle.

**Horizontal (or Sliding) Method**

This method has proved to be effective, especially in cases in which the septal puncture is made too caudally and/or the left ventricle assumes a more horizontal orientation. The balloon is first directed toward the mitral valve by keeping the stylet twisted counterclockwise. The distal catheter segment is then made more flexible by withdrawing the stylet clear out of the balloon segment. Once the slightly inflated balloon is at the mitral orifice, cardiac contractions cause the balloon segment to tilt upward during systole. In
diastole, the balloon segment aligns with the catheter shaft. With the operator carefully watching the rhythmic motion of the cardiac cycle, only the catheter is advanced forward (with the stylet kept fixed) during diastole to cross the valve. The stylet is then advanced to help align the catheter with the orifice-apex axis.

**Posterior Loop Method**

First, a vertical loop is made (as in Fig. 41-4B) and the stylet is then withdrawn to a point 2 to 3 cm proximally to make the balloon segment more flexible. With the stylet twisted clockwise, the balloon tip is brought toward the posterior and inferior wall of the left atrium; thus, the catheter forms a loop in the left atrium.

With the stylet held firmly, only the balloon catheter is advanced, allowing the balloon to move forward to the mitral orifice. When the balloon enters the left ventricle, its tip usually points upward. The loop is then reduced by carefully withdrawing the catheter and slightly advancing the stylet to the balloon segment to align the distal catheter with the orifice-apex axis. This method is infrequently used in the authors’ experience.

**Discussion of the Methods**

In the vertical and direct methods, the major causes of valve crossing failure are (1) bending of the distal balloon segment, resulting in malalignment of the balloon segment with the mitral orifice, and (2) insufficient counterclockwise rotation of the stylet, thus failing to bring the catheter balloon segment sufficiently anteriorly to align toward the mitral orifice. Therefore, it is important to insert the stylet all the way to the balloon catheter tip to straighten the latter. Occasionally, however, the stylet may be too short to reach the catheter tip, thus making a slight bend in the catheter tip. If this occurs, the rubber grip at the proximal end of the stylet can be pulled further back to lengthen the exposed segment of the stylet, or failing that, the rubber grip can be cut at 1 to 2 mm from its distal end and removed. In addition, the stylet must be kept twisted at all times. An extra counterclockwise twist is occasionally needed to direct the catheter tip anteriorly. Less commonly, inappropriate stylet tip curving may also contribute to the failure. If this occurs, the stylet should be reshaped.
according to the positional relationship between the septal puncture site and the valve orifice.

In the catheter sliding or the posterior loop method, the catheter has a propensity to enter the left atrial appendage region during a failed valve-crossing attempt because the distal balloon catheter is more horizontally oriented. Therefore, the stylet should not be pulled back too vigorously to avoid excessive forward movement of the catheter toward the appendage region.

**BALLOON INFLATION PROCEDURES**

*Ensuring Free Balloon Movement in Left Ventricle*

Once the mitral valve has been crossed, the free movements of the partially inflated distal balloon in the left ventricle should be ascertained to prevent disastrous consequences (ie, rupture of chordae, papillary muscles, or leaflets) stemming from its subsequent full inflation within the chordae. This is done by simultaneously pushing the catheter and pulling the stylet slightly in opposite directions (“accordion” maneuver)\(^{22}\) to ensure that the partially inflated distal balloon slides freely along the orifice-apex axis.

After crossing the mitral valve, the catheter balloon may point more vertically and deviate away from the orifice-apex axis. This suggests that the catheter has strayed among the chordae. To correct this situation, the distal balloon is inflated larger to prevent the balloon from being inadvertently retracted into the atrium, and the catheter is carefully pulled back to assume a more horizontal orientation. After satisfactory alignment of the catheter with the orifice-apex axis, the catheter is advanced toward the apex, and the previously described accordion maneuver is performed before initiating the inflation procedure. Similarly, a twist in the balloon during the inflation process may also indicate that the catheter has tethered among the chordae. In this case, the inflation should be promptly aborted and the balloon repositioned.

*Reassessment of Subvalvular Status*

Before BMV, mitral valvular status is determined by preprocedural
transthoracic echocardiography and fluoroscopy (for the presence of valvular calcification), and an appropriate balloon catheter is then chosen accordingly. Extensive subvalvular disease has been found by various investigators to be a predictor of significant mitral regurgitation. Because echocardiography often underestimates the severity of subvalvular disease, severe mitral regurgitation may be created during BMV despite the presence of apparently favorable valve morphology. Therefore, during the actual balloon dilations, vigilance is required to identify the presence of previously undetected severe subvalvular disease. We and others have found other more reliable signs of significant subvalvular involvement. The most commonly encountered sign is a distorted balloon due to compression by severe subvalvular disease when it is being inflated. Even in patients in whom no severe subvalvular disease is demonstrated by echocardiography, when the presence of severe subvalvular disease is suspected during the balloon inflation process, the balloon dilation protocol should be altered accordingly as described below (see Balloon Sizing).

**Controlled Stepwise Dilations**

To avoid or minimize the complication of severe mitral regurgitation, the selection of an appropriate balloon catheter and the controlled stepwise dilation technique are mandatory. In addition, one should be familiar with the pressure-volume relationship and inflation limit of the catheter balloon.

**Balloon Pressure-Volume Relationship**

The intraballon pressure transits from the “low-pressure” to the “high-pressure” zone as the balloon is inflated to within 2 mm of its nominal size (eg, the 24- to 26-mm zone in a 26-mm balloon catheter). Each catheter can be safely inflated to a maximal diameter of 1 mm above the nominal size because of the built-in safety margin. Initial balloon inflation is never to be performed with balloon diameter in the high-pressure zone, regardless of the valvular morphology.

**Balloon Sizing**

As indicated earlier, balloon sizing for the stepwise dilation technique is
crucial in avoiding the complication of severe mitral regurgitation. By adhering to the cautionary methods outlined below, especially in patients with severe subvalvular disease, creation of significant mitral regurgitation (increase of ≥2+ angiographically) can be minimized.²³

1. Pliable, noncalcified valves. In patients with pliable, noncalcified valves and no severe subvalvular lesions, as determined by the subvalvular reassessment outlined earlier, an RS-matched balloon catheter is selected as stated previously. The initial inflated balloon diameter is RS minus 2 mm. In subsequent dilations, the balloon size is increased by 1 mm. When there is preexisting mitral regurgitation or any question of increase in the degree of mitral regurgitation, the increment should be 0.5 mm in the high-pressure zone. This approach also applies when unilateral commissural splitting occurs during the previous dilation, as observed by asymmetrical balloon waists on fluoroscopy. The final diameter is best kept within 1 mm above the RS to avoid oversizing; that is a risk factor for creating severe mitral regurgitation in this group of patients.¹²

2. Calcified valves and/or severe subvalvular disease. In patients with either fluoroscopically visible valvular calcification or severe subvalvular lesions as observed by transthoracic echocardiography, instead of an RS match, a balloon catheter 1 size smaller than the RS match is selected at the outset. For those whose subvalvular lesions are not detected by preprocedural echocardiography, the RS-matched catheter already placed in the patient may still be used if the dilation procedures are carried out with extra care. Ideally, the catheter should be exchanged for a smaller one, but this is quite costly.

For the first dilation, a balloon diameter 4 mm less than the RS is used. For subsequent dilations, the balloon size is increased by 1 mm in the low-pressure zone and by 0.5 mm in the high-pressure zone until satisfactory results are obtained or until mitral regurgitation develops or worsens. In cases where the gradient has already been reduced to one-half and several more dilation attempts have failed to reduce it further, the procedure is terminated to avoid creating severe mitral regurgitation. Reducing the mitral valve gradient by one-half should result in a 41% increase in the mitral valve area, as calculated by the Gorlin formula, provided that heart rate and cardiac output remain the same. Our previous study²¹ suggests that a 40% increase in
the valve area is sufficient for symptomatic improvements in patients with a more sedentary lifestyle.

**Exchange for Different-Sized Balloon Catheters**

Exchange of balloon catheters is carried out for 2 reasons. The first is to downsize the catheter in the presence of severe subvalvular disease that may have evaded detection by echocardiography but was noted during the BMV procedure itself. The second occurs in the rare instance when there is a need to upsize the balloon catheter to one that is 1 size larger because of inadequate hemodynamic improvement with the initial balloon catheter. In such a situation, before exchanging for a larger catheter, it is vital that the initial catheter’s final balloon diameter be remeasured and reverified after its complete removal from the patient, particularly when it has been inflated beyond its nominal size. This precautionary exercise is essential because, not uncommonly, despite pretesting, the balloon size is smaller than what it is supposed to be after in vivo usage. When this occurs, the original balloon catheter is retested to determine the actual volume of diluted contrast in the syringe necessary to achieve maximum balloon size (the balloon tolerates about 1-2 mm in excess of its nominal size before rupturing), the original balloon catheter is reintroduced into the patient, and the dilation process is repeated. However, if the balloon matches its predefined size, an exchange for a larger-sized catheter is made and dilations with the larger balloon are performed. Failing to reverify the maximum balloon size before inflating a much larger balloon may risk the creation of severe mitral regurgitation.

**Balloon “Popping” to Left Atrium**

When the mitral valve has already been enlarged by dilations, the balloon may occasionally slip into the left atrium during subsequent inflations with larger balloon diameters. To prevent the latter from occurring, the stylet is advanced far into the balloon segment to stiffen the catheter, and before the catheter is retracted to anchor the balloon at the orifice, the distal balloon is inflated to a diameter slightly larger than the previous one. As soon as the balloon assumes an hourglass configuration, the catheter is advanced slightly to prevent it from jerking out into the left atrium, and full balloon expansion is then executed. With this extra dilation, although the mitral gradient may be
unchanged, enhanced splitting of the commissures, as assessed by echocardiography, is often observed.

The balloon “popping” signals enlargement of the mitral orifice with wide splitting of the commissures. It is usually encountered in patients with pliable, noncalcified valves and foretells excellent BMV results. However, suboptimal hemodynamic results are occasionally observed despite the balloon “popping” sign, especially in the presence of atrial fibrillation. In these cases, although the mitral valve with split commissures can be forced to accommodate the fully inflated balloon, the effective mitral valve area is, in reality, limited by the thickened and stiff leaflets and by ineffective atrial contractions in the beating heart.

**Assessment After Each Valve Dilation Procedure**

After each balloon inflation procedure, the catheter balloon is withdrawn to the left atrium. The effects of the balloon dilation are assessed by observing the left atrial pressure waveforms, by measuring the transmitral gradient, and also by auscultation. If mitral regurgitation is suspected by the appearance of a large or giant “v” wave and by a new or worsening systolic murmur, echocardiography or left ventriculography may be performed. Although not essential, transthoracic or online transesophageal echocardiography is an excellent tool to assess and monitor the valve status after each balloon dilation if the logistics permit its use. However, the tool is too sensitive for detection of new or increasing mitral regurgitation, and thus, sole dependence on the echocardiography findings may result in premature termination of the procedure.

**AVOIDING LEFT ATRIAL APPENDAGE**

Left atrial appendage thrombus may be unsuspected when BMV candidates are screened only with insensitive transthoracic echocardiography. Balloon catheter encroachment on the left atrial appendage region must thus be avoided in order to minimize the risk of inadvertent thrombus dislodgement and systemic embolism. Under 30° RAO fluoroscopic view, the anterolaterally located appendage is cephalad to and right of the pigtail catheter segment in the left ventricle (see Fig. 41-4B). Therefore, the balloon
catheter tip should always be kept to the left of the pigtail catheter during catheter manipulation in the left atrium by adopting the following steps:

1. Deep placement of balloon catheter in the left atrium (see Fig. 41-4A).
2. Mitral valve crossing. The balloon catheter tip is more horizontally orientated when performing the catheter sliding or the posterior loop method (see Fig. 41-4) in crossing the mitral valve. The catheter tip is thus more prone to entering the left atrial appendage region during a failed valve-crossing attempt. Therefore, the stylet should not be pulled back too vigorously during the crossing attempt to avoid excessive forward movement of the catheter toward the appendage region.
3. Catheter withdrawal to the left ventricle. After each balloon inflation procedure, in order to exert better control over the catheter tip, the stylet is advanced halfway into the balloon segment and the catheter is withdrawn just out of the mitral orifice from the left ventricle. Then, a slight clockwise twist to the stylet is applied to direct the catheter tip posteriorly. The balloon catheter can then be safely retrieved to the atrium by cautiously withdrawing the catheter and the stylet in steps until the catheter stands straight upward.
4. Mitral valve gradient measurement. After each valve dilation procedure, a transmitral valve gradient measurement is performed without fluoroscopy. Thus, care should be exercised to avoid pushing the catheter forward into the appendage.

After the precautions have become rote, it is possible to perform BMV safely even in the presence of left atrial appendage thrombi. Despite our safe and successful experience in performing BMV in patients with thrombi confined to the appendage, the subject has remained controversial even among experienced operators of Inoue-BMV. Therefore, the alternative approaches are either to subject patients with appendage thrombi to mitral valve surgery or to defer BMV for stable patients until resolution of the thrombi after warfarin treatment.

ETIOLOGY AND PATHOLOGY

Degenerative disease of the aortic valve occurs with age. Areas of cusp flexion over time develop fibrosis and calcification, impeding valve excursion and creating obstruction to left ventricular outflow. The most common cause of aortic stenosis (AS) is calcification of a normal trileaflet or congenital bicuspid valve. Calcific AS is an active disease process characterized by lipid accumulation, inflammation, and calcification, with many similarities to atherosclerosis. The degenerative process usually occurs in the sixth decade of life and beyond, but patients with additional valve pathology (bicuspid aortic valves, rheumatic heart valvular disease, radiation valvulopathy) can present much earlier in life with deterioration of valve function and consequent symptoms.

The 2 most common etiologies of AS amenable to percutaneous treatment are: (1) congenitally bicuspid aortic valves and (2) calcified tricuspid valves. Unicuspid or quadricuspid valves are not normally candidates for a percutaneous approach, with unicuspid disease typically associated with stenosis and quadricuspid valves with regurgitation. Isolated rheumatic AS, rare even in countries with a high prevalence of rheumatic heart disease, is highly amenable to percutaneous intervention because the mechanism of improvement is splitting of the fused commissures.
Bicuspid aortic valves occur in approximately 1.5% of the population, and associated stenosis presents much earlier in life than tricuspid aortic valve disease.\(^7\) AS in adolescents and young adults is usually noncalcific, is the result of fused bileaflet valves, and is highly amenable to percutaneous balloon intervention. In contrast, AS in bicuspid and tricuspid valves of adults is associated with calcification of the valve that results in thickening, rigidity, and immobility of leaflets, often without commissural fusion.

Balloon aortic valvuloplasty (BAV) has been shown to relieve obstruction of the stenotic valve by 3 mechanisms: (1) fracture of calcium deposits in the leaflets, (2) splitting of fused commissures, and (3) stretching of the aortic annulus.\(^8\)\(^9\) Calcium deposits are broken into separate fragments with balloon inflation, facilitating leaflet flexion and allowing better excursion during systole. Splitting of commissures is quite effective by BAV. Stretching of the valve may explain the early gains by BAV, but valve recoil can occur within hours to days, and in this case, results of BAV may be fleeting. Late restenosis (after several months) probably results from progression of the original lesions that produced stenosis.

**CLINICAL FEATURES AND INDICATIONS FOR TREATMENT**

The development of symptoms can trail the onset of degeneration of the aortic valve by several decades.\(^10\) When present, initial symptoms tend to be dyspnea on exertion and effort angina, although some patients may present with syncope or heart failure.\(^11\) Exertional fatigue may be the first manifestation of severe AS in the elderly. Once symptoms are detected, the prognosis is poor without intervention: patients often have mortality within 5 years of angina, 3 years of syncope, and 2 years of heart failure.\(^12\)\(^13\) Cohort B of the Placement of Aortic Transcatheter Valves Trial (PARTNER) consisted of inoperable patients randomized to transfemoral transcatheter aortic valve replacement (TF-TAVR) versus medical therapy (including BAV as necessary). The study demonstrated 50% mortality at 1 year with medical therapy including BAV.\(^14\) More recently, 2-year results from the PARTNER trial demonstrated a mortality of 68% with medical therapy and BAV.\(^15\)

Surgical aortic valve replacement (SAVR) has been the standard of care
for treatment of symptomatic patients with severe AS. SAVR is accepted to alleviate symptoms and prolong survival; however, up to one-third of patients are denied SAVR because of prohibitive surgical risk (eg, advanced age, significant left ventricular dysfunction). Results from the PARTNER trial have shown that transcatheter aortic valve replacement (TAVR; covered in Chapters 42 and 43) is the standard of care for extremely high-risk or “inoperable” patients and is a valid alternative to surgery for high-risk but “operable” patients with symptomatic AS. The introduction of TAVR has brought resurgence in the use and utility of BAV.

Standalone BAV has been reserved for a subset of patients who are too sick to undergo SAVR and are considered inappropriate patients for TAVR. BAV is used in contemporary practice as a bridge to subsequent SAVR or TAVR (class IIb indication). In the current era of percutaneous valve replacement, BAV may be used to assess initial clinical improvement and future candidacy for TAVR.

**Clinical Subsets**

Several important clinical subsets of patients with AS exist with mean aortic valve gradients of less than 40 mm Hg in whom BAV may be used as a diagnostic and therapeutic procedure.

An important group of patients are those with severe AS and secondary depression of left ventricular function. In this subset of patients, the aortic valve gradient is low due to the inability of the left ventricle to sufficiently open the stenotic valve. In this group, pharmacologic agents, such as dobutamine, that increase flow across the valve will result in a dramatic rise in gradient. These patients typically benefit from relief of aortic valve obstruction. In contrast, patients with moderate AS and left ventricular dysfunction do not have an increase in gradient with dobutamine and do not benefit from SAVR. In cases where there remains an uncertainty after dobutamine challenge, we have performed BAV to evaluate whether increasing the valve area correlates with improved clinical symptoms and ventricular recovery.

Another complicated group of patients has only been distinctly identified in the past several years. These patients have small hypertrophied ventricles, preserved ejection fraction, and low aortic valve gradients. This group
sometimes has high valvuloarterial impedance AS and has low gradient because of decreased stroke volume. In these patients, when an uncertainty exists about the degree of AS, we have performed BAV as a diagnostic procedure and have been aggressive with blood pressure control (afterload reduction). Those with an excellent clinical response can be sent for SAVR or TAVR with mortality benefit. BAV can be used to assess clinical response in patients with severe lung disease as well.

**HISTORY OF THE BAV PROCEDURE**

BAV was originally performed in 1985 and was initially proposed as an alternative to SAVR in patients who were considered too elderly or high risk with severe AS. Initial enthusiasm in the late 1980s was subsequently tempered by studies demonstrating high rates of complications, lack of durability, and little or no impact on long-term survival, particularly in centers with low experience. Until recently, the use of BAV had significantly waned; it was restricted to very-high-risk patients with severe heart failure or cardiogenic shock and was often used as a bridge to SAVR.

The introduction of TAVR in 2002 and technical improvements with reduction of sheath diameter, rapid pacing, and vascular closure devices have brought the nearly dormant BAV technique back into the mainstream. The problem of restenosis has been addressed by the advent of TAVR. Several very busy structural heart centers such as ours perform more than 200 BAVs a year, a volume that has been sufficient to train multiple attending physicians and fellows. For these trainees, BAV has been a gateway procedure for learning the essentials of TAVR.

**PREPROCEDURE EVALUATION**

The evaluation of AS begins with the patient history and physical examination. Often, only transthoracic echocardiography (TTE) is used to quantify the degree of stenosis as retrograde catheterization has been associated with an increased risk of stroke, particularly if prolonged attempts are needed to cross the aortic valve. If there is any discrepancy between the patient’s presentation and echocardiographic results, retrograde
catheterization should be performed to measure the simultaneous gradient across the aortic valve (class I indication), as described below. In patients with low transvalvular gradient and low cardiac output, dobutamine infusion can aid in diagnosing patients with true AS from those with “flow-dependent” stenosis. Assessment of concomitant coronary artery disease is important prior to BAV and can often be accomplished in the same session. Venous and arterial access sites should also be evaluated prior to the procedure.

After assessing candidacy for BAV, it is important to obtain and review multimodality imaging for optimal procedural planning. TTE is the initial, and often only, imaging modality of choice due to its ease and safety. TTE establishes the diagnosis of AS and allows assessment of valve morphology (ie, bicuspid, functionally bicuspid, or trileaflet valve), left ventricular outflow tract size, and baseline left ventricular function. Understanding valve morphology prior to BAV is critical as balloon dilatation of a bicuspid or functionally bicuspid valve with an oversized balloon may result in acute severe aortic regurgitation.

Computed tomography (CT) provides a wealth of cardiac, thoracic, and peripheral information in assessing a patient’s feasibility for TAVR and procedural planning. A CT scan will show in detail the aortic root anatomy (including annular, sinotubular, and sinus of Valsalva dimensions as well as coronary heights above the annulus), aortobifemoral anatomy, and details of arterial diameters and calcification. A gated, contrast CT with less than 1-mm slices will allow detailed 3-dimensional reconstruction, which can be invaluable for evaluation of the aortic annulus and peripheral arteries. Review of the CT scan prior to BAV aids in procedural planning. The lower extremity with larger diameter iliofemoral caliber is reserved for potential future TF-TAVR. Additionally, accurate assessment of the femoral bifurcation and areas of calcification will guide arterial access for BAV and successful percutaneous arteriotomy closure.

Factors contributing to limited reserve (ie, depressed left ventricular ejection fraction, last remaining coronary vessel/graft, biventricular failure, or hemodynamic shock) should be identified prior to BAV to assist with procedural planning. These patients tend to not tolerate pacing runs, and it may be more beneficial to perform BAV without rapid ventricular pacing. Additionally, in patients with hemodynamic shock or in those who cannot lay supine, hemodynamic support devices (intra-aortic balloon counterpulsation)
and a wedge may be used.

**TECHNIQUE OF BALLOON AORTIC VALVULOPLASTY**

Patients are prepared from the upper thigh to the subxiphoid area in case emergent pericardiocentesis is required. Defibrillator pads are placed in the anterior-posterior position to facilitate treatment of ventricular arrhythmias during the procedure. Patients with difficulty in breathing are positioned semi-recumbent with the assistance of a wedge cushion. The procedure begins with the administration of minimal conscious sedation and local anesthesia.

**Special Instruments and Pharmacologic Agents**

- “Micropuncture” access kits that use a 21-gauge needle and 0.018-inch wire for arterial entry are best for fluoroscopic or ultrasound-guided access.
- Percutaneous arteriotomy closure devices such as the Perclose ProGlide (Abbott Vascular, Abbott Park, IL), ProStar XL (Abbott Vascular), and Angio-Seal (St. Jude Medical, St. Paul, MN).
- For patients with depressed ejection fraction, low coronary reserve, or hemodynamic compromise, 10-mL syringes of norepinephrine (16 μg/mL) and epinephrine (0.1 mg/mL) are helpful when treating acute hypotension. Background low doses of norepinephrine continuous infusion may also be helpful to maintain blood pressure, particularly with escalating doses of sedation.

**Antithrombotic Therapy**

Unfractionated heparin (dose of 5000 IU) should be used after arterial access to maintain an activated clotting time (ACT) of 250 to 300 seconds. Direct thrombin inhibitors have been used in patients with heparin allergies. Cases can be performed without any anticoagulation, although stroke risk is higher. In those cases, frequent catheter exchanges are performed to minimize
clotting on the wire used during BAV, and procedure time is minimized.

**Vascular Access, Right Heart Catheterization, and Supra-aortic Angiography**

Right common femoral arterial access is obtained with a micropuncture access kit and cannulated with a 6- or 7-Fr sheath. If the right femoral artery is unavailable for access, the left femoral artery, the brachial artery, the axillary artery, or an antegrade transseptal approach via the femoral vein can be used. To limit vascular complications in the arm, we recommend a cut down and maximum sheath size of 10-Fr. Common femoral venous access is obtained and cannulated with a 7-Fr sheath. A 7-Fr Swan-Ganz catheter is advanced from the femoral vein, and baseline right-sided pressures are recorded. Cardiac output measurements using either thermodilution or the Fick principle should wait until the aortic valve has been crossed to reduce error if calculation of the aortic valve area is performed during catheterization. After a right heart catheterization is performed, a temporary pacing wire is advanced to a stable position in the right ventricular apex. Placement of the lead in the base of the right ventricular free wall can increase the risk of perforation or loss of capture. A 6-Fr pigtail catheter is then advanced from the femoral artery and placed superior to the aortic valve. Aortic angiography in the left anterior oblique projection is not mandatory but can be helpful to define the details of the valve anatomy and assess the degree of insufficiency (Fig. 41A-1). Patients with more than moderate aortic regurgitation are in general not considered for BAV. Patients with moderate aortic insufficiency or less are reasonable candidates for BAV, particularly if the valve is trileaflet.
A regular, J-tipped 0.035-inch wire is inserted at the main arterial access site, and the 6- or 7-Fr sheath is removed. The arteriotomy is “preclosed” using a percutaneous suture device. Over a stiff, 0.035-inch wire such as the Amplatz Extra-Stiff wire (Cook Medical, Bloomington, IN), the arteriotomy is serially dilated to accommodate the BAV sheath, which is 12 or 14-Fr (CheckFlow, Cook Medical). The use of a 12-Fr arterial introducer and routine preclosure of the arteriotomy have markedly decreased the rate of local complications at the femoral puncture site. Smaller sheath sizes have been used with lower profile balloons and may not require preclosure. Twelve- and 14-Fr sheaths can be postclosed with suture-based closure devices.\textsuperscript{19}

**Preclosure**

**Crossing the Native Valve**

Proper technique permits negotiation of the stenotic aortic valve within 60 seconds in all cases. This is achieved most commonly with a 6-Fr Amplatz left (AL) catheter, although multiple other catheters may be used, such as 7-
Fr Sones (B type), pigtail catheter, Judkins right, multipurpose, or hockey-stick. A straight, 0.035-inch wire is used to cross the stenotic valve (Figs. 41A-2 and 41A-3). If a hydrophilic wire is used, it is important to make sure that the wire passes through the valve orifice and does not pass through a leaflet perforation prior to advancement of any catheters. The starting position of the Amplatz catheter should be with the tip pointed at the orifice between the left and right cusps, and the starting position of the Sones catheter is in the left coronary cusp with the tip pointed superiorly. With either catheter, a slow pull back with clockwise rotation and careful probing with the guide wire should negotiate the stenotic orifice. The Amplatz catheter is more useful than the Sones catheter when the plane of the aortic valve is more vertical. Once the valve has been crossed, the wire position is confirmed in the right anterior oblique projection, and the crossing catheter is advanced into the left ventricle. Failure to cross the valve with the catheter usually means the wire has biased into a commissure. Repositioning the wire, which includes making a loop in the ventricle, may be required to move the wire more toward the central orifice. Care needs to be taken not to puncture the apex. If one cannot cross, alternative strategies include recrossing, exchanging for a smaller catheter, or torquing the catheter in the ascending aorta out of the commissure. With the crossing catheter in place or exchanged for a pigtail catheter, the transvalvular gradient can be obtained, using the lateral arm of the sheath to record aortic pressure.
FIGURE 41A-2 A. The Amplatz catheter (AL) is directed toward the aortic orifice (valve calcifications above the dotted line). B. The straight guide wire (GW) has passed through the stenotic orifice (valve calcifications above the dotted line).
The Sones catheter (SC) is advanced over a guide wire (GW) in the left coronary cusp in the left anterior oblique view. The guide wire is used to probe the valve orifice (above the dotted line). The guide wire has passed through the stenotic orifice (valve calcifications above the dotted line).

The straight guide wire is removed from the crossing catheter and replaced by a 0.035-inch, 260-cm Amplatz Extra-Stiff wire (Cook Medical). The flexible end of the guide wire is preshaped before introduction into an exaggerated pigtail curve using a standard hemostat or with the hand. The curve in the distal wire decreases the risk of left ventricular trauma, perforation, and ventricular arrhythmia. The stiff wire is important to provide adequate support during advancing or inflating of the balloon catheter. We do not advocate the routine use of wires that are stiffer than an Amplatz Extra-Stiff wire (Cook Medical).

**Balloon Catheters**

The balloon catheters used at our institution are the TYSHAK (B. Braun Interventional Systems, Bethlehem, PA), ZMED, ZMEDII (NuMed, Hopkinton, NY), Cristal (BALT, Montmorency, France), and TRUE (Bard Peripheral Vascular, Tempe, AZ) dilatation balloons. The TRUE balloons inflate and deflate faster and are highly resistant to ruptures, punctures, and tears. The TYSHAK and Cristal balloons are the lowest profile, although they are more compliant and prone to rupture. All balloons are inserted over the stiff guide wire and purged of air outside of the body or in the descending aorta. We use a 30-mL syringe filled with an adequate volume of contrast and saline (10:90 mixture) to easily and completely inflate the valvuloplasty balloon. This dilution of contrast is adequate for visualization of the balloon under fluoroscopy and also decreases the time of deflation.

The balloon should pass the stenotic orifice without difficulty in most cases. If the balloon does not pass, the wire is probably biased into a commissure. In this situation, an empty 20- or 30-mL syringe can provide additional negative pressure to decrease the balloon profile. The wire position can also be changed by advancing the wire further into the ventricle or tracking the wire during balloon advancement. In special cases, we have purged the balloon of air after crossing the native valve in order to facilitate crossing. In most valvuloplasties, we begin with a 23-mm balloon; however, in patients with a small aortic annulus (<20 mm by TTE) or heavily calcified
valve, sequential inflations starting with a 20-mm balloon are prudent. In these cases, progression to a large-size balloon is acceptable if the initial result is insufficient, the balloon size appears undersized, and there is no visible waist during inflation. We rarely inflate a balloon that is >3 mm larger than the aortic annulus as measured on long-axis views on TTE.

**Rapid Pacing and Balloon Inflation**

Maintaining the position of the balloon catheter during inflation is critical for effective dilatation. This positioning is facilitated by rapidly pacing the right ventricle causing electrically induced arrest of the heart. The pacing lead should be connected to an external pulse generator that is capable of pacing at rates >200 bpm. Starting at 180 stimulations per minute, the minimal rate that causes a rapid and predictable decrease in systolic pressure to 30 to 40 mm Hg should be found (Fig. 41A-4). Typically a rate of 200 to 220 bpm is needed, although some patients will require rates as low as 140 to 160 bpm for adequate capture and hypotension. A back up rate of 60 bpm should be set to prevent episodes of bradycardia after dilatation.

**FIGURE 41A-4** Aortic and electrocardiogram (ECG) tracing during rapid stimulation depicts a predictable and abrupt decrease in cardiac output during which balloon valvuloplasty can be performed safely.
With markers of the balloon on either side of the valve calcification (Fig. 41A-5), rapid stimulation is started and coupled with cine-angiographic imaging and maximal balloon inflation. Normally, balloon deflation and arrest of stimulation are done simultaneously. Maintaining wire position is important, and pushing of the wire to ensure that the wire is against the outer curvature of the aorta provides extra support to the balloon during inflation. Balloon sizing of the annulus during BAV may be particularly helpful prior to TAVR when the annulus is questionably too large for a given transcatheter valve: supravalvular aortography is performed during BAV with rapid pacing, and any leakage of contrast into the left ventricle suggests that a larger valve will be needed\textsuperscript{35} (Fig. 41A-6). Upon deflation, the balloon is quickly withdrawn from the valve orifice to promptly restore antegrade blood flow.

**FIGURE 41A-5** The balloon markers (BM) are centered around the aortic valve calcification (white dotted lines) prior to inflation. The guide wire tip (GW) has an exaggerated curve to prevent ventricular trauma or arrhythmia. PL, pacer lead; black dotted lines, mitral annulus calcification.
FIGURE 41A-6 Balloon aortic valvuloplasty to size the aortic valve annulus. If a supravalvular aortogram is completed during maximum inflation of an appropriately sized balloon (1 mm less than the proposed valve’s size), balloon valvuloplasty can be used to predict whether or not the proposed valve will seal the annulus. In panel A, the absence of any leak around a 22-mm balloon suggests that a 23-mm valve will be large enough. In panel A, the left coronary system fills with contrast at peak balloon inflation and suggests a low likelihood of obstruction. In panel B, contrast is leaking around a 25-mm balloon, which suggests that a 26-mm valve will be too small and may leave significant paravalvular leak.

The valve is dilated in the same fashion once or twice more, depending on the quality of dilatation (adequate balloon size without movement at maximal inflation) (Fig. 41A-7). The goal of valvuloplasty should be greater than 50% decrease in transvalvular gradient and a valve area ≥1.0 cm$^2$. To decrease the number of pacing runs, we escalate to the final and largest balloon size quickly. Two dilatations are performed with the largest size balloon. Even with perfect technique and strategy, adequate reduction of mean gradient may not be possible in 20% of patients.
FIGURE 41A-7 A. Lack of rapid pacing results in movement of the balloon catheter (BC) distal to the aortic valve (dotted lines, aortic valve calcification) and inadequate dilatation. GW, guide wire. B. Rapid pacing stabilizes the balloon during inflation, resulting in adequate valve dilatation. PL, pacing lead; arrow, aortic valve calcification.

Antegrade and Double-Balloon Dilatation

If arterial access is limiting, the aortic valve can be dilated via the antegrade route or a double balloon technique using lower profile systems. The antegrade route (Fig. 41A-8) requires venous access, transseptal catheterization, and a guide wire that is looped in the left ventricle and across the aortic valve. Although this method is not recommended for inexperienced operators because of potential damage to the atrial septum and mitral valve, we have performed this technique safely in patients under special circumstances. The double balloon technique requires the use of 2 smaller balloons such that the addition of the individual diameters is 1 to 2 mm larger than the aortic annular diameter as measured by TTE. This technique may be beneficial in the adult patient with bicuspid AS.
FIGURE 41A-8 The guide wire (GW) is seen entering the heart from the right atrium and then crosses the left atrium, mitral valve, left ventricle, and aortic valve. A balloon catheter is inflated in the aortic valve (arrows, valve calcification). A Sones catheter (SC) from the left femoral artery is used to stabilize the balloon during inflation, although this technique is not necessary for routine valvuloplasty. PL, pacing lead.

POSTPROCEDURE MANAGEMENT

The transvalvular gradient and cardiac output should be measured as previously described. A final supra-aortic angiogram should define the degree of aortic regurgitation. Some centers may choose to evaluate aortic regurgitation and mean gradient after BAV with TTE in the catheterization laboratory. Immediately after the procedure, the balloon catheters and arterial sheaths are removed. The femoral artery entry site is closed using the predelivered percutaneous sutures in the vast majority of cases. In case of technical failure, pneumatic compression devices are sufficient and protamine can also be administered to reverse the effects of heparin. When BAV is applied in the context of severely impaired left ventricular function or cardiogenic shock, inotropic support or intra-aortic balloon counterpulsation.
may be transitorily required in the days following the procedure. If high-degree atrioventricular block occurs, temporary pacing should be used for 24 to 48 hours; if there is no recovery of conduction, a permanent pacemaker should be considered. In uncomplicated cases, the patients can be discharged after 1 day. Long-term follow-up is sequentially assessed on clinical and echocardiographic evaluations. Only in patients in whom the recurrence of symptoms is delayed by 6 months or longer should repeat BAV be performed. In these cases, results are similar to initial BAV.  

COMPLICATIONS

Vascular Injury

The rate of complications associated with BAV has markedly decreased since initial registries. The incidence of major vascular injury, traditionally the most common complication, has been reduced to less than 2% by the use of lower profile arterial introducers and closure devices.  

Significant Aortic Regurgitation

Significant aortic regurgitation (AR) after BAV can be a fatal complication. In patients with small stature or heavily calcified valves, sequential dilatation is useful to prevent this problem. Acute, severe, native AR after BAV is best treated with implantation of a new valve. For this reason, some operators prefer to prepare the new valve for implantation prior to performing BAV in TAVR procedures. If balloon sizing is needed to determine the size of the newly implanted valve, then pre-BAV preparation of the new valve is not possible. Bradycardia should be avoided in the setting of significant AR, and pacing may be a helpful temporizing measure.

Cardiac or Proximal Aorta Trauma

While rare, it is important to consider cardiac trauma as the cause of hypotension during BAV. Right ventricular perforation from a temporary pacing wire may cause pericardial effusion or tamponade. Large inspiratory drops in systemic arterial pressure (pulsus paradoxus) suggest a
hemodynamically significant effusion, and echocardiography may be confirmatory. Treatment with pericardiocentesis is reasonable since the bleeding into the pericardium is often self-limited. If blood loss is substantial, blood may be autotransfused from the pericardium into a systemic vein while preparation is made for surgical exploration. The site of perforation may not be identifiable at surgery.

Aortic root trauma may be immediately catastrophic or may present subtly with thickening of the interatrial septum on echocardiography and subsequent development of pericardial effusion. Effusion may be treated as above, and surgical repair may be considered. Immediate treatment with protamine and blood pressure control are recommended for conservative management.

**Embolic Events**

In our experience, the occurrence of clinically apparent cerebral events (<1%) is less common with BAV than reported with retrograde catheterization.\textsuperscript{19,32} Intravenous heparin should be used at the beginning of the procedure, and the valve should be crossed with the minimal number of guide wire passes. Stroke can also occur during prolonged hypotension, manipulation of hardware across the diseased aorta (particularly in patients with extensive vascular disease or previous stroke), or balloon inflation. Preventing hypotension can be done by minimizing sedation or using background pharmacologic hemodynamic support for those who require deeper sedation. Shorter balloon inflation/deflation time, shorter rapid stimulation time (<10 seconds), and moving to the final balloon size without many inflations with intermediate sizes are also helpful. The development of neurologic changes should prompt urgent imaging and consultation with a neurologist, particularly in stroke centers where interventional removal of embolic debris can be done quickly and effectively.

New-generation embolic protection devices, such as the Montage Dual-Filter System (Claret Medical, Santa Rosa, CA), have shown some preliminary feasibility in deflecting or capturing emboli during TAVR and may serve a future role in BAV.\textsuperscript{39}

**Mortality**

Procedural death (within 24 hours), the result of fatal arrhythmia, progressive
heart failure, rupture of the aorta, or disruption of the aortic valve, can be seen in patients with severely depressed left ventricular function, cardiogenic shock, heavy calcification of the aortic valve, asymmetric bicuspid valves, and porcelain aorta. If hypotension occurs during the procedure, the etiology should be sought immediately. Liberal use of echocardiography is invaluable, and pericardiocentesis can be lifesaving, particularly as a bridge to surgical therapy.

The National Heart, Lung, and Blood Institute (NHLBI) registry reported an 11% cardiovascular mortality by 30 days, including 3% of patients dying on the catheterization table. In more recent registries, complication rates are significantly lower, with a mortality rate of <3% and, in our centers, <1%. Lower rates of complications in modern BAV are largely driven by lower vascular complications due to more slender arterial introducers and systematic use of vascular closure devices. The most important predictor of event-free survival after BAV is baseline left ventricular function (ejection fraction >25%).

In the PARTNER Cohort B (TF-TAVR vs medical management) trial, (inoperable) patients who were not randomized to TAVR had 50% 1-year mortality despite BAV in 84%. There is evidence to suggest that patients who undergo repeat BAV have higher long-term survival rates than those who undergo isolated BAV. Perhaps repeat BAV in these patients is a viable treatment strategy while awaiting definitive therapeutic options. The lack of sustained impact on mortality is most likely due to restenosis, and a plan for a more definitive solution should be part of the procedure discussion with patients and their families before they become symptomatic as signs and symptoms of AS can have an accelerated recurrence. For this reason we often meet patients at 4 to 6 weeks after BAV to discuss therapeutic options.

CONCLUSION

Current guidelines recommend BAV as a bridge to SAVR or TAVR in patients who are at high risk for surgery with severe symptomatic AS. Isolated BAV may also be considered as a palliative procedure in select individual cases where surgical and TAVR risk is prohibitive or ineffective secondary to severe comorbidities. In the TAVR era, BAV can serve both a
diagnostic purpose to predict the potential benefit of TAVR as well as a therapeutic purpose to temporize symptoms while awaiting definitive therapy. In particular, assessing improvement in impaired left ventricular function, severe pulmonary hypertension, mitral regurgitation, and cognitive dysfunction after BAV may help drive clinical decisions making. Further prospective randomized studies are warranted to better elucidate the indications and the potential benefit of BAV in the contemporary era of TAVR.

Patient Selection, Procedural Techniques, and Complications of Balloon-Expandable Transcatheter Aortic Valve Replacement

Ayaz Rahman
Alain Cribier
Vasilis Babaliaros

HISTORY AND RATIONALE OF THE PROCEDURE

Aortic stenosis (AS) is the most common acquired valvular disease in adults.\(^1\) The incidence of AS has steadily increased along with population life expectancy and age, affecting almost 5% of patients over the age of 75 years.\(^2\) The most common cause of valvular AS in adults is calcification of a normal trileaflet valve or a congenital bicuspid valve.\(^3\) Severe symptomatic AS has a poor prognosis when treated medically, with a mortality of almost 80% at 2 years.\(^4\) Surgical aortic valve replacement (SAVR) is currently the standard of care and accepted to alleviate symptoms and prolong survival; however, up to one-third of patients are denied SAVR because of prohibitive surgical risk (eg, advanced age, significant left ventricular dysfunction).\(^5\)

In 2002, Cribier and colleagues\(^6\) successfully performed the first
transcatheter aortic valve replacement (TAVR) in an elderly inoperable patient for the treatment of severe AS. This approach marked the feasibility of percutaneous valve implantation, and TAVR has emerged as a less invasive alternative to conventional SAVR.\(^7\) Results from the Placement of Aortic Transcatheter Valves (PARTNER) trial have allowed TAVR to become the standard of care for extremely high-risk or “inoperable” patients, and TAVR is a valid alternative to surgery for selected high-risk but “operable” patients with symptomatic AS.\(^8,9\) TAVR has been performed for over 10 years with >100,000 implantations worldwide, and this innovative technology has allowed a paradigm shift in the treatment of AS.\(^10\)

**INDICATIONS FOR TREATMENT**

TAVR is recommended for patients with symptomatic, severe, calcific stenosis of a tricuspid aortic valve who have predicted survival >12 months and either prohibitive surgical risk (defined by >50% estimated risk of mortality or irreversible morbidity at 30 days, frailty, prior cobalt chest irradiation, porcelain aorta, coronary bypass graft adhesion to the posterior sternum preventing safe reentry into the chest, or severe pulmonary or hepatic disease) or high surgical risk (Society of Thoracic Surgeons [STS] mortality risk ≥8% with predicted actual mortality >15%).\(^11,12\) Trials are ongoing to evaluate TAVR in a medium-risk population (STS mortality risk 3%-8%; PARTNER II trials).

**AVAILABLE BALLOON-EXPANDABLE VALVES**

Currently, the most data available for TAVR are based on the balloon-expandable SAPIEN valves (Edwards Lifesciences, Irvine, CA; Fig. 42-1). The Edwards SAPIEN transcatheter heart valve system has been used extensively worldwide and was used in the PARTNER I trial.\(^7\) Based on this trial, the SAPIEN valve was the first transcatheter aortic valve to be granted approval by the US Food and Drug Administration (FDA) in November 2011 for use in surgically inoperable patients and in 2012 for use in surgically
The Edwards SAPIEN consists of a trileaflet, bovine pericardial valve mounted on a stainless steel stent with a polyethylene terephthalate skirt and seals at the aortic annulus with the stent frame deployed just beneath the coronary ostia. It was available in 2 sizes: 23 mm (for aortic annuli between 18 and 22 mm) and 26 mm (for aortic annuli between 21 and 25 mm) with a sheath and delivery catheter system of 22 Fr and 24 Fr, respectively. Dimensions and adequate requirements for the SAPIEN valve are provided in Table 42-1. More recently, the SAPIEN was replaced by the SAPIEN XT in Europe, Canada, and the United States (June 2014). Dimensions and adequate requirements for the SAPIEN XT valve are provided in Table 42-2. SAPIEN XT also consists of a bovine pericardial valve but is mounted to a thinner cobalt-chromium stent with fewer struts to allow for a lower profile delivery system. The SAPIEN XT is available in a wider range of sizes (23, 26, and 29 mm). Additionally, the Edwards eSheath (Edwards Lifesciences) combines a low profile with a dynamic expansion mechanism and is available in 16, 18, and 20 Fr (23-, 26-, and 29-mm valve, respectively). The eSheath allows for transient sheath expansion during delivery system passage and reduces the time the access vessel is expanded.

Table 42-1 Dimensions and Anatomic Requirements for Approved Edwards SAPIEN Transcatheter Heart Valves and Retroflex Delivery Systems
The most recent generation of the SAPIEN series of valves is the SAPIEN 3 (S3). The S3 consists of a bovine pericardial valve mounted on a cobalt-chromium stent with an outer skirt (polyethylene terephthalate) designed to enhance sealing and minimize paravalvular leak. The S3 is a taller valve (decreases the likelihood of native leaflet tissue prolapse) with 4 rows and 4 columns of cells between each commissure for high radial force. The S3 is available in 20, 23, 26, and 29 mm and can be delivered through a reduced profile 14- and 16-Fr (for the 29-mm valve) eSheath. Dimensions and adequate requirements for the S3 valve are provided in Table 42-3. In addition, the latest iteration of the delivery system (Commander) has several characteristics intended to facilitate accurate positioning, including increased flexion capability to engage the native valve coaxially and a fine alignment mechanism to make precise adjustments prior to deployment. The low-profile S3 valve and delivery system may facilitate fully percutaneous implantation in a broader range of patients with more accurate positioning and less paravalvular regurgitation. Improvements in valve technology will make it feasible for less experienced centers to make the transition to a complete

| Table 42-2 Dimensions and Anatomic Requirements for Approved Edwards SAPIEN X Transcatheter Heart Valves and NovaFlex Delivery Systems |
|-------------------------------|-----------------|-----------------|-----------------|
|                                | 23-mm Valve     | 26-mm Valve     | 29-mm Valve     |
| Acceptable aortic annular size range (by 2D TEE) | 18-22 mm        | 21-25 mm        | 24-27 mm        |
| Acceptable aortic annulus area by CT | 314-415 mm²     | 415-530 mm²     | 530-660 mm²     |
| Valve height                   | 14 mm (17 mm crimped) | 17 mm (20 mm crimped) | 19 mm (22 mm crimped) |
| eSheath outer diameter         | 6.7 mm          | 7.2 mm          | 8.0 mm          |
| Minimum access vessel diameter | 6.0 mm          | 6.5 mm          | 7.0 mm          |

Note: Aortic annular size is often more accurate and larger by transesophageal echocardiography (TEE) compared to transthoracic echocardiography (TTE). Computed tomography (CT) sizing is the most accurate, and optimal oversizing is 10% to 15%. The ranges suggested in this table are for general guidance and should not substitute for clinical judgment and experience.

**BASELINE EVALUATION AND PATIENT SELECTION FOR TAVR**

The assessment of a patient’s surgical risk, clinical status, and feasibility for TAVR is best accomplished by a multidisciplinary heart team consisting of clinical cardiologists, cardiac imaging specialists, interventional cardiologists, and cardiothoracic surgeons. We begin to establish surgical risk using the STS Predicted Risk of Mortality (PROM) score, which evaluates factors such as age, renal function, type of surgery, and pulmonary function. An STS-PROM score (mortality rate) of >8% signifies high risk (as defined by the inclusion criteria of the PARTNER trial cohort A group), and a score of 4% to 8% signifies moderate surgical risk (as defined by the inclusion criteria of the PARTNER II trial cohort A group).

The STS-PROM scoring system provides a formal means of risk stratification; however, it fails to include several important patient characteristics, including frailty and disability, which are particularly relevant to the elderly AS cohort. Several standardized models of frailty exist, and all seem to indicate that frailty has a significant impact on outcomes after cardiac surgery. Elderly patients with a low level of independent functioning (Katz Index of independent activities of daily living) were found to have twice the
surgical mortality and 6 times the risk of prolonged institutional care following cardiac surgery.\textsuperscript{15} Even crude measures of disability, such as gait speed, have been found to increase the risk of mortality or major morbidity by 2 to 3 times for any given STS-PROM score after cardiac surgery.\textsuperscript{16} A high frailty score (which includes assessment of gait speed, grip strength, serum albumin, and activities of daily living) has been independently associated with increased 1-year mortality following TAVR.\textsuperscript{17} These findings serve to remind clinicians that although risk stratification begins with validated models, a comprehensive assessment must consider other factors that may not be so easily measured.

A small but significant number of patients with AS are unable to have surgery due to a myriad of anatomic and medical conditions. Reasons for technical inoperability include porcelain aorta, previous mediastinal radiation, chest wall deformity, and potential for injury to previous bypass graft on sternal reentry.\textsuperscript{18} Cirrhosis, lung disease, and frailty are other medical conditions that when present are often thought to imply excessive surgical risk. Patients undergoing TAVR secondary to anatomic and advanced medical comorbidities have significant survival benefit when compared to standard therapy.\textsuperscript{18} Patients with bicuspid aortic valves have been excluded from most TAVR registries and trials. However, there are data to suggest that TAVR can be performed with good clinical outcomes in patients with bicuspid aortic valves.\textsuperscript{19} Patients with moderate dementia who would not fare well after cardiopulmonary bypass can be considered for TAVR. Patients who cannot afford to have a prolonged recovery after SAVR due to ongoing chemotherapy, need for additional operations, and upcoming transplantation can be considered for TAVR. Consideration of such factors outside of formal risk prediction models makes it crucial to allow assessment of anticipated risk for SAVR or TAVR by an experienced heart team.

**PREPROCEDURAL PLANNING FOR TAVR**

Perhaps the 2 most significant challenges to TAVR are the larger size of the delivery sheaths and the reliance on indirect visualization of the heart. To overcome these obstacles and perform safe TAVR, meticulous preprocedure
planning and intraprocedure imaging are needed. Evaluation prior to TAVR should seek to determine several factors, including (1) iliofemoral vessel size, calcification, and tortuosity; (2) anatomic details of the aortic valve leaflets; (3) annulus, sinotubular, and sinus of Valsalva dimensions; and (4) distance from the aortic annulus to the coronary ostia.

TAVR was initially conceived as a fully percutaneous procedure performed through the iliofemoral vessels without the need for a vascular cutdown. The transfemoral (TF) approach is the preferred access route for TAVR because it is less invasive than alternative routes. For patients without adequate iliofemoral vessels, operators have investigated more novel routes for delivery of the SAPIEN bioprosthesis. The SAPIEN device can be deployed via a transapical (implantation through the cardiac apex after a lateral thoracotomy), transaortic (direct cannulation of the ascending aorta with a mini-sternotomy), transcarotid (following a cutdown with Javid shunt), transcaval, or transseptal approach. In earlier Edwards SAPIEN registries, 30% to 50% of patients required an alternative approach due to peripheral artery disease or vessels unable to accommodate the larger delivery sheaths available at the time. In more recent reports using the 16/18/20 Fr SAPIEN XT and 14/16 Fr S3 delivery sheaths, an alternative access site has been used in 7% to 10% of cases.

PREPROCEDURE IMAGING

To determine which patients are suitable for a true percutaneous approach and which would be best served by an alternative access approach, we propose multimodality imaging assessment as an important step in planning TAVR. Imaging guides both access route and device sizing.

Echocardiography

Transthoracic echocardiography (TTE) is the initial imaging modality of choice due to its ease and safety. TTE is important to establish the diagnosis of AS and valve morphology (ie, bicuspid vs trileaflet valve), assess aortic annulus size, and evaluate left ventricular function and other concomitant valvular disorders, right ventricular dysfunction, and pulmonary hypertension. TTE is useful in identifying the location of any large, calcific
nodules, their relationship to the coronary ostia, and calcium that tracks into the left ventricular outflow tract (Fig. 42-2). Precise sizing of the aortic annulus is crucial for proper valve prosthesis selection and in order to avoid complications of inappropriate sizing (see section on computed tomography [CT]). TTE tends to underestimate true open surgical sizing and transesophageal echocardiography (TEE) may be helpful to provide better assessment of the annulus (Fig. 42-3).\textsuperscript{23,24} Balloon sizing of the annulus during balloon aortic valvuloplasty may be particularly helpful when the annulus is questionably too large for a given valve; supravalvular aortography is performed during balloon aortic valvuloplasty with rapid pacing, and any leakage of contrast into the left ventricle suggests that a larger valve will be needed (Fig. 42-4).\textsuperscript{25} Invasive techniques to assess aortic annular sizing may not be necessary with the advent of cross-sectional 3-dimensional TEE and CT imaging.\textsuperscript{26}
FIGURE 42-2 Calcified nodules in the aortic valve leaflets. A and B. Images from the same patient show a calcified nodule associated with the right coronary leaflet. This nodule is relatively less likely to cause significant paravalvular leak since it may be displaced into the sinus with valve deployment. LA, left atrium; RA, right atrium;
RV, right ventricle.

**FIGURE 42-3** Aortic root anatomy by echocardiography. Transthoracic echocardiography with 2-dimensional imaging (A) can be used to measure the aortic valve annulus as well as the sinuses and sinotubular junction (STJ). The annulus is frequently elliptical, and 3-dimensional transesophageal echocardiography provides a more complete assessment including the annular area (B). For this patient, the annular area of 620 mm$^2$ suggests that a SAPIEN 26-mm valve (nominal area 530 mm$^2$) would be too small.
FIGURE 42-4 Balloon aortic valvuloplasty to size the aortic valve annulus. If a supravalvular aortogram is completed during maximum inflation of an appropriately sized balloon (1-2 mm less than the proposed valve’s size), balloon valvuloplasty can be used to predict whether or not the proposed valve will seal the annulus. In panel A, the absence of any leak around a 22-mm balloon suggests that a 23-mm valve will be large enough. In panel B, contrast is leaking around a 25-mm balloon, which suggests that a 26-mm valve will be too small and may leave significant paravalvular leak. Panel C shows deployment of a 29-mm bioprosthesis after balloon sizing with a 25-mm balloon. Panel D shows final supravalvular aortography after deployment of a 29-mm bioprosthesis with no evidence of paravalvular regurgitation.
Computed Tomography

CT provides a wealth of cardiac, thoracic, and peripheral information in assessing a patient’s feasibility for TAVR and procedural planning.\(^{26}\) A CT scan will show in detail the aortic root anatomy (including annular, sinotubular, and sinus of Valsalva dimensions as well as coronary heights above the annulus), aortobifemoral anatomy, and details of arterial diameters and calcification. A gated, contrast CT with less than 1-mm slices will allow detailed 3-dimensional reconstruction, which can be invaluable for evaluation of the aortic annulus and peripheral arteries. Given the ellipsoid shape of the aortic annulus, 2-dimensional imaging techniques, such as TTE, may not accurately represent the size of the annulus (Fig. 42-5). Three-dimensional gated CT imaging of the aortic root may provide even more accurate assessment than surgical sizing.\(^{27}\)
Computed tomography with 3-dimensional reconstruction of the aortic valve annulus may provide the most complete assessment of aortic root anatomy and, like 3-dimensional echocardiography, can be used to measure the annular area. For this patient, the annular area of 532 mm$^2$ suggests that a 29-mm valve (nominal area 649 mm$^2$) would provide 22% oversizing for the S3 valve.

An appreciation of the complex, 3-dimensional, and nearly uniformly ovoid shape of the aortic annulus is important for appropriate prosthesis sizing. Inappropriate prosthesis size selection is associated with
paravalvular regurgitation, aortic annular rupture, coronary occlusion, and
device embolization. CT annular area measurements are usually performed in
systole at 25% or 35% of the RR interval when the annulus is largest.\textsuperscript{29} 
Nominal external areas for the SAPIEN 23- and 26-mm valves are 415 and
531 mm\textsuperscript{2}, respectively, and for the SAPIEN XT 23-, 26-, and 29-mm valves,
they are 415, 531, and 661 mm\textsuperscript{2}, respectively. Area oversizing of 8% to 10%
is considered optimal; however, most patients will not meet this stringent
target due to the large increments between prostheses sizes, and therefore, a
range extending up to 20% oversizing is acceptable in proposed sizing
algorithms.\textsuperscript{30} For borderline aortic annular dimensions, intentional
underexpansion of balloon-expandable valves by reducing the balloon
volume by 10%, which results in an intermediate inflow diameter between
the fully expanded valve and the next smaller transcatheter valve, has been
proposed.\textsuperscript{30} The S3 valve incorporates a paravalvular sealing system, and the
target annular oversizing range is 5% to 15% (see Table 42-3 for nominal
area for the 20-, 23-, 26-, and 29-mm valves). If oversizing by 20% to 30% is
anticipated, underfilling the deployment balloon by 1 to 3 mL or undersizing
the prosthesis by up to 5% should be considered.\textsuperscript{31}

Another application of cardiac CT is to establish a fluoroscopic projection
that defines the precise aortic valve plane that is perpendicular to the axis of
implantation and allows optimal deployment of the valve prosthesis. By using
CT to determine the “deployment angle,” operators can avoid performing
multiple aortic root angiograms. Additionally, CT imaging provides
information such as leaflet length, leaflet calcification, and height from the
annulus to the coronary ostia. These factors may predict the complication of
coronary occlusion during TAVR. Generally, a distance from annulus to
ostium of 11 to 14 mm is considered reasonable, and less than 7 mm is
possibly prohibitive for TAVR, particularly with narrow sinuses of Valsalva
(see Table 42-1). Adverse root features, including more than minimal left
ventricular outflow tract calcification, increase the risk for aortic rupture and
paravalvular regurgitation.\textsuperscript{32}

CT assessment of the minimum diameter of the iliofemoral vasculature is
important in assessing the feasibility of TF TAVR. The Edwards SAPIEN
bioprosthesis requires a minimum diameter of 8 mm throughout the
iliofemoral system for the 26-mm valve and of 7.3 mm for the 23-mm valve
(see Table 42-1). The outer diameter of the 22- and 24-Fr Edwards delivery
sheaths are 8.4 and 9.2 mm, respectively (see Table 42-1). The SAPIEN XT requires a minimum of 6.0 mm for the 23-mm valve, 6.5 mm for the 26-mm valve, and 7.0 mm for the 29-mm valve (see Table 42-2). The S3 requires a minimum of 5.5 mm for the 23- and 26-mm valves and 6.0 mm for the 29-mm valve (see Table 42-3). It is also important to assess the degree of tortuosity and calcification of the pelvic vasculature. Extensive calcification in relatively straight common iliac arteries maybe acceptable as long as the dimension is larger than the outer diameter of the sheath. Moderate calcification in tortuous external iliac arteries (which frequently dive deep into the pelvis) may increase the likelihood of major vascular complications. A noncalcified artery will often stretch 1 mm without major complication using a nonexpandable sheath, although dissection can still occur postprocedure. With the e-Sheath, we have seen noncalcified arteries temporarily stretch >2 mm without complication. Contrast-enhanced CT is preferred in the assessment of the peripheral vasculature, but in patients with significant renal insufficiency, a noncontrast study may be adequate.

**Angiography**

Invasive coronary and bypass graft angiography is also needed to evaluate anatomy suggestive of a large burden of ischemic myocardium; however, complete revascularization may not be necessary prior to TAVR. An invasive, digitally subtracted distal abdominal aortobifemoral angiogram using a marked pigtail catheter can be complimentary to CT and very helpful in defining the size and course of the iliofemoral system. In patients with borderline diameter of the pelvic vessels, intravascular ultrasound may be helpful to determine candidacy for the TF approach.

**Carotid Ultrasound**

Carotid duplex ultrasound may identify severe, flow-limiting carotid disease that may increase the risk of stroke associated with significant cardiogenic shock during TAVR, although this is exceedingly rare with TF TAVR. Percutaneous or surgical carotid revascularization may be considered prior to TAVR; however, procedure-related hypotension may be devastating and, thus, this procedure is not recommended by our center. We also measure the diameter of the common carotid artery in addition to the disease burden of the
carotids to determine candidacy for a transcarotid approach if no other access is feasible or safe.

**ANESTHESIA**

TF TAVR is commonly performed under general anesthesia but may be safely performed in experienced centers using only local anesthesia and minimal or no sedation. The advantage of general anesthesia is that operators early in their experience can perform TAVR without being rushed or concerned about airway management if a complication occurs. TAVR performed with conscious sedation allows for quicker recovery and hospital discharge of the patient. It also decreases the utilization of resources for TAVR, which may have important economic implications.

**TF TAVR PROCEDURE**

The following text describes the practical aspects of TF TAVR for patients with native valve AS using the Edwards SAPIEN valve.

*Antibiotics*

Routine antibiotic prophylaxis should be administered immediately prior to the procedure. Often, the same antibiotics that are used perioperatively for open surgical aortic replacement are used (eg, cefuroxime). Drugs effective against gram-positive skin flora such as cefazolin and vancomycin (in cases of penicillin allergy) are appropriate when a fully percutaneous approach is used. Antibiotic prophylaxis for the implanted bioprosthesis is indicated with subsequent dental procedures according to intersociety guidelines.

*Patient Preparation*

Patients are prepared and draped in the supine position with exposure from the upper thigh through the subxiphoid area, which should be available if emergent pericardiocentesis is required. An adhesive, iodophor-impregnated incise drape may be helpful in preventing access site infection.
Intraoperative Echocardiography

Intraoperative echocardiography may be transesophageal or transthoracic and is helpful in positioning the new valve prior to deployment as well as in evaluating postdeployment valve function. In the setting of hypotension after valve deployment, echocardiography is critical in assessing for valvular regurgitation, pericardial effusion, left ventricular dysfunction, and injury to the aortic root. Aortic regurgitation, if present, should be identified as transvalvular or paravalvular, quantified, and treated appropriately; management of aortic regurgitation will be discussed later in this chapter.

Special Instruments

• “Micropuncture” access kits that use a 21-gauge needle and 0.018-inch wire for arterial entry facilitate fluoroscopy-guided access.
• Uninterrupted capture during rapid ventricular pacing is critical to stable valve deployment, and for this reason, a Mullins (transseptal) sheath may be placed across the tricuspid valve to support the temporary pacing wire.
• Suture-based, percutaneous arteriotomy closure devices such as the Perclose ProGlide and ProStar XL (Abbott Vascular, Abbott Park, IL) are needed for fully percutaneous TF TAVR procedures.
• When TF TAVR is performed without an anesthesiologist, prepared 10-mL syringes of norepinephrine (16 μg/mL) and epinephrine (0.1 mg/mL) are helpful when immediately available to operators for as-needed treatment of hypotension.

Antithrombotic Therapy

Unfractionated heparin should be used after arterial access is obtained to maintain an activated clotting time (ACT) of 250 to 300 seconds. Heparin administration based on baseline ACT levels results in a significantly lower occurrence of major bleeding with TAVR. Direct thrombin inhibitors have been used for those with heparin allergies. We routinely administer a loading dose of clopidogrel prior to TF TAVR based on anecdotal evidence. Dual antiplatelet therapy with aspirin and clopidogrel is indicated after TAVR to prevent thromboembolic complications, but there is no consensus on the indicated duration of therapy. Six months of therapy with aspirin and
clopidogrel after TF TAVR are reasonable in most patients, and aspirin is indicated indefinitely thereafter. Clopidogrel can probably be omitted for patients who will be therapeutically anticoagulated with warfarin.

**Arterial and Venous Access**

In addition to femoral arterial access for the valve’s delivery sheath, a second (typically 6 Fr) arterial access is needed for insertion of a pigtail catheter into the aortic root. Venous access is needed for insertion of the temporary pacing wire.

**Device Preparation**

The family of SAPIEN valves uses dedicated delivery systems, and the balloon inflation lumen is connected to an Atrion inflation device (Atrion Medical, Arab, AL). The balloon ends in a nose cone, which facilitates crossing of the stenotic native valve. A crimping tool is a compression device that symmetrically collapses the valve over the delivery balloon catheter. The crimper is composed of a crimp aperture, which allows compression by means of a rotary knob; a balloon gauge, which verifies the delivery balloon diameter at full inflation; and a crimp gauge to verify the size of the balloon/valve assembly and to ensure that the delivery system has been suitably crimped. The newer generation SAPIEN valves (XT and S3) do not require measurement of the delivery balloon prior to crimping as a predetermined volume in the balloon is adequate. The entire system needs to be de-aired carefully. It is important to always check to see if the valve is mounted correctly on the balloon (fabric skirt toward the nose cone for the TF approach). The SAPIEN valves can be fully crimped for 15 minutes before insertion without compromising subsequent valve performance. Preparation of the delivery system and valve should be timed appropriately with the flow of the case.

**Step by Step Procedure**

After appropriate anesthesia, arterial and venous accesses are obtained on the side contralateral to where the delivery sheath will be inserted. A temporary pacing wire is advanced to a stable position in the right ventricular apex,
tested, and secured. The wire may be placed through a Mullins sheath (positioned across the tricuspid valve) for stabilization. The most stable position for the pacer lead is at the right ventricular apex. Placement of the lead in the base of the right ventricle free wall can lead to loss of capture or perforation (Fig. 42-6).

![Optimal positioning of the temporary pacing wire](image)

**FIGURE 42-6** Optimal positioning of the temporary pacing wire. Hand injection of a small volume of contrast through a Mullins sheath (or other catheter) positioned across the tricuspid valve can reveal the location of the right ventricular apex and facilitate safe positioning of the temporary pacing wire there. Wire placement on the right ventricular free wall or outflow tract may increase risk of perforation and loss of capture, respectively. Loss of capture may lead to valve malpositioning or embolization during deployment.

For fully percutaneous procedures, a 6-Fr Judkins right number 4 or similar catheter is then advanced to the aortic-iliac bifurcation, where it is used to selectively engage the contralateral iliac artery and create a digital “roadmap” of the femoral artery where the delivery sheath will be inserted. Using this image, a 21-gauge needle is placed coaxially into the center of the common femoral artery under real-time fluoroscopic guidance. Using the CT
scan for preprocedure planning, the location of the puncture can be selected to avoid the superficial femoral artery/profunda bifurcation and avoid a high arteriotomy through the inguinal ligament. Proper location of this puncture is critical to facilitate subsequent arteriotomy closure. Areas of heavy calcification are purposefully avoided. A 6- or 7-Fr sheath is inserted. Surgical cutdown to the planned femoral access site or external iliac conduit may alternatively be performed (Fig. 42-7).

**FIGURE 42-7** Accessing the femoral artery for valve implantation. Digital fluoroscopy equipment allows a femoral angiogram (created with contrast injection from contralateral access) to be stored as a “roadmap,” as depicted in panel A, where the tip of the arrow indicates the ideal site of puncture (1 cm above the femoral bifurcation) and the direction of the dotted line indicates the ideal angle of approach with the 21-gauge needle (coaxial with the femoral artery at the site of the planned puncture). Front-wall (B) puncture is essential for percutaneous closure, which provides immediate hemostasis at the end of the procedure (C). Access can also be obtained surgically. Panels D-F show how the external iliac artery may be accessed surgically using a conduit, which is brought out through a second skin incision in the groin. This approach may be helpful when femoral disease precludes transfemoral sheath insertion.
The catheter in the aortic bifurcation is exchanged for a pigtail catheter, which is advanced into the aortic root. Often the deployment angle can be predetermined by CT to align all 3 aortic cusps without overlap, with the nadir of the cusps defining the annular plane. A shallow left anterior oblique/cranial or right anterior oblique/caudal projection is typical. With the catheter sitting in the right sinus, a hand-injection aortogram is completed, allowing more detailed assessment of annular perpendicularity to the image. If the right cusp is too aortic, the image intensifier is moved cranially, and supra-aortic angiography is repeated. If the right cusp is too ventricular, the camera is moved caudally. The image projection is changed, and aortography is repeated until the annulus is visualized perfectly on edge. This “deployment angle” is saved into a still frame as a guiding picture for later valve deployment (Fig. 42-8).

![FIGURE 42-8 Optimal projection for valve deployment. In panel A, the right cusp is too high and overlying the noncoronary cusp. By moving the image detector cranially by 5°, the right coronary cusp is lower but not in line with the other cusps (B). In panel C, the image detector is moved an additional 5° and the bases of all 3 sinuses are aligned.](image)

A regular, J-tipped 0.035-inch wire is inserted at the main arterial access site, and the 6- or 7-Fr sheath is removed. The arteriotomy is “preclosed” using a pair of offset percutaneous suture devices. The matched pairs of suture ends are fixed together and secured as each is deployed (Fig. 42-9). Over a stiff, 0.035-inch wire such as the Amplatz Extra-Stiff wire (Cook...
Medical, Bloomington, IN), the arteriotomy is serially dilated to accommodate the balloon aortic valvuloplasty (BAV) sheath, which may also be the valve delivery sheath.

![Image](https://via.placeholder.com/150)

**FIGURE 42-9** Suture-based, percutaneous arteriotomy closure. Perclose ProGlide devices can be placed at the arteriotomy site before it is dilated to accommodate the large sheath. Two sutures are typically placed at a 45° offset (A). More offset may lead to higher risk of suture-mediated stricture when the site is closed. The sutures are secured during valve replacement (B), noting which pair of sutures was placed second. The second suture is usually tied first after sheath removal. An angiogram is completed prior to removal of the access site wire and final tightening of the last suture (C).

Once the larger sheath is inserted, a 6-Fr Amplatz left number 1 (AL1) catheter is inserted into the ascending aorta over a regular, J-tipped 0.035-inch wire. The J-tipped wire is removed, and a straight, 0.035-inch wire is used to cross the stenotic valve (see Chapter 41A, which describes techniques for crossing the stenotic aortic valve). The AL1 catheter is advanced into the left ventricle, and the aortic valve gradient is measured by transducing pressures simultaneously from the AL1 catheter and the side port of the large
sheath.

The same, stiff, 0.035-inch wire is reshaped to include a pigtail curve at its tip with roughly the same diameter as the left ventricular apex. We have found that the smallest diameter curve that can be shaped in the wire is best, as often it will grow to fill the left ventricular apex. The reshaped wire is inserted via the AL1 catheter into the left ventricular apex, and the AL1 catheter is removed. The valvuloplasty balloon is advanced across the aortic valve under fluoroscopic guidance, and BAV is performed during rapid ventricular pacing. One predilation is adequate for the subsequent delivery of the TAVR. The valvuloplasty balloon is sized to the short axis of the annulus or smaller to avoid interim severe aortic insufficiency (20-mm balloon for 23-mm TAVR and 23-mm balloon for 26-mm TAVR). Larger balloons can be used for balloon sizing as an adjunct to noninvasive imaging for prosthesis selection. Balloon sizing of the annulus may be particularly helpful prior to TAVR when the annulus is questionably too large for a given transcatheter valve. Supravalvular aortography is performed simultaneously during BAV with rapid pacing, and any leakage of contrast into the left ventricle suggests that a larger valve will be needed.\textsuperscript{25,39}

After the balloon is removed, the new transcatheter valve delivery system is introduced through the large sheath. The SAPIEN XT and S3 valves involve aligning the stent on the balloon within the aorta and use the NovaFlex and Commander delivery systems (Edwards Lifesciences), respectively. The SAPIEN XT and S3 devices are delivered via the low-profile Edwards eSheath, as described earlier.

While the delivery system is introduced, it is important to note wire position in the left ventricle and to allow the wire to float without any traction during advancement of the device. Prior to crossing the aortic arch, delivery catheter flexion is initiated and a left anterior oblique projection is obtained while advancing with countertraction on the guide wire. This maneuver allows for precise guidance of the delivery system in the mid-aorta and avoidance of atheromatous/debris embolization. The only part of the delivery system that may be touching the aorta while advancing around the arch is the nose cone. Strategies to ensure that the final position of the prosthesis is coaxial to the left ventricular outflow tract and thus perpendicular to the aortic annulus include wire manipulation with traction during advancement, clockwise rotation of the entire delivery system, and changing catheter flexion. Every effort should be made to advance the transcatheter valve
through the center of the aortic valve to increase the possibility of coaxial positioning. After crossing the aortic valve, we return to the deployment angle, and it is the role of the primary operator to go through the “5 Ps” as a checklist immediately before deployment (appropriate deployment picture, pigtail in noncoronary cusp, pusher catheter withdrawn so as to not interfere with balloon inflation, pacer advanced to make contact with the right ventricle, and position of the prosthesis). The implanter then needs to focus on the base of the native annulus that is located by identifying the basal attachment points of the leaflets by fluoroscopy or by echocardiography. It is in relation to this annular plane that the transcatheter valve is placed. Ideal position for the SAPIEN and SAPIEN XT is 50%/50% aortic/ventricular. To optimize positioning, identifying the leaflet tips is important to ensure that the prosthesis covers the native leaflets and the native annulus. Alignment of the aortic end of the prosthesis with the tips of the native aortic valve leaflets can be confirmed by echocardiography. The S3 is a taller valve, and positioning is accomplished by lining the middle balloon marker with the nadir of the aortic cusp (marked by the pigtail catheter). In cases of significant oversizing and/or significant subannular calcification, the S3 valve is placed 1 to 2 mm more aortic. Because ventricular shortening of the S3 may be limited in these conditions, placing the S3 more aortic helps approximate the ventricular skirt with the annulus. Ideal valve positioning is determined by a combination of fluoroscopy, echocardiography, and aortic root angiography. Significant aortic regurgitation during valve positioning can be mitigated by increasing the baseline pacing rate, which decreases diastolic filling time and affords additional time for positioning. Rapid pacing and/or arrested respiration during aortic root angiography may be helpful when there is significant valve movement with cardiac or respiratory motion. After satisfactory positioning, the new valve is deployed during rapid ventricular pacing. The rapid pacing should cause controlled hypotension. If 1-to-1 capture with the ventricle does not occur with the burst pacing, the deployment attempt should be aborted and reattempted at a slower pacing rate. If the burst pacing rate captures ventricular excitation consistently but does not cause a significant drop in blood pressure, the rate can be increased with rapid pacing (eg, start burst pacing at 160 beats per minute and increase to 200 beats per minute after initial capture). Deployment can be “active” to correct excessive movement of the device. Adjustments can be made if the valve dives too ventricular by
pulling back the prosthesis or pushing the guide wire. Pushing the valve forward or pulling the wire will prevent excessive aortic motion. Simultaneous root injection of the pigtail catheter in the noncoronary cusp will allow detailed visualization during deployment. A stepwise or gradual inflation will allow active deployment techniques. A prolonged pacing sequence (>20 seconds), however, can result in slow ventricular recovery, particularly in patients with depressed ejection fraction.

FIGURE 42-10 Optimal valve position by fluoroscopy and supravalvular aortography. Hand-injection aortography and fluoroscopic correlation with calcified landmarks help to optimize predeployment valve positioning relative to the base of the annulus as well as areas of calcification and the leaflet tips. Valve positioning is too aortic in panel A and too ventricular in panel B. Valve positioning in panel C is good.
FIGURE 42-11 Optimal valve position by echocardiography. Echocardiography is also important in optimizing predeployment valve positioning, including coaxiality (which cannot be completely assessed by single-plane aortography). Valve positioning is too aortic in panel A and too ventricular in panel B. Valve positioning in panel C is appropriate.

After deployment, the delivery system is withdrawn from the annulus, and prosthesis function is assessed echocardiographically, angiographically, and by hemodynamics. It is critical to understand the degree of aortic insufficiency and origin of the regurgitant jets because of the long-term adverse clinical impact that has been reported. Importantly, it is easier to correct the regurgitation during the index procedure compared with re-intervening on the patient at a later date. Patients with an aortic regurgitation index (defined as [diastolic blood pressure – left ventricular end-diastolic pressure]/systolic blood pressure × 100) of less than 25 have a significantly increased 1-year mortality compared with patients who have an aortic regurgitation index of ≥25. If significant transvalvular regurgitation appears to be related to the stiff wire against the leaflets, the delivery system may be removed and the wire exchanged for a multipurpose or pigtail catheter. If paravalvular regurgitation is severe, repeat balloon inflation by adding 1 mL of volume to the balloon can be successful. Balloon postdilatation may only be effective in 50% of cases and may come at the expense of higher cerebrovascular events. In extreme cases, a second valve can be implanted with excellent resolution of regurgitation. The final aortic valve gradient is measured using a multipurpose or pigtail catheter and the large sheath’s side port.
**Closure**

The large sheath is removed over a wire, and the arteriotomy is closed with the previously deployed sutures. The contralateral arterial access is used to perform a digitally subtracted, aortobifemoral angiogram after removal of the large sheath, thereby identifying any major vascular complications immediately. If the operator has a high level of suspicion for vascular rupture, contrast injections can be done gently through the large sheath during withdrawal. Protamine may be given if bleeding concerns outweigh thrombotic concerns. The pacing wire and contralateral sheaths are removed subsequently.

If the preplaced sutures do not provide hemostasis, additional suture(s) may be placed. With additional percutaneous sutures comes additional risk of creating a stricture or occlusion at the arteriotomy site, particularly if the sutures are deployed angulated. If arteriotomy closure remains incomplete after 3 or 4 sutures have been deployed, the partially closed arteriotomy may be occluded by insertion of a short, smaller (4-8 Fr) sheath. The smaller sheath may be removed and manual hemostasis achieved when the ACT is normalized. In cases of completely failed hemostasis, the larger sheath can be reintroduced and the patient can be sent for surgical repair of the arteriotomy. If concern for hemostasis exists, an adjunctive crossover balloon occlusion technique can be used with a wire and balloon from contralateral arterial access for tamponade and hemostasis of the arteriotomy site.44

**Postoperative Management**

Patients are typically transferred to a cardiovascular intensive care unit after TF TAVR, but uncomplicated cases may be transferred to regular telemetry beds in experienced centers. Systemic inflammatory response syndrome (SIRS) may be seen after TAVR and may manifest with leukocytosis, low-grade fever, hyperventilation, tachycardia, and vasodilation. Post-TAVR SIRS is a strong predictor of mortality and can be easily identified by a significant increase in the leukocyte count and treated with fluid and/or vasopressor support.45 Mild SIRS often resolves by the second day after TAVR. Continuation or late presentation of fever should prompt an investigation for infection. Acquired thrombocytopenia is common after TAVR and mostly resolves at patient discharge. However, nadir platelet
count of less than $50 \times 10^9/L$ may be predictive of higher 30-day and 1-year mortality.\textsuperscript{46} The duration of hospitalization after TF TAVR is determined by the patient’s baseline status and post-TAVR course, but patients may be discharged as early as postoperative day 1.

**TRANSAPICAL TAVR PROCEDURE**

The transapical (TA) approach has the advantages of facilitated implantation of a bioprosthetic device in patients who do not have favorable lower extremity access. TA TAVR procedures are performed by a team of cardiac surgeons, cardiologists, and anesthesiologists. The procedure is most favorably performed in a hybrid room with both fixed fluoroscopic imaging and TEE.

The patient is placed supine on the operating room table and prepped from the chin to the ankles. The chest, groin, and both legs are draped into the surgical field. Femoral arterial and venous access is obtained, the patient is anticoagulated with heparin to maintain an ACT of $>250$, a transvenous pacing wire is placed in the right ventricle, and a pigtail catheter is placed in the aortic root as described for the TF TAVR procedure. The apex of the left ventricle is identified by palpation, fluoroscopy, and/or echocardiography. An anterolateral thoracotomy is made in the 5th or 6th intercostal space, a rib-spreading retractor is placed, and the pericardium is incised to expose the left ventricular (LV) apex. Two pledgeted 2-0 prolene purse-string sutures are placed into the myocardium just cephalad to the apex lateral to the left anterior descending artery. In patients with previous sternotomy, opening the pericardium may not be necessary as sutures can be placed through the pericardium that are strongly adherent to the myocardium.

Fluoroscopy is used to align all 3 aortic cusps in the same plane. The LV cavity is accessed with an arterial needle, and a 0.035-inch wire is passed into the LV, across the aortic valve and into the ascending aorta. The wire is maintained in the ascending aorta and not allowed to pass into the right carotid artery. A 7-Fr sheath is placed through the LV apex and across the aortic valve. The 0.035-inch wire is manipulated into the descending aorta using a 6-Fr right Judkins 4 catheter. The 0.035-inch wire is exchanged for a stiff wire (Amplatz super stiff; Boston Scientific, Natick, MA) and left in the abdominal aorta. The 7-Fr sheath is exchanged for a TA delivery sheath,
which is positioned 4 cm inside the LV. A valvuloplasty balloon (20-22 mm, Z-med; Numed Inc., Hopkinton, NY) is placed over the wire and across the aortic valve. Under rapid ventricular pacing at 180 to 200 beats per second, BAV is performed. The balloon is removed, and the valve is crimped and placed through the LV delivery sheath and positioned across the valve.

Positioning of the valve uses TEE and fluoroscopic imaging. One-half of the valve is positioned above the aortic annulus, and the valve is aligned to be coaxial to the long axis of the aorta and perpendicular to the aortic annulus by manipulating the super stiff wire.\(^4^{7}\) Once the optimal position is confirmed, the valve is deployed during rapid ventricular pacing. Echocardiography with color Doppler and angiography are employed to evaluate valve position and assess the amount of paravalvular regurgitation.

All catheters and wires are removed, and the apex sutures are tied down during rapid ventricular pacing. Protamine is administered, and additional stitches may be placed in the LV apex to achieve hemostasis. The pericardium is closed over the LV apex surgical site, and a chest tube is placed in the left pleural space. Once hemostasis has been achieved, local anesthetic may be injected into the intercostal bundle, and the chest is closed in multiple layers.

**ALTERNATIVE ACCESS SITES**

In the recent past, operators have investigated more novel routes for delivery of the SAPIEN bioprosthesis. Direct cannulation of the ascending aorta (transaortic) with the delivery sheath has been successfully performed using a mini-sternotomy incision.\(^4^{8}\) A transaortic approach can be considered when there is inadequate iliofemoral anatomy and relative contraindications to TA TAVR (severe LV dysfunction and chronic obstructive pulmonary disease). Additionally, transcarotid and transsubclavian delivery after surgical cutdown has been successfully performed. Venous approaches with revival of the antegrade transseptal approach and transcaval approach (inferior vena cava to abdominal aorta puncture) have been reported. Minimal morbidity and mortality can be achieved when the appropriate alternative access approaches are tailored to the TAVR patient.\(^4^{8}\)
OUTCOMES OF TAVR

Hemodynamic Improvements

By invasive measurements, there is immediate improvement in hemodynamic measurements after TAVR and near-complete resolution of aortic gradients. For the SAPIEN series of valves, mean aortic gradients are reduced to less than 10 mm Hg and tend to be lower with larger prostheses. Aortic valve areas between 1.5 and 2.3 cm$^2$ are expected after implantation by echocardiography.$^{49-51}$

Few comparisons have been made between the hemodynamic performance of the transcatheter bioprosthesis and surgical prosthesis, but results suggest a favorable profile with TAVR. In a retrospective study of patients with AS and low ejection fraction, the Edwards SAPIEN bioprosthesis achieved a 20% larger reduction in mean aortic gradient than with SAVR and a 55% larger aortic valve area. Furthermore, the incidence of prosthesis-patient mismatch favored TAVR (16% with TAVR vs 29% with SAVR), and at 1 year, improvement in LV ejection fraction was significantly greater with TAVR (14% with TAVR vs 7% with SAVR; $P = .01$).$^{52,53}$

Quality of Life

Quality of life outcomes are particularly important in patients undergoing TAVR due to their often advanced age and accumulated comorbidities. Investigators have used several well-validated tests to assess subjective improvements in quality of life, including the Medical Outcomes Study Short Form-36 Item Health Survey, New York Heart Association (NYHA) functional class, Kansas City Quality of Life Questionnaire, Minnesota Living With Heart Failure Questionnaire, and 6-minute walk distance. Significant improvements in NYHA heart failure symptoms have been noted as early as 30 days after TAVR.$^{54}$ The PARTNER study found that NYHA symptoms improved between 30 days and 6 months and were stable at 1 year, such that 75% of surviving patients were in NYHA class I/II compared with only 8% at baseline.$^8$
Mortality

There have been a number of multicenter US, Canadian, and European registries of TAVR using various generations of the Edwards device. The only reported randomized trial comparing balloon-expandable TAVR to either medical therapy or SAVR comes from the PARTNER trial.

The PARTNER trial randomized patients among 2 different cohorts. Cohort A consisted of patients with high surgical risk (STS >10) randomized to TAVR (TF or TA) versus SAVR and was designed to demonstrate the noninferiority of TAVR. Cohort B consisted of inoperable patients randomized to TF TAVR versus medical therapy (including BAV as necessary) and was designed to demonstrate the superiority of TAVR.

The results of cohort B were published first and consisted of 358 randomized patients with an average age of 83 years, STS score >11, and numerous comorbidities including stroke, coronary artery disease, chronic obstructive pulmonary disease, pulmonary hypertension, atrial fibrillation, and frailty. The study demonstrated an impressive 20% absolute mortality reduction (50.7% vs 30.7%; \( P < .001 \)) with TF TAVR at 1 year. More recently, 2-year results demonstrated the continued survival advantage of TF TAVR in this group of patients (mortality, 43.3% vs 68.0%; \( P < .001 \)).

Subsequently, the cohort A findings were published and consisted of 699 patients with an average age of >83 years and STS score >11, and also with a significant prevalence of comorbidities. The TAVR was either aborted or converted to open surgery in 4.6% of patients. The primary end point (death from any cause at 1 year) was realized in 24.2% of the TAVR group and 26.8% of the surgical group (\( P = .44 \)), demonstrating noninferiority of the transcatheter procedure. These results are further substantiated by the recently provided 2-year data, with mortality rates of 35.0% and 33.9% in the SAVR and TAVR groups, respectively.

COMPLICATION MANAGEMENT OF TAVR

A major key to success in performing TAVR is complication prevention (CT scan and appropriate sizing of both annulus and iliofemoral anatomy) and
rapid identification and management if complications occur. Multimodality imaging, particularly echocardiography, has been instrumental in the recognition of complications and is key in guiding therapy. In assessing outcomes from the various published TAVR registries, it is often difficult to make comparisons, because outcome definitions were not standardized until the Valve Academic Research Consortium recently convened and published their criteria.\textsuperscript{56}

**Hypotension**

Acute hypotension during TF TAVR is not uncommon and may be due to acute aortic insufficiency, LV dysfunction (due to “stunning” with rapid pacing, ostial coronary occlusion, or other factors), pericardial effusion (typically from right ventricular perforation by the pacing wire or aortic root trauma), arrhythmia, peripheral vascular injury, a “suicide ventricle” (hyperdynamic intraventricular obstruction after unloading by BAV or TAVR), mitral valve injury, annular or root rupture, and ventricular septal defect.\textsuperscript{58} Treatment of acute hypotension is dictated by its etiology. Intra-aortic, intraventricular, or intravenous boluses of epinephrine or norepinephrine are immediately effective as temporizing measures. The suicide ventricle, while uncommon, is suggested by high residual dynamic gradients (obstruction worse after a premature beat) and can be identified echocardiographically. It is important to differentiate from other causes of acute heart failure as it will be aggravated by diuresis and positive inotropes but can be effectively treated with volume, vasoconstrictors, and negative inotropes. In addition to finding the root cause analysis, additional causes of hypotension are discussed in detail below.

**Vascular Complications**

Assurance of appropriate vascular size and minimal calcification and tortuosity on the preprocedural evaluation is paramount. Major vascular complications are those that cause limb-threatening ischemia or require additional interventions, either surgical or endovascular. The rate of major vascular complications was 14.0% in the PARTNER trial cohort A group and 16.2% in the PARTNER trial cohort B group.\textsuperscript{8} The rate of complications in the PARTNER trial should be tempered by knowledge of the substantial
decline (up to 3-fold) in major vascular complications that has been demonstrated with the smaller, second-generation SAPIEN XT bioprosthesis. The routine use of arterial preclosure with suture-based devices has also resulted in substantial decreases in vascular complications.

Aortoiliac avulsion or perforation may be suspected during arterial dilatation and insertion of the delivery sheath, but it may not be clinically manifest until removal of the delivery sheath. If perforation is identified at sheath removal, the sheath should be immediately reinserted (with dilator in place) to help tamponade the bleeding while preparation for more definitive treatment is made. Depending on the site and severity of injury, an aortic occlusion balloon such as the Coda balloon (Cook Medical) may be inserted from the contralateral arterial access site to the level of the distal abdominal aorta. With control of blood flow to the ruptured vessel, ipsilateral repair can be performed swiftly with either a balloon-expandable (Atrium iCAST; Atrium Medical Corporation, Hudson, NH) or self-expanding (Gore Viabahn; W.L. Gore and Associates, Inc., Flagstaff, AZ) covered stents. If the rupture involves partial or complete avulsion of the internal iliac artery, temporizing measures should be followed by prompt surgical intervention (Fig. 42-12). The internal iliac receives collateral circulation from the contralateral internal iliac, making injury in this vessel difficult to treat percutaneously without preemptive vascular plugging. Iliofemoral dissection is usually retrograde and does not limit flow, but severe dissections may be flow-limiting or even occlusive. Flow-limiting dissections should be treated with endovascular or surgical repair. Suture-mediated, severe stenosis of the common femoral artery at the access site often responds to gentle balloon dilatation, which does not need to completely eliminate the narrowing to be successful; mild to moderate residual narrowing is rarely symptomatic and is often resolved at follow-up.
FIGURE 42-12 Iliac rupture and management. Injecting contrast through the delivery sheath during slow withdrawal is prudent when iliac injury is suspected. If rupture is identified (A), the dilator is immediately reinserted. Sheath and dilator are immediately reinserted (B) to tamponade bleeding while an aortic occlusion balloon is deployed from contralateral access. Covered stents can then be used to seal the perforation percutaneously (C).

Aortic Regurgitation

Acute, moderate or severe native aortic regurgitation after BAV is best treated with implantation of a new valve. For this reason, some operators prefer to prepare the new valve for implantation prior to performing BAV, and some operators prefer to predilate with a small balloon (20 mm). If balloon sizing is needed to determine the size of the newly implanted valve, then pre-BAV preparation of the new valve is not possible. The risk of severe aortic insufficiency in patients with trileaflet AS is uncommon, with higher incidence seen in patients with bicuspid valves of any variety. Bradyarrhythmia should be avoided in the setting of significant aortic regurgitation, and increasing the pacing rate to 95 to 100 beats per minute may be a helpful
Acute, moderate or severe prosthetic aortic regurgitation after TAVR will be paravalvular, transvalvular, or mixed. It should be treated according to its etiology. Acute paravalvular regurgitation in the setting of an undersized or underexpanded valve may respond to postdilatation. Paravalvular regurgitation related primarily to malpositioning of the valve (too aortic or too ventricular) may require implantation of a second valve. Transvalvular regurgitation may occur due to incomplete valve closure when the valve is deployed in the setting of systemic arterial hypotension, and this improves when the blood pressure is increased. The valve also may simply require a brief period of time (minutes) to “warm up” and achieve full leaflet mobility. Transvalvular regurgitation may be severe when due to a “frozen” leaflet, and a pigtail or other catheter may be helpful in pushing the leaflet down so that it can begin to function. This condition may also require a second valve promptly, particularly if the native valve leaflets are overhanging and interfering with prosthetic valve function. This complication has not been reported with the longer S3 valve.

Chronic, moderate or severe paravalvular aortic regurgitation after TAVR may be treated percutaneously by implantation of a second valve or by implantation of 1 or more vascular plugs (Fig. 42-13).
FIGURE 42-13 Percutaneous paravalvular leak closure. Paravalvular leak may be treated by postdilatation, deployment of second valve, and/or implantation of vascular plugs. This patient had a focus of moderate to severe paravalvular leak despite deployment of second valve, and implantation of a vascular plug (seen here while still attached to deployment cable) was curative.

**Stroke**

A major concern for operators and patients is the risk of stroke during TAVR. Stroke in association with TAVR may occur because of atheroembolism, thromboembolism, calcium fragments, cardiogenic shock during the procedure, preexisting cerebral vascular disease, or interaction of these factors. In the PARTNER trial cohort B group, the risk of major stroke at 30 days with TAVR compared with medical management was 5.0% versus 1.1% ($P = .06$), and the combined risk of major and minor stroke was 6.7% versus 1.7% ($P = .03$). Importantly, quality of life metrics still demonstrated
substantial improvements in the TAVR group.\textsuperscript{64} More recent registry data with the second-generation SAPIEN XT device show a stroke rate of 2\%.\textsuperscript{65}

In the PARTNER trial cohort A group, the risk of major stoke at 30 days was 3.8\% with TAVR (TF and TA approaches) and 2.1\% with SAVR ($P = .20$), and at 1 year, the rates were 5.1\% and 2.4\%, respectively ($P = .04$).\textsuperscript{9} It is important to note, however, that while stroke was significantly greater at 30 days in the TAVR group (4.6\% vs 2.4\%), when followed out to 2 years, there was no significant difference between the 2 groups (7.7\% vs 4.9\%; $P = .52$).\textsuperscript{57}

New-generation embolic protection devices, such as the Embrella (Edwards Lifesciences) and the Montage Dual-Filter System (Claret Medical, Santa Rosa, CA), have shown some preliminary feasibility in deflecting or capturing emboli during TAVR, and clinical trials of the devices are eagerly anticipated.\textsuperscript{63} Cerebrovascular events are highest periprocedurally (the first 24 hours after TAVR), and the risk remains for approximately 2 months. These data have implications for potentially discontinuing dual antiplatelet therapy 2 months after TAVR.\textsuperscript{66}

Major ischemic stroke may be treated by catheter-based mechanical embolic retrieval where available. This strategy is particularly helpful in patients who undergo TAVR with conscious sedation because neurologic compromise can be identified rapidly in this patient population and immediate intervention can be performed. Thrombolysis may also be considered, although the expected benefit may be reduced (particularly with atheroembolism); bleeding risk is typically high because of patient age and morbidity as well as the arteriotomies created for TAVR.

Of note, it has recently been demonstrated that up to one-third of patients undergoing TAVR develop new-onset atrial fibrillation, and this was associated with an increased risk of stroke at 30 days and 1 year.\textsuperscript{67} Further study should focus on optimal antiplatelet and anticoagulant strategies to minimize stroke risk.

**Permanent Pacemaker Implantation**

The aortic annulus is in close proximity to the left bundle branch and atrioventricular node. Pressure exerted on this region by a stented valve may cause left bundle branch block and complete heart block either immediately
after implantation or in the days thereafter. The incidence of permanent pacemaker implantation with the Edwards SAPIEN device is 5% (4.5% in the PARTNER trial cohort B group and 5.7% in the PARTNER trial cohort A group; not significantly different than the incidence with medical therapy or SAVR). When compared to self-expanding valves, permanent pacemaker rates with the newer SAPIEN XT valve are significantly lower.\textsuperscript{68} Risk of permanent pacemaker with the SAPIEN valves is between 3% and 10%. Other factors that may contribute to the need for a pacemaker include the presence of a baseline right bundle branch block, extensive leaflet calcification, and an oversized transcatheter valve.\textsuperscript{69}

**Coronary Occlusion**

Obstruction of the coronary ostium by the native aortic leaflets occurs in <1% of patients undergoing TAVR.\textsuperscript{51} A narrow sinus of Valsalva, a short distance between the annulus and the coronary ostium, and the presence of bulky leaflet calcification may all contribute to coronary obstruction. Fortunately, these factors can be assessed on preprocedural imaging, and if concern exists, a pre-TAVR valvuloplasty with root angiography to assess coronary artery patency can be performed.

Acute, aorto-ostial coronary occlusion may be treated effectively with percutaneous coronary intervention, which may be facilitated in high-risk cases by placing a 0.014-inch coronary interventional wire with balloon or stent preemptively into the coronary artery prior to deployment of the new valve. The coronary stent will be placed to create a tunnel that covers the coronary ostium, the transcatheter valve stent, and the native aortic leaflet (Fig. 42-14).\textsuperscript{70}
Coronary occlusion treated with percutaneous intervention. Acute, aorto-ostial coronary occlusion was suspected prior to deployment of a second bioprosthesis, and the left main coronary artery was preemptively cannulated and wired with placement of a balloon (A). Post–transcatheter aortic valve replacement angiography revealed significant narrowing at the ostium of the left main coronary artery (B). Angioplasty of the left main coronary artery was successfully performed with a balloon (C). Final angiography after stent deployment revealed no significant narrowing with Thrombolysis in Myocardial Infarction (TIMI) grade 3 flow (D).

Cardiac or Proximal Aorta Trauma
While rare, it is important to consider cardiac trauma during TAVR. Right ventricular perforation may cause pericardial effusion, which can be hemodynamically significant. Large inspiratory drops in systemic arterial pressure (pulsus paradoxus) suggest a hemodynamically significant effusion, and echocardiography may be confirmatory. Treatment with pericardiocentesis is appropriate since the bleeding into the pericardium is often self-limited. If blood loss is substantial, blood may be autotransfused from the pericardium into a systemic vein while preparation is made for surgical exploration. The site of perforation may not be identifiable at surgery.

Aortic root trauma may be immediately catastrophic or may present subtly with thickening of the interatrial septum on echocardiography and subsequent development of pericardial effusion. Effusion may be treated as above, and surgical repair may be considered. Immediate treatment with protamine and blood pressure control is recommended for conservative management. Late presentation of subclinical rupture has been seen at follow-up echocardiography.

**Valve Embolization**

Valve embolization is most commonly due to loss of capture during rapid ventricular pacing (leading to ejection of the incompletely deployed valve from the annulus), but it also may be due to malpositioning. Embolization is best avoided by confirmation of stable pacing, careful valve positioning, and slow, controlled deployment. In the event of aortic movement during deployment, the valve may be immediately pushed back into the annulus if the second operator has maintained pressure on the inflation syringe (to hold the no-longer-crimped valve on the partially inflated balloon) without further inflation or deflation. If the valve cannot be pushed back across the annulus, then it may be pulled into the arch (and ideally into the descending aorta) before being deployed. If the deployment balloon has been deflated, the valve will be loose on the wire and should be recaptured with the balloon and deployed in a safe location, either just distal to the left subclavian artery or immediately proximal to the common iliac bifurcation (Fig. 42-15). Wire position across the valve must be maintained to prevent the valve from turning and obstructing the aorta. After the embolized valve is secured, a second valve may be implanted in the annulus to complete the TAVR. Valve
embolization into the left ventricle is less common and almost always requires surgical intervention.

**FIGURE 42-15** Distal deployment of an embolized valve. Valve embolization may be treated by distal deployment, as in panel A. The valve replacement procedure is completed using a second valve (B). A postoperative computed tomography scan (C) shows the embolized valve deployed in the distal arch and the second valve successfully deployed within the aortic valve annulus.

**FUTURE DIRECTIONS**

The field of TAVR is still young, and there are a number of future directions that show great promise. The initial case series, multiple registries, and the PARTNER I trial were all performed in patients with high or prohibitive surgical risk. Recent experience in Europe has demonstrated efficacy and safety of the procedure in lower surgical risk patients, and the PARTNER II trial aims to study patients with moderate surgical risk (STS score, 3%-8%). It will be interesting to determine whether the procedure is safe.
and effective enough to be extended to lower risk groups. In lower risk patients, more data can be acquired to assess long-term valve performance.

**Newer Devices**

While the early experience with the SAPIEN bioprosthetic devices have shown that TAVR is feasible, newer devices aim to make delivery simpler and more suitable for broader commercial use. Most new devices currently undergoing clinical testing are self-expanding and include the Lotus valve (Boston Scientific), St. Jude Medical Portico valve (St. Jude Medical, Saint Paul, MN), and the Direct Flow valve (Direct Flow Medical Inc., Santa Rosa, CA). The advantage of a self-expanding valve is that it offers the potential for retrievability. The S3 valve recently acquired approval in Europe (CE mark, or Community European) and is a lower profile, balloon-expandable valve that is designed to further reduce paravalvular regurgitation. It is the only commercial valve available that can be delivered through a 14-Fr expandable sheath (eSheath). In 2013, the JenaValve (JenaValve Technology Inc., Munich, Germany) received the CE mark approval for the treatment of high-risk and inoperable patients with aortic insufficiency. This device has a unique anchoring and clipping mechanism (JenaClip), allowing the patient’s native valve leaflets to be clipped onto the valve and enabling the device to be firmly anchored in the correct anatomic position.

**Expanded Indications**

Bicuspid aortic valves occur in nearly 1% of the population and are the most common congenital cardiac abnormality. AS is common, affecting nearly 75% of patients.\(^7\) Calcification, which tends to be severe and asymmetric in bicuspid valves, may affect the circularity of a transcatheter heart valve in the annulus, thereby increasing the risk of severe paravalvular regurgitation or embolization. For self-expanding systems, there is concern that the nitinol frame may not generate sufficient radial force, leading to underexpansion. For these reasons, patients with bicuspid valves have been excluded from TAVR trials and registries. However, the success of TAVR for patients with AS, including those with functional bicuspid valves, has prompted investigation of its feasibility in congenitally bicuspid valves. Recent data suggest that TAVR can be performed with good clinical outcomes with
stenotic bicuspid valves. Additional applications for TAVR may also include patients with a degenerated bioprosthetic SAVR. Surgeons are increasingly likely to use bioprosthetic valves that have the advantage of not requiring anticoagulation. The consequence is that more people will have degeneration of their surgical valves as the bioprosthesis ages. In an effort to avoid further surgery, implantation of transcatheter heart valves within degenerated bioprosthetic devices at all valvular positions has been attempted and has been successful. Bioprosthetic valves are sized according to the outer diameter, and information about the inner diameter can be obtained from the manufacturer. Recently, a commercially available computer application has been developed that assists in identifying the correct size SAPIEN valve and correct position of implant for different surgical valves and homografts. Because the inner diameter of the surgical valve is often small and rigid, transcatheter devices are often underdeployed. Although the hemodynamic performance of the valve-in-valve implants reported was similar to reports of surgical valves, it remains to be seen if underdeployment will accelerate the degradation of the transcatheter heart valves and lead to earlier valve failure. Early data have shown that valve-in-valve therapy is a safe and feasible alternative to treat high-risk patients for failing bioprosthesis with improvement seen in hemodynamics (Fig. 42-16).
FIGURE 42-16 Valve-in-valve transcatheter aortic valve replacement (TAVR) for failing surgical aortic valve replacement. Valve-in-valve application by Dr. Vinayak Bapat providing specifications for a Perimount 2700 25-mm surgical bioprosthetic (A) in a patient with severe valvular regurgitation. Success of valve-in-valve therapy is based on the correct identification of the surgical valve and choosing the correct size of the TAVR valve. The valve-in-valve application provides gross and fluoroscopic images to guide TAVR (B). Panel C shows final deployment of a 26-mm SAPIEN transcatheter bioprosthesis inside a Perimount 2700 25-mm valve with no residual valvular regurgitation.

CONCLUSION

The number of patients with severe symptomatic AS is steadily on the rise, and historically, a large percentage of these patients were unfit for SAVR. In
the current era, however, TAVR has emerged as the standard of care for inoperable patients and is a valid alternative to surgery for selected high-risk patients with symptomatic AS. When performed for appropriate patients and with attention to procedural detail, TAVR can be an elegant procedure leading to improved quality of life and survival. Pre- and postoperative management are as important as intraprocedural management. As technology, techniques, and patient selection improve in the future, TAVR may be an alternative to surgery in lower risk patients.

**MULTIPLE CHOICE QUESTIONS**

1. What are the current indications for transcatheter aortic valve replacement (TAVR)?
   A. Patients with severe symptomatic aortic stenosis (AS) who are at
prohibitive/high surgical risk
B. Patients with severe symptomatic AS who are at intermediate surgical risk
C. “Valve-in-valve” therapy for patients with bioprosthetic aortic valve failure
D. Patients with severe symptomatic aortic regurgitation who are at prohibitive surgical risk
E. A, B, and C

2. What is the preferred access site for TAVR?
   A. Transfemoral
   B. Transapical
   C. Transaortic
   D. Transsubclavian
   E. Transcarotid
   F. Transcaval

3. True or false? TF TAVR under conscious sedation can be performed with minimal morbidity and mortality compared to TF TAVR under general anesthesia.

4. Which modality allows for the most accurate assessment for aortic annular sizing and transcatheter heart valve selection?
   A. Transthoracic echocardiography (TTE)
   B. Transesophageal echocardiography (TEE)
   C. Multidetector computed tomography (MDCT)
   D. Balloon sizing

5. What are the risk factors for coronary occlusion in patients undergoing TAVR?
   A. Low coronary ostial heights
   B. Shallow sinuses of Valsalva
   C. Bulky native leaflet calcification
   D. All of the above

**ANSWERS**
1. E

Results from the PARTNER trial have allowed TAVR to become the standard of care for prohibitive risk patients with severe AS and to be seen as a valid alternative to surgery for high surgical risk patients. In 2016, TAVR received US Food and Drug Administration (FDA) approval for patients with severe AS who are at intermediate risk for death or complications associated with open-heart surgery (Society of Thoracic Surgeons [STS] risk score of 4%-8%). In 2015, the FDA approved an expanded indication to include “valve-in-valve” repair of failed surgical bioprosthetic aortic valves. Currently, there are no transcatheter valves that have been FDA approved for the treatment of severe symptomatic aortic regurgitation. In Europe, a TAVR system (JenaValve) is an option to treat severe native aortic valve regurgitation in patients with high or greater risk for open surgical valve replacement or repair.

2. A

The transfemoral (TF) method is the most commonly used approach, with the majority of TAVR devices being deployed by this technique. TF procedures are now performed using a fully percutaneous “preclosure” technique as described. Advantages of the TF technique include the fact that it is the least invasive approach and can be performed in most patients with lower profile delivery systems (14 and 16 Fr). Most local vascular complications, including dissection, can be managed with endovascular techniques.

3. True

Babaliaros and colleagues reported in a series of 142 patients that TF TAVR under conscious sedation using a “minimalist approach” could be performed with minimal morbidity and mortality compared to TF TAVR under general anesthesia. Minimalist approach TAVR under conscious sedation allowed for a shorter length of stay and lower resource use than standard TF TAVR under general anesthesia. Minimalist approach TAVR resulted in significantly lower hospital costs.

4. C

TTE is the initial imaging modality of choice due to its ease and safety. TTE tends to underestimate true open surgical sizing, and TEE may be useful to
help provide a more accurate assessment of the aortic annulus. Balloon sizing of the annulus during balloon aortic valvuloplasty may be particularly helpful when the annulus is questionably too large for a given valve. MDCT allows for the reconstruction of the annulus in its true axis in a reproducible fashion. MDCT allows for careful evaluation of the aortic root and left ventricular outflow tract and an in-depth understanding of the potential risk of annular rupture. Computed tomography (CT) measurements of the annulus and root are also invaluable for the identification of patients at increased risk of coronary occlusion during TAVR. MDCT also provides information on the aortobifemoral anatomy and details of arterial diameter and calcification, which are invaluable for procedural access planning. Another application of CT is to establish a fluoroscopic projection that defines the precise aortic valve plane that is perpendicular to the axis of implantation and allows optimal deployment of the valve prosthesis. By using CT to determine the “deployment angle,” operators can avoid performing multiple aortic root angiograms.

5. D

Obstruction of the coronary ostium by the native aortic leaflets occurs in <1% of patients undergoing TAVR. Patients with low coronary ostial heights as determined by MDCT (<12 mm for a male and <11 mm for a female) are at increased risk of coronary occlusion. In addition, shallow sinuses of Valsalva (SOV) <30 mm and, more significantly, a ratio of SOV/annulus diameter <1.25 have been associated with the highest risk of coronary occlusion. The severity of valve calcification, especially the presence of bulky calcium nodules on the left or right aortic leaflets, may contribute to coronary occlusion after TAVR. Fortunately, information derived from CT has become incredibly useful to improve the safety profile of TAVR and reduce the risk of coronary occlusion.
Balloon-Expandable Transcatheter Aortic Valve Replacement

Hemal Gada
Susheel Kodali

INTRODUCTION

Transcatheter aortic valve replacement (TAVR) has been shown to improve mortality and quality of life in patients with severe aortic stenosis who are designated inoperable or high risk for surgical aortic valve replacement (SAVR).\textsuperscript{1-5} The first implantation of a transcatheter heart valve (THV) in the aortic position was performed by Cribier et al\textsuperscript{6} to treat an inoperable patient with severe symptomatic aortic stenosis. From the development of the porcine model to the first clinical implantation in the aortic position, the makeup of a THV was a foldable biological cardiac valve sewn inside an expandable stent frame. This device would be crimped onto a balloon in order to deploy the THV via inflation. With this concept, the technology has emerged as one of the most transformative in the field of interventional cardiology. Given the initial focus on development of a balloon-expandable THV to facilitate TAVR, the largest experiences with TAVR are with balloon-expandable THVs. The main objectives of this chapter are to review the available devices, methods of implantation, clinical outcomes, valve hemodynamics, and durability associated with these systems.
THE BALLOON-EXPANDABLE TRANSSCATHETER HEART VALVE

The initial large-scale clinical experience with the balloon-expandable THV was with the Cribier-Edwards balloon-expandable aortic stent valve (Edwards Lifesciences, Irvine, CA). This consisted of a trileaflet tissue valve composed of equine pericardium mounted on a stainless steel frame.\textsuperscript{6}

Subsequent improvements to this system led to the development of the second-generation Edwards SAPIEN THV (Edwards Lifesciences). Major differences between the first- and second-generation devices were the incorporation of pretreated bovine pericardium as the material for the valve leaflets, which had been demonstrated to decrease valve calcification, in addition to a polyethylene terephthalate skirt, which extended to a larger expanse of the stent frame, thus improving sealing and potentially reducing paravalvular regurgitation (PVR).\textsuperscript{7} The 2 sizes of this device, the 23- and 26-mm diameter THVs, could be inserted via 22- and 24-Fr delivery systems for transfemoral (TF) TAVR and through a 29-Fr sheath via transapical access for patients without vascular adequate for the TF approach.

The third-generation of the balloon-expandable Edwards THVs is the SAPIEN XT THV (Edwards Lifesciences). This also consists of a trileaflet pericardial bovine valve, but the leaflets have a scallop shape to improved leaflet durability and the valve is mounted on a cobalt chromium stent frame.\textsuperscript{7} The latter decreases the profile of the THV, given the thinner struts and fewer rows between commissures. The SAPIEN XT THV is available in 23-, 26-, and 29-mm sizes in the United States, with a 20-mm size available internationally. The sheath sizes are smaller than those of the previous generation Edwards THVs because of the lower profile characteristics, as described earlier. The NovaFlex+ delivery system replaced the original RetroFlex3 sheath used for the previous generation device (Edwards Lifesciences). Through this system, the 20- and 23-, 26-, and 29-mm SAPIEN XT can be advanced through 16-, 18-, and 20-Fr expandable TF delivery sheaths, respectively. The clinical manifestations of these reduced catheter profiles are discussed later.

The latest generation of Edwards THVs is the SAPIEN 3 THV, recently approved by the US Food and Drug Administration (FDA); it improves upon
the previous generation by the addition of an outer skirt, which is used to further fill paravalvular gaps and reduce paravalvular leak. The crimped cobalt chromium stent frame shortens significantly (up to 8 mm depending on valve size used) when deployed. This foreshortening is a critical component of the sleek delivery profile. Through the latest generation TF delivery system, the Commander (Edwards Lifesciences), 20- and 23-mm and 26- and 29-mm THVs can be deployed through 14- and 16-Fr expandable sheath systems, respectively. The Commander system also has increased flex properties and a fine-tuning dial, which may facilitate less traumatic and more precise valve deployments. The SAPIEN 3 THV is currently in use internationally and has recently been approved based on data from the Placement of Aortic Transcatheter Valves (PARTNER) II Trial, as described later.

OVERVIEW OF CLINICAL TRIALS AND OUTCOMES

After the first 4 TAVR cases, Cribier and colleagues petitioned the French government to start a feasibility trial, which was restricted to compassionate use. The first study was the Initial Registry of Endovascular Implantation of Valves in Europe (I-REVIVE) trial, which involved 7 patients receiving antegrade or retrograde approach for implantation. Twenty additional patients were recruited into the Registry of Endovascular Critical Aortic Stenosis Treatment (RECAST) trial, involving only antegrade access. There was an 80% procedural success rate in these initial small studies, and although many of these critically ill patients died of their comorbidities, some survived years, and all had no prosthesis dysfunction. Future feasibility analyses supported the use of TAVR in at least inoperable patients, with demonstrated survival extending well beyond that of patients without TAVR.

The PARTNER trial was the world’s first prospective randomized TAVR trial and analyzed inoperable patients (cohort B), who had an estimated mortality or major morbidity from SAVR of >50%. This trial demonstrated that TF TAVR is superior compared to standard medical therapy and resulted in a 20% absolute reduction in mortality at 12 months. This trial also included a high-risk operable arm (cohort A) that included patients with
estimated mortality from SAVR of at least 15%. The results from this analysis showed that transapical (TA) and TF TAVR have similar 1-year survival compared to SAVR. As a result of these impressive results, the FDA approved TF TAVR using the Edwards SAPIEN THV in November 2011 for treatment of aortic stenosis in inoperable patients. In 2012, this approval was extended for the TF and TA access routes to high-risk patients who are eligible for surgery but face high risk of serious complications or death.

Long-term data for balloon-expandable THVs are currently limited and will become available with further follow-up of existing trials and registries. Toggweiler et al\(^{12}\) published the first 5-year outcome data, following 88 patients who received the second-generation Edwards SAPIEN THV. Survival rates at 1, 2, 3, 4, and 5 years were 83%, 74%, 53%, 42%, and 35%, respectively. Interpretation of mortality per year is limited by the small patient numbers and also from the learning curve given the early experience of the center. However, no patient developed severe transvalvular regurgitation or prosthetic stenosis. Recently presented data for PARTNER I cohort B showed 5-year mortality of 93.6% in the standard therapy arm versus 71.8% in the TF TAVR arm (\( P < .01 \)). Longer term follow-up of the surgical arm (cohort A) demonstrated equivalent survival between TAVR and SAVR at 5 years with high mortalities in both arms (~70%).\(^{13}\) Importantly, valve durability was demonstrated with no increase in transvalvular gradient or significant attrition of valve area during the 5-year follow-up of both arms.\(^{13,14}\)

The second randomized PARTNER trial (PARTNER II) has also completed recruitment. Cohort B of this trial was designed to investigate the performance and outcomes with the third-generation SAPIEN XT THV and the NovaFlex+ delivery catheter in patients deemed inoperable. In comparison to the Edwards SAPIEN THV, the SAPIEN XT demonstrated similar survival at 30 days but lower rates of important complications including bleeding and vascular complications. The surgical arm of the trial (cohort A) was designed to investigate outcomes related to TAVR versus SAVR in patients at intermediate surgical risk. Enrollment has been completed in this arm, and results will be forthcoming in 2016.

The PARTNER II trial also incorporated the use of the latest generation SAPIEN 3 THV in an attached registry of high-risk and intermediate-risk patients, completed in 2014. The results of the SAPIEN 3 registry showed
excellent early results. All-cause and cardiovascular mortality rates at 30 days were 2.2% and 1.4% for the high-risk/inoperable registry and only 1.1% and 0.9% for the intermediate-risk registry, respectively. The frequencies of stroke and disabling stroke were 1.5% and 0.9% for the high-risk/inoperable registry and 2.6% and 1.0% for the intermediate-risk registry, respectively. Finally, rates of moderate or severe PVR were 2.9% and 4.2% in the high-risk/inoperable and intermediate-risk registries, respectively. These outcomes will markedly influence TAVR indications as well as the landscape of available balloon-expandable THV technologies.

PREPROCEDURE PLANNING

Hallmarks of planning prior to performing TAVR with a balloon-expandable THV include assessments of the aortic valve annulus and vascular access. Multimodality imaging is essential for patient screening and procedural guidance during TAVR and has been incorporated into consensus statements, reviews, and guidelines. Correct valve sizing for a balloon-expandable THV requires meticulous attention to 3-dimensional imaging, including multislice computed tomography (CT) and transesophageal echocardiography (TEE). A multislice CT is also a gold standard assessment in determining the adequacy of peripheral access, in addition to evaluating anatomy relevant to the alternative access options discussed in the following section. Optimal TAVR implantation requires: (1) determining anatomic features that would preclude or make advantageous the use of a particular access route; (2) valve sizing based on established criteria for measuring the annulus dimensions matched to the specific valve type; and (3) accurate valve positioning (axial height and alignment) within the annular valve plane. The challenge of valve sizing and positioning cannot be underestimated and requires an intimate understanding of the anatomy of the aortic valve complex. Correct sizing and placement of transcatheter aortic valves will result in excellent valve hemodynamics, no or trace PVR, low requirements for new pacemakers due to conduction abnormalities, and no evidence of coronary obstruction or annulus injury.

ACCESS ALTERNATIVES
The first TAVR with a balloon-expandable THV was performed via an antegrade approach through the femoral vein, incorporating a transseptal puncture through which the THV crossed the mitral valve and led to final positioning in the aortic valve annulus. Because of the difficulty and complexity inherent in these approaches, the contemporary TF and TA approaches were developed after improvements in valve design and delivery systems as mentioned earlier.

Factors that may determine preferred TAVR vascular access include peripheral arterial disease (inadequate vessel diameter, severe calcification, or extreme tortuosity of the iliofemoral vessels), the presence of extensive calcification of the ascending aorta (ie, porcelain aorta), hostile chest wall anatomy (due to either orthovoltage radiation exposure or chest wall deformities), previous coronary bypass graft surgery with mammary conduits adherent to the chest wall, and severe lung disease. The 4 most common techniques for TAVR access with the balloon-expandable THV are the retrograde TF, antegrade TA, and the more recently developed direct or transaortic (TAo) approach. In the PARTNER trial, using the larger profile SAPIEN RetroFlex3 introducer sheath (outer sheath diameter of 9.2 mm for the 26-mm valve), there were frequent major vascular complications associated with TF TAVR procedures. In the PARTNER II trial, the previous-generation SAPIEN system was compared to the lower profile SAPIEN XT system and its NovaFlex+ introducer sheath (33% lower cross-sectional area), and major vascular complications were reduced from 15.5% to 9.6% ($P = .04$). This highlights the importance of lower profile delivery systems in maximally using safe fully percutaneous TF TAVR as a primary default access strategy. The SAPIEN XT system was approved by the FDA in 2014 for commercial use in high-risk and inoperable patients and uses the NovaFlex+ introducer sheath replacing the larger profile SAPIEN RetroFlex3 introducer sheath.

The TA approach has also become lower profile with the SAPIEN 3 THV, which uses the Certitude delivery system (Edwards Lifesciences), an 18-Fr system. This is much lower in profile than the previous generation Edwards SAPIEN and SAPIEN XT systems, requiring at least 24-Fr, and therefore potentially reduces the occurrence of bleeding due to myocardial tears and the incidence of myocardial injury. The TA approach avoids peripheral access issues, but also has limitations, including increased length of hospitalization and increased risk of 30-day and 1-year all-cause
mortality. These adverse TA outcomes may have been influenced by differences in underlying baseline comorbidities between the 2 populations, given the “TF first” approach often adopted by clinicians, which relegated only patients with significant peripheral vascular disease to TA TAVR. Recently, a propensity matched analysis from the PARTNER I trial comparing TF and TA approaches demonstrated higher 30-day mortality and increased length of stay with the TA approach. Other adverse outcomes associated with the TA approach include a higher likelihood of periprocedural bleeding, increased risk of hemodynamic instability, and greater patient discomfort, due to pain related to the anterolateral thoracotomy. In an analysis of PARTNER cohort A health-related quality of life (HRQoL) outcomes, Reynolds et al showed short-term differences in favor of TF TAVR when compared to SAVR. However, in patients deemed unsuitable for a TF approach and thus meriting TA TAVR, HRQoL was not significantly different from that of SAVR across all studied follow-up time points. This was further validated in an analysis of the PARTNER TA TAVR nonrandomized continued access registry.

The TAo access site for balloon-expandable TAVR has been introduced more recently. In the largest series of TAo cases, when compared with a contemporary group of TA patients, there was a lower combined bleeding and vascular event rate (27% vs 46%; \( P = .05 \)), shorter median intensive care unit length of stay (3 vs 6 days; \( P = .01 \)), and a favorable learning curve. Transcarotid access and antegrade transseptal access via the femoral vein have also been described, but like TAo, these approaches have not been studied in a randomized controlled trial. Access alternatives present themselves as individual to each patient, taking into account several variables such as caliber, atherosclerotic disease, and calcification of the vasculature, in addition to various patient comorbidities. While the TF approach is currently preferred, there remains a somewhat undefined niche for each access method, given the lack of data comparing TAVR access alternatives.

PRE- AND POSTDILATION

Balloon aortic valvuloplasty (BAV) has traditionally been performed before balloon-expandable THV deployment. This provides better transition of the valve through the annulus and potentially avoids mechanical complications
related to the force and contour of the delivery system. However, BAV carries independent risks of atrioventricular block requiring permanent pacemaker (PPM), aortic insufficiency, and cerebrovascular accident (CVA). Garcia et al\textsuperscript{29} more recently studied forgoing pre-TAVR BAV with the SAPIEN XT THV. In this small study, 10 patients with moderate calcification, homogenous distribution of calcium, symmetric opening of the valve, and some degree of aortic insufficiency as defined by TEE underwent SAPIEN XT valve placement without antecedent BAV. No patients were found to merit need for postdilation, and PVR was classified as none or trivial in all patients.\textsuperscript{29} TAVR without predilation thus appears to be a feasible technique with potential benefits but has not yet been investigated comprehensively.

Undersizing of the valve, which may be unavoidable given limited size availability of current platforms, or valve underexpansion can result in PVR or device migration. The impetus to avoid PVR after valve deployment needs to be balanced with the risk of annular rupture with postdilation. Barbanti et al\textsuperscript{30} studied 31 patients receiving balloon-expandable valves who experienced rupture and compared them to a group of matched controls to define predictors of rupture. These included subannular/left ventricular outflow tract calcification, annular area oversizing ≥20\%, and balloon postdilation. Figure 43-1, adapted from Barbanti et al,\textsuperscript{30} shows case examples of 2 patients demonstrating the interplay of these variables on clinical outcome. As a potential modification, a routine strategy of initial underexpansion of the valve and subsequent postdilation when deemed necessary showed potential in reducing the risk of annular injury and PVR in selected patients.\textsuperscript{31}
FIGURE 43-1 Annular area oversizing and left ventricular outflow tract (LVOT) calcification and the risk of annular rupture. Case examples of 2 patients who underwent transcatheter aortic valve replacement (TAVR) with a 26-mm (A, B) and a 23-mm (C, D) SAPIEN XT valve. In these cases, significant annular area oversizing (27.9% and 38.5%, respectively) resulted in different outcomes. The case shown in panels A and B (multidetector computed tomography double-oblique transverse and coronal projections, respectively) with severe LVOT calcification (white arrow) experienced annular rupture during TAVR complicated by procedural death. The second case (C and D) displays an absence of LVOT calcification, and despite comparable prosthesis oversizing, this patient underwent an uneventful TAVR. (Reproduced from Barbanti M, Yang TH, Rodes Cabau J, et al. Anatomical and procedural features associated with aortic root rupture during balloon-expandable transcatheter aortic valve replacement. Circulation. 2013;128:244-253. Copyright © American Heart Association, Inc. All rights reserved.)

With pre- and postdilation, as well as dilation during deployment, the
importance of rapid ventricular pacing, most frequently with a temporary ventricular pacemaker advanced via the internal jugular or femoral veins, cannot be understated. To provide the least amount of movement during valve deployment and the most reliable positioning of a pre- or postdilation balloon, rapid ventricular pacing provides, in effect, ventricular standstill and prevents unnecessary and unpredictable movement during these critical maneuvers.

**MULTIMODALITY IMAGING**

Multimodality imaging appears essential for procedural guidance during TAVR and has been incorporated in consensus statements, reviews, and guidelines. The goals of imaging during implantation incorporate achieving the best prosthesis-patient match, assessing valve position and function before and after deployment, and identifying immediate complications. The annular plane can be identified by preimplantation CT scan or angiography, but can also be assessed via intraprocedural rotational angiography with rapid pacing and subsequent CT reconstruction. This latter technique involves contrast opacification and is thus riskier in patients with advanced renal disease. Assessment of the annular plane is essential to appropriate valve positioning because “off-axis” annulus determinations may increase the risk of malaposition and PVR. Intraprocedural TEE can provide a real-time biplane assessment of the annulus during deployment, thus fostering precise valve positioning and prediction as well as detection of PVR and other complications, including coronary artery obstruction, annular rupture, pericardial tamponade, severe mitral regurgitation, aortic dissection, and left ventricular pseudoaneurysm. This form of imaging becomes even more valuable in the setting of lower profile balloon-expandable delivery systems, which incorporate a significant element of foreshortening on valve deployment, meriting judicious positioning and repositioning. TEE also provides an assessment of coaxiality and shows the tips of the native leaflets to ensure stent coverage of the native aortic valve. TEE likely mandates general sedation and endotracheal intubation, which may introduce risk in patients who are hemodynamically unstable or have underlying severe lung disease.

The motivation to eliminate the need for general anesthesia has led to an
increasing interest in intracardiac echocardiography (ICE) imaging. However, single-plane ICE imaging cannot accurately visualize the oval annulus, and a single-plane annular dimension, such as that provided by transthoracic echocardiography, does not provide comprehensive assessment of annular size. Coronary heights cannot be reliably measured due to the limited intracardiac planes of imaging and atrial catheter position. Because of significant acoustic shadowing of the valve after deployment, PVR may not be reliably assessed with ICE. This form of imaging holds further promise to ascertain valve positioning once newer 3-dimensional ICE catheters are developed, although acoustic shadowing may still be a limitation to this modality. Appropriate valve positioning is best performed with multimodality assessment, although considerations inherent to the clinical context may limit use of certain imaging modalities.

**DIAGNOSING AND MANAGING COMPLICATIONS**

**Paravalvular Regurgitation**

The 2-year follow-up to PARTNER cohort A showed that TAVR resulted in significantly worse PVR than SAVR, with >50% of TAVR patients having at least mild PVR after the procedure. Moreover, even mild PVR after TAVR was associated with a 10% to 15% higher mortality at 2 years than procedures resulting in trace or less PVR (Fig. 43-2). This finding was confirmed in an analysis of 2270 patients from the PARTNER trial and its registries, which demonstrated a stepwise increase in mortality with none to trace, mild, and moderate to severe PVR. What remains unknown is whether PVR is causative or simply associated with higher mortality due to unidentified confounding variables. This study demonstrated that moderate or severe PVR resulted in hemodynamic effects on the left ventricle with increases in left ventricle volume size compared to those without significant PVR. This same effect was not seen with mild PVR, suggesting that the increase in mortality may not be causative. Also, it is uncertain whether PVR as a prognostic entity and its associated adverse outcomes are particular to balloon-expandable systems because trials with self-expanding systems have
not demonstrated the same effects of mild PVR.\textsuperscript{2,37} However, there are many factors that make the assessment of PVR and its impact challenging, including the variable echocardiographic grading of PVR across studies. Trial data from newer generations of existing devices, including their expansion into lower risk profiles, and the implementation of other device systems should further elucidate the significance of PVR. The SAPIEN 3 THV employs the use of an external sealing cuff at the bottom of the stent frame to reduce the incidence of PVR. A small study of 27 patients compared the incidence of PVR between the SAPIEN 3 THV and the previous generation SAPIEN XT THV. Although the mean residual gradient and effective orifice area were similar in both groups, the need for postdilation and the incidence of PVR were greater with the SAPIEN XT THV (≥mild: 42%; moderate: 8%) than with the SAPIEN 3 THV (≥mild: 7%; moderate: 0%; \(P = .002\) for ≥mild vs SAPIEN XT THV). A prospective multicenter study involving 150 patients with severe symptomatic AS of intermediate or high risk who underwent TAVR with the SAPIEN 3 THV demonstrated low rates of significant PVR (moderate PVR 3.5%, severe PVR 0%) at 30 days.\textsuperscript{38} Rates of moderate or severe PVR were very low for both high-risk and intermediate-risk patients in the 30-day outcomes of the PARTNER II SAPIEN 3 THV registries (2.9% and 4.2%, respectively).\textsuperscript{15} Further study will elaborate the clinical significance of PVR. In the interim, expertise in multimodality imaging to achieve the best valve size and position is essential to minimize PVR.
FIGURE 43-2 Relation of aortic regurgitation to all-cause mortality in the transcatheter aortic valve replacement (TAVR) as-treated population of the Placement of Aortic Transcatheter Valves (PARTNER) trial. In this analysis by Kodali et al,\textsuperscript{35} paravalvular leak of mild or greater severity (A, B) and total aortic regurgitation (C, D) were related to higher all-cause mortality. (Reproduced from Kodali SK, Williams MR, Smith CR, et al. Two-year outcomes after transcatheter or surgical aortic-valve replacement. \textit{N Engl J Med}. 2012;366:1686-1695. Cerebrovascular Accident

CVA in the setting of TAVR remains a major peri- and postprocedural complication manifesting in a significant quality of life detriment and increased mortality. About half of these events following TAVR occur within
the first 24 hours after the procedure, and mechanical factors such as valve embolization, multiple valve positioning attempts, and balloon postdilation have been identified as predictors of these acute events, whereas other factors such as atrial fibrillation have been associated with a higher rate of subacute (>24 hours) events. In an analysis by Kahlert et al, high-intensity transient signals on transcranial Doppler evaluation, deemed to be a surrogate for microembolization, were more frequent during positioning of the balloon-expandable THV when compared with other aspects of the procedure.

Several magnetic resonance imaging studies have shown that the rate of silent cerebral embolism may approach 80% in patients after TAVR. Van Mieghem et al confirmed the hypothesis of procedure-related embolism, noting 75% of TAVR procedures resulted in capture of debris when a filter-based embolic protection device was used. However, a meta-analysis of >10,000 patients in 53 studies confirmed that TAVR results in an acceptable periprocedural stroke rate of 1.5% and a 30-day CVA/transient ischemic attack rate of 3.3%. Thus, whether capturing periprocedural debris translates into a clinical benefit remains uncertain at this time.

Risk stratification for CVA based on patient characteristics is essential in defining who would likely benefit from cerebral embolic protection devices, as well as for tailoring postprocedural management (eg, surveillance for postprocedural atrial fibrillation). No study to date has identified any effect of valve type (balloon-expandable vs self-expandable) on TAVR stroke rate. Although initially rates of stroke with TAVR were noted to be higher when compared with SAVR, subsequent randomized trials have noted no difference in 30-day stroke rates. In fact, the emergence of TAVR and the rigorous clinical trials associated with its development have highlighted the importance of neurologic oversight when assessing stroke risk after any procedure. A recent study demonstrated that stroke rates following SAVR might be more than doubled when assessed by a neurologist.

Vascular Events and Bleeding

In an analysis performed from PARTNER data, Genereux et al reported that 15.3% of PARTNER high-risk and inoperable patients experiencing Valve Academic Research Consortium (VARC) major vascular complications had significantly higher rates of 30-day and 1-year mortality.
In this analysis, the only identifiable independent predictor of major vascular complications was female sex (hazard ratio, 2.31; \( P = .03 \)). Major vascular complications are an independent predictor of major bleeds, which were found to be the strongest independent predictor of 1-year mortality in PARTNER cohort A, although there was a much more significant prognostic impact in the SAVR arm. In an analysis by Hayashida et al, VARC major vascular complications increased 30-day mortality and were predicted by low procedural experience, femoral calcification, and sheath-to-femoral artery ratio greater than 1.05. As mentioned previously, 1-year data from PARTNER IIB showed a reduction in major vascular complications, from 15.5% to 9.6% \( (P = .04) \), with the lower profile SAPIEN XT delivery system. As it pertains to the TF approach, reduction in vascular and bleeding events is dependent on appropriate radiographic and angiographic screening of access and development of lower profile valve delivery systems, in addition to implementation of advanced percutaneous closure techniques. With newer generation valve delivery systems, using 14- to 18-Fr sheaths, the risk of vascular complications has been shown to drop below 5%.

**Conduction Abnormalities**

The difference in the PPM implantation rate between the balloon-expandable SAPIEN valve and self-expanding CoreValve (Medtronic, Dublin, Ireland), quantified as 6.5% with SAPIEN versus 25.8% with CoreValve \( (P < .001) \) in a large meta-analysis, was confirmed in the US CoreValve Pivotal Trial Extreme Risk cohort results. In this trial, CoreValve was associated with a rate of PPM implantation of 22.2% at 30 days and 27.1% at 1 year. In an analysis of PARTNER outcomes, Nazif and colleagues showed predictors of PPM implantation with balloon-expandable valves to include preexisting right bundle branch block, the ratio of prosthesis diameter to left ventricular outflow tract diameter, and left ventricular end-diastolic dimension. In this study, at 1 year, PPM implantation was associated with significantly higher mortality or repeat hospitalization \( (42.0\% \text{ vs } 32.6\%; \ P = .007) \).

In a separate analysis of PARTNER outcomes, Nazif et al reported that persistent, new-onset left bundle branch block occurred in 10.5% of TAVR patients with normal baseline conduction. This finding did not increase all-cause mortality, as it had in a retrospective study, but was associated with a
higher rate of PPM implantation and failure of improvement in left ventricular ejection fraction (Fig. 43-3). Device-related factors, such as the depth of the device implant in the left ventricular outflow tract and the continuous radial force exerted by self-expanding valves upon deployment, appear to predispose TAVR patients to conduction abnormalities. Use of real-time multimodality imaging is warranted in order to curtail the frequency of this adverse outcome, although device modification is necessary given the health and economic ramifications of high PPM incidence after TAVR.

**FIGURE 43-3** Post–transcatheter aortic valve replacement (TAVR) left bundle branch block (LBBB) and evolution of left ventricular ejection fraction (LVEF). In this analysis of patients undergoing TAVR in the Placement of Aortic Transcatheter Valves (PARTNER) trial and continued access registry, Nazif et al. studied the impact of a new LBBB on clinical outcomes. The evolution of LVEF over time is shown for (A) the overall population and stratified by baseline left ventricular function: (B) LVEF < 35%, (C) LVEF 35% to 50%, and (D) LVEF 50%. This demonstrates a lack of improvement in LVEF with development of LBBB after TAVR and is most marked in patients with the lowest baseline LVEF (B). (Adapted
Other post-TAVR conduction abnormalities, such as atrial tachycardia and atrial fibrillation, have also been associated with increased morbidity. In an analysis by Urena et al.,\textsuperscript{58} in patients without known atrial fibrillation or atrial tachycardia before the procedure, the occurrence of these arrhythmias during a 24-hour electrocardiogram recording after TAVR was associated with a significantly higher rate of 30-day cerebrovascular events (7.1% vs 0.4%; \( P = .03 \)).

\textbf{Coronary Occlusion}

A rare, but potentially fatal, consequence of balloon-expandable THV implantation is coronary occlusion. The risk of this particular complication is usually adequately assessed with preprocedural multidetector CT or TEE, which would evaluate the height of the coronary ostia from the annular plane and the width of the sinus of Valsalva. In a large multicenter registry of over 6000 patients, of whom 44 had symptomatic coronary occlusion after TAVR, mean coronary ostial heights (10.6 ± 2.1 mm vs 13.4 ± 2.1 mm; \( P < .001 \)) and sinus of Valsalva diameters (28.1 ± 3.8 mm vs 31.9 ± 4.1 mm; \( P < .001 \)) were lower in patients with obstruction than in control subjects.\textsuperscript{59} In this analysis, 30-day mortality with coronary occlusion during TAVR was 40.9%. In borderline cases, morbidity may decrease with preemptive wiring of a susceptible coronary artery and potentially positioning of an undeployed stent in the coronary artery at risk, which could then be deployed against the stent frame of the balloon-expandable THV to ensure adequate coronary flow. Finally, predilation under TEE guidance may also add to the risk assessment of coronary occlusion, through visualization of calcium in the annular apparatus or native leaflet moving close to the ostium of a susceptible coronary artery upon balloon inflation.

\textbf{OTHER BALLOON-EXPANDABLE THV SYSTEMS}
The Innovare balloon-expandable system (Braile Biomedica, Sao Jose do Rio Preto, Brazil) consists of a trileaflet bovine pericardial valve mounted in a cobalt-chromium stent frame, is implanted transapically, and is available in 4 sizes: 20, 22, 24, and 26 mm. A feasibility study of 33 patients showed an implantation success rate of 91%. The 30-day and 1-year mortality rates were 18.2% and 39.5%, respectively. The valve hemodynamics at hospital discharge showed some degree of aortic insufficiency in 10 patients, and the peak and mean gradients at 1-year follow-up were 21.3 ± 12.4 mm Hg and 10.5 ± 6.9 mm Hg, respectively.

Another balloon-expandable THV anticipated to undergo feasibility study is the Colibri THV (Colibri Heart Valve, Broomfield, CO). This is a 14-Fr premounted, precrimped, and prepackaged ready-for-use TAVR system. The valve is made of 3 independent pieces of porcine pericardium, which are created using a unique folding method and then sewn into a stainless steel laser-cut frame. Besides the low profile of this system, the unique feature of this valve is that it is stored dry in a crimped state and the valve can be used directly off the shelf in a manner similar to coronary stents.

**CONCLUSIONS**

Since the inception of TAVR, balloon-expandable THVs have been at the forefront of technological development and large-scale clinical trials impacting the field. The PARTNER trial has shown the superiority and noninferiority of TAVR with the balloon-expandable Edwards SAPIEN THV compared to medical treatment in inoperable patients and SAVR in high-risk patients, respectively. There have been excellent long-term hemodynamic results after implantation of balloon-expandable THVs, although residual PVR may be a poor prognostic sign and merits modification of the technology. Identification of these adverse clinical events, made apparent through large randomized clinical trials, has led to the development of the SAPIEN 3 THV, which has been designed to reduce PVR and has a lower profile delivery system than its predecessors, facilitating TF access for a larger portion of TAVR patients. The improved safety and efficacy of balloon-expandable systems will allow their incorporation into the treatment of lower risk populations and through less invasive means.

Clinical Outcomes With Self-Expanding Transcatheter Aortic Valve Bioprostheses

Jeffrey J. Popma

Since the introduction of the 18-Fr CoreValve self-expanding transcatheter aortic valve replacement (TAVR), over 70,000 implants have been performed worldwide. The use of this self-expanding bioprosthesis has provided an alternative to surgery in patients who are suboptimal for conventional surgical aortic valve replacement and has resulted in improved survival and quality of life for thousands of patients worldwide. There are a number of potential advantages of a self-expanding bioprosthesis over alternative transcatheter designs, including the progressive self-expansion of the inflow frame reducing the degree of paravalvular regurgitation (PVR) over time; supra-annular location of the porcine pericardial valve, which improves hemodynamics and potentially improves long-term durability; and large cell diameter, which provides access to coronary arteries after implantation.

The purposes of this chapter are to review the CoreValve self-expanding frame design and newer iterations of the self-expanding prosthesis, discuss the clinical evidence for use of the self-expanding devices in an expanding population, and outline the risks and benefits of this device in patients with aortic stenosis.
COREVALVE SELF-EXPANDING BIOPROSTHESIS

The CoreValve System consists of 3 components: a transcatheter bioprosthesis, the delivery catheter system, and the compression loading system. The transcatheter bioprosthesis is composed of a self-expanding nitinol frame that supports a trileaflet porcine pericardial valve available in 23-, 26-, 29-, and 31-mm diameters that treat an annulus range from 18 to 29 mm (Fig. 44-1). The inflow portion of the frame is designed to conform to the annulus and to stabilize the frame at the annular location. The lowest 12 mm of the frame contains a porcine pericardial skirt to seal the annulus. The valve is located in a supra-annular position at the waist (constrained portion) of the valve frame. The outflow portion of the valve frame is constructed to support the valve commissures and orient the frame to facilitate laminar flow. All valve sizes are delivered using an 18-Fr catheter delivery system. The valve is deployed without rapid pacing and is partially repositionable until annular contact with the transcatheter heart valve (THV) is made. The CoreValve bioprosthesis has now been replaced commercially with the Evolut R transcatheter system (see below), which allows repositioning of the valve if the initial deployment is suboptimal.
EARLY COREVALVE REGISTRIES

Early European registries between 2007 and 2010 demonstrated the value of self-expanding transcatheter replacement in patients who were not optimal candidates for surgical valve replacement, but transcatheter replacement was limited by 2-dimensional echocardiographic-based valve sizing, the availability of only 26- and 29-mm sizes, and delivery systems that had high friction, resulting in forward movement into the ventricle of the device with deployment. In the initial CE Mark series, 126 patients (mean age, 82 years; 42.9% male; mean logistic European System for Cardiac Operative Risk Evaluation score [EuroSCORE], 23.4%) with severe aortic valve stenosis underwent treatment with the CoreValve self-expanding bioprosthesis. The
Overall technical success rate was 83.1%, and the 30-day mortality rate was 15.2%, without significant differences in the subgroups. All-cause mortality at 2 years was 38.1%, and the mean aortic valve gradients remained unchanged from 30 days (8.5 ± 2.5 mm Hg) to 2 years (9.0 ± 3.4 mm Hg). There was no incidence of structural valve deterioration in this early series. The major limitations of these early series were postprocedural PVR (10%-15%) and high rates of conduction system disorders resulting in relatively high permanent pacemaker implantation rates (20%-40%).

The European Advance Registry included 1015 patients at high risk for surgical aortic valve replacement with an age of 81 ± 6 years and mean logistic EuroSCORE of 19.4% ± 12.3%. Self-expanding TAVR resulted in a 30-day all-cause mortality of 4.5%, rate of stroke of 3.0%, and life-threatening or disabling bleeding rate of 4.0%. The 12-month rates of all-cause mortality were 11.1%, 16.5%, and 23.6% among patients with a logistic EuroSCORE ≤ 10%, EuroSCORE of 10% to 20%, and EuroSCORE > 20% (P < .05), respectively. At 3 years, the Society of Thoracic Surgeons Predicted Risk of Mortality (STS PROM) ≤7% group had a lower rate of all-cause mortality (28.6% compared with 45.9% in patients with an STS >7%; P < .01). In patients with STS PROM ≤7%, mortality at 3 years was higher in those with moderate or severe aortic regurgitation at discharge than in those with mild or less aortic regurgitation (39.9% vs 22.9%, respectively; P < .01).

The Italian CoreValve Registry reported the 5-year outcomes after self-expanding TAVR. The all-cause mortality rate was 55.0% at 5 years, and the overall neurologic event rate was 7.5%. Rehospitalization occurred in 46% patients, most of which (42.7%) were due to acute heart failure. Importantly, mean transaortic gradients remained low 5 years later (12.8 ± 10.9 mm Hg). Late prosthesis failure occurred in 5 cases (1.4%); among these, redo TAVR was successfully carried out in 2 patients (0.6%). The remaining 3 cases of prosthesis failure did not undergo additional invasive interventions. Ten patients (2.8%) showed late mild stenosis with a mean transaortic gradient ranging from 20 to 40 mm Hg. No other cases of structural or nonstructural valvular deterioration were observed.
The US CoreValve Extreme Risk and High Risk Pivotal Trial and Registries were performed to evaluate the safety and efficacy of the CoreValve bioprosthesis in patients with severe aortic stenosis. This portfolio of studies evaluated patients who were deemed extreme risk or high risk for surgery by a local heart team and included both pivotal trials and continued access and expanded use registries.

**CoreValve US Extreme Risk Study**

Given the lack of clinical equipoise for subsequent randomized study in patients without surgical options, the CoreValve US Pivotal Study was a prospective, multicenter, nonrandomized investigation that included 489 patients with severe aortic stenosis who were deemed at extreme risk for surgery, defined as a ≥50% predicted 30-day mortality or irreversible morbidity at 30 days. The primary end point was a composite of all-cause mortality or major stroke at 12 months and was compared with a prespecified objective performance goal. The rate of all-cause mortality or major stroke at 12 months was 26.0%, compared with a 43.0% performance goal ($P < .0001$). Individual 30-day and 12-month events included all-cause mortality (8.4% and 24.3%, respectively) and major stroke (2.3% and 4.3%, respectively). The frequency of moderate or severe PVR was lower 12 months after self-expanding TAVR (4.2%) than at discharge (10.7%; $P = .004$ for paired analysis).

The benefits of self-expanding TAVR in extreme-risk patients were sustained at 2 years; the rate of all-cause mortality or major stroke was 38.0% (all-cause mortality, 36.5%; major stroke, 5.1%). Multivariable predictors of all-cause mortality at 2 years included the presence of coronary artery disease and admission from an assisted living center (Fig. 44-2). An STS PROM >15% was also predictive of 2-year all-cause mortality. The frequency of moderate or severe PVR (4.3% at 1 year; 4.4% at 2 years) was unchanged between the first and second years. These findings further reinforce that 2-year clinical outcomes are determined by comorbid conditions rather than
valve performance in these complex patients.\textsuperscript{9}

Clinical outcomes after self-expanding TAVR using an alternative access approach were also evaluated in the CoreValve US Extreme Risk Study. Reardon et al\textsuperscript{10} evaluated 150 patients with prohibitive iliofemoral anatomy who were treated with the CoreValve THV delivered by way of the subclavian artery (n = 70) or a direct aortic approach (n = 80). The preoperative aortic valve area was 0.72 ± 0.27 cm\textsuperscript{2}, and mean aortic valve gradient was 49.5 ± 17.0 mm Hg.\textsuperscript{10} After the TAVR, the effective aortic valve area was 1.82 ± 0.64 cm\textsuperscript{2} at 1 month and 1.85 ± 0.51 cm\textsuperscript{2} at 12 months.\textsuperscript{10} The mean aortic valve gradient was 9.7 ± 5.8 mm Hg at 30 days and 9.5 ± 5.7 mm Hg at 12 months.\textsuperscript{10} The primary end point was all-cause mortality or major stroke at 12 months and occurred in 15.3% of patients at 30 days and 39.4% at 12 months.\textsuperscript{10} The individual rates of all-cause mortality and major stroke were 11.3% and 7.5% at 30 days and 36.0% and 9.1% at 12 months, respectively.\textsuperscript{10} These data show that the CoreValve THV delivered by an alternative access provides a suitable alternative for treatment of extreme-risk patients with symptomatic severe aortic stenosis who have prohibitive iliofemoral anatomy and no surgical options. Three-dimensional access planning and real-time image guidance for direct aortic access TAVR may be facilitated using co-registration of multidetector computed tomography (CT) and noncontrast DynaCT image co-registration.\textsuperscript{11}

TAVR with a self-expanding bioprosthesis resulted in substantial
improvements in both disease-specific and generic health-related quality of life in extreme-risk patients, but there remained a large minority of patients who died or had very poor quality of life despite TAVR. In a detail health status analysis that evaluated 436 patient who were extreme risk for surgery, there was substantial improvement in both disease-specific and generic health status measures, with an increase in the Kansas City Cardiomyopathy Questionnaire Overall Summary Score (KCCQ-OS) of 23.9 points at 1 month, 27.4 points at 6 months, and 27.4 points at 12 months (P < .003 compared with baseline). A large minority of patients (39%) had a poor outcome after TAVR that was predicted by the presence of being wheelchair dependent or having a lower mean aortic valve gradient, prior coronary artery bypass grafting, oxygen dependency, or very high predicted mortality with surgical aortic valve replacement, and low serum albumin.

**CoreValve US High-Risk Pivotal Trial**

The CoreValve High-Risk Pivotal Trial enrolled patients deemed to be at elevated surgical risk. Two cardiac surgeons and 1 interventional cardiologist at each site needs to confirm the estimated 30 days surgical mortality or irreversible morbidity to be >15%. Because of the limitations of the standard STS PROM, additional non-STS factors, such as severe comorbidity, frailty, and disability, were also considered in the assessment of surgery risk. A total of 795 patients were randomly assigned in a 1:1 fashion to self-expanding TAVR or surgical aortic valve replacement. The primary end point, the rate of death from any cause at 1 year in the as-treated population, was significantly lower in TAVR patients than in surgery patient (14.2% vs 19.1%, respectively), with an absolute reduction in risk of 4.9 percentage points (upper boundary of the 95% confidence interval [CI], –0.4; P < .001 for noninferiority; P = .04 for superiority).

Hemodynamic differences between self-expanding transcatheter and surgical bioprostheses were found in the CoreValve US High-Risk Clinical Study. Compared with surgery patients, TAVR patients had a lower mean aortic valve gradient, larger valve area, and less patient-prosthesis mismatch (all P < .001), but more PVR at discharge, which decreased at 1 year. Surgery patients experienced a significant right ventricular systolic dysfunction at discharge and 1 month, with normal right ventricular function
Preimplantation aortic regurgitation rated as mild or worse was associated with reduced mortality hazard for both the TAVR patients (hazard ratio [HR], 0.48; 95% CI, 0.27-0.85; \( P = .01 \)) and the surgery patients. Aortic regurgitation rated as mild or worse after TAVR was associated with increased risk for all-cause mortality (HR, 1.95; 95% CI, 1.08-3.53; \( P = .03 \)). This benefit was consistent along a broad array of patient subsets (Fig. 44-3).

![FIGURE 44-3 Outcomes of patient subsets with self-expanding transcatheter aortic valve replacement (TAVR) and surgery. Subgroup analysis for the rate of death from any cause at 1 year: The survival benefit with TAVR was consistent across 9 clinical subgroups. The percentage of patients with an event represents the Kaplan-Meier event rate at 1 year. Horizontal lines indicate 95% confidence intervals (CIs). The body mass index is the weight in kilograms divided by the square of the height in meters. The Society of Thoracic Surgeons Predicted Risk of Mortality (STS PROM) provides an estimate of the rate of death at 30 days among patients undergoing surgical aortic valve replacement on the basis of a number of demographic and procedural variables. CABG, coronary artery bypass grafting.](From Adams DH,)

Kaul\textsuperscript{17} provided an overview of the benefit-risk analysis of the CoreValve US Pivotal Trial suggesting an overall net benefit of self-expanding TAVR in these patients (Fig. 44-4).

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{figure44-4.png}
\end{figure}

Reardon et al\textsuperscript{18} reported the 2-year results of the CoreValve US High-Risk Pivotal Trial and found that the rate of 2-year all-cause mortality was significantly lower in the TAVR group (22.2\% vs 28.6\% in the surgery group; log-rank $P < .05$), with an absolute reduction in risk of 6.5 percentage points. Importantly, the rate of death or major stroke at 2 years was significantly lower in the TAVR patients (24.2\% vs 32.5\% in surgery patients; log-rank $P = .01$).\textsuperscript{18} The hemodynamic (Fig. 44-5) and clinical
beneficial effect of TAVR over surgery was maintained at 3 years after the procedure.\textsuperscript{19}

![Diagram showing hemodynamic of self-expanding transcatheter aortic valve replacement (TAVR) versus surgery at 3 years. Reduction in aortic valve (AV) mean gradient and increased AV area are maintained through 3 years. Data reported on the basis of site-reported echocardiographic findings in patients with echocardiographic measurements at all time points reported. Paired sets of mean AV gradient data were available for 174 TAVR and 113 surgical aortic valve replacement (SAVR) patients; AV area was available for 126 TAVR and 85 SAVR patients. TAVR was associated with significantly lower gradients and larger aortic valve areas at each time point (all $P < .05$). (Reprinted from Deeb GM, Reardon MJ, Chetcuti S, et al. 3-Year outcomes in high-risk patients who underwent surgical or transcatheter aortic valve replacement. \textit{J Am Coll Cardiol.} 2016;67:2565-2574, Copyright © 2016, with permission from American College of Cardiology Foundation.)

Overall stroke rates are lower in patients undergoing TAVR than patients undergoing surgery.\textsuperscript{20} The 30-day, 1-year, and 2-year stroke rates were 4.9%, 8.7%, and 10.9%, respectively, for TAVR and 6.2%, 12.5%, and 16.6%, respectively, for surgical aortic valve replacement ($P = .46$, .11, and .05, respectively).\textsuperscript{20} The impact of stroke was profound, with an all-cause mortality in TAVR patients with a major stroke of 83.3% and in surgery patients of 54.5% ($P = .29$).\textsuperscript{20} Late major stroke was disproportionately
higher (23.8% at 2 years) among patients with poor iliofemoral access randomized to surgery. Predictors of early stroke included peripheral vascular disease and falls within 6 months, and late strokes were predicted by severe aortic calcification and high Charlson scores. Lack of dual antiplatelet therapy use during and after TAVR was associated with early stroke.

**Prosthesis-Patient Mismatch**

Another potential reason for the benefit of TAVR over surgery is superior hemodynamics in the TAVR group, understanding that the frequency of patient-prosthesis mismatch (PPM) is higher in patients undergoing surgery than TAVR. In an analysis of patients enrolled in the US High-Risk Pivotal Trial randomized to TAVR or surgery, patients were characterized as having severe PPM, defined as an effective orifice area index (EOAi) ≤0.65 cm²/m², or no PPM, defined as an EOAi >0.65 cm²/m². The incidence of severe PPM in the surgery group at 1 year was 25.7% compared with 6.2% in the TAVR group (P <.0001). At 1 year, the rates of all-cause mortality and acute kidney injury were significantly greater in patients with severe PPM compared with no severe PPM (20.6% vs 12.0% [P = .0145] for death; Fig. 44-6; and 19.2% vs 8.5% [P = .0008] for acute kidney injury, respectively). These findings demonstrate that severe PPM is more common in patients treated with surgery than those treated with TAVR and that patients with severe PPM are a greater risk for death and acute kidney injury than patients without severe PPM.

**Cost-Effectiveness Analysis**

A health status evaluation in patients enrolled in the CoreValve US Pivotal Trial found that health status improved substantially in surviving patients who were treated with either self-expanding TAVR or surgery.\(^{22}\) TAVR via the iliofemoral route was associated with better early health status compared with surgery.\(^ {22}\) In this analysis, among surviving patients eligible for iliofemoral access, there was a clinically relevant early benefit with self-expanding TAVR across all disease-specific and generic health status measures.\(^ {22}\) Among the alternative access cohort, however, most health status measures were similar for TAVR and surgery.\(^ {22}\) There were no consistent differences in health status between TAVR and surgery at the later time points.\(^ {22}\)

Reynolds et al\(^ {23}\) performed a formal economic analysis in patients enrolled in the CoreValve US High-Risk Pivotal Trial using empirical data
regarding survival and quality of life and medical resource use and hospital costs through 12 months. Relative to surgery, TAVR reduced initial length of stay an average of 4.4 days, decreased the need for rehabilitation services at discharge, and resulted in superior 1-month quality of life. In contrast, index admission and projected lifetime costs were higher with TAVR than with surgery ($Δ$ $11,260 and $17,849 per patient, respectively). TAVR provided a lifetime gain of 0.32 quality-adjusted life-years. Lifetime incremental cost-effectiveness ratios were $55,090 per quality-adjusted life-year gained and $43,114 per life-year gained. Sensitivity analyses indicated that a reduction in the initial cost of TAVR by approximately $1650 would lead to an incremental cost-effectiveness ratio <$50,000 per quality-adjusted life-year gained.

SPECIFIC PATIENT AND ANATOMIC SUBSETS

The benefits of self-expanding TAVR were examined in a number of patient subsets.

Female Sex

Despite a higher cardiovascular risk profile in men, studies have not shown differences in outcomes after self-expanding TAVR between men and women. Forrest et al compared the clinical outcomes in women and men in 3687 patients (1708 women and 1979 men) enrolled in the CoreValve US Pivotal Trials and Registries. Women tended to be slightly older and to have more frailty, but fewer cardiac comorbidities, higher left ventricular systolic function, less coronary artery disease, and fewer previous strokes. All-cause mortality was 5.9% for women and 5.8% for men at 30 days ($P = .87$) and 24.1% and 21.3%, respectively, at 1 year ($P = .08$). Similarly, the incidence of stroke was 5.7% in women and 4.0% in men at 30 days ($P = .02$) and 9.3% and 7.7%, respectively, at 1 year ($P = .05$). Women had a higher incidence of bleeding, including more life-threatening bleeds, and a greater incidence of major vascular complications than men at 30 days.

In women at increased risk for surgery, women treated with self-
expanding TAVR had better outcomes than women treated with surgery. Baseline characteristics and predicted risk were comparable in the 2 groups, although the frequency of diabetes mellitus was lower in patients undergoing TAVR (33.3% vs 45.3% in the surgery group; \( P = .02 \)) in the US High-Risk Pivotal Trial.\(^\text{26}\) One-year mortality was lower in TAVR patients (12.7% vs 21.8% in surgery patients; \( P = .03 \)).\(^\text{26}\) The composite all-cause mortality or major stroke rate was also lower in TAVR patients (14.9% vs 24.2% in surgery patients; \( P = .04 \); Fig. 44-7).\(^\text{26}\)

**Prior Coronary Artery Bypass Graft**

Patient with prior coronary artery bypass graft may benefit from self-expanding TAVR compared with repeat surgery. In an analysis of 226 patients with prior coronary artery bypass graft surgery enrolled in the CoreValve US High-Risk Trial, 1-year all-cause mortality was 9.6% for
TAVR versus 18.1% for surgical aortic valve replacement ($P = .06$); cardiovascular mortality was 7.0% for TAVR versus 13.8% for surgical aortic valve replacement ($P = .09$).$^{27}$ A combination of STS PROM risk score >7 and age >80 years was a significant predictor of mortality, with TAVR demonstrating a survival advantage ($P = .03$).$^{27}$ No differences were seen for stroke.$^{27}$ The surgical aortic valve replacement group had longer intensive care unit and hospital stays and increased incidence of acute kidney injury, life-threatening or disabling bleeding, and major adverse cardiac and cerebrovascular events ($P < .05$).$^{27}$

**Reduced Left Ventricular Function**

It is estimated that one-third of patients with symptomatic aortic stenosis have reduced left ventricular ejection fraction (LVEF) before TAVR. In an analysis by Dauerman et al,$^{28}$ 156 patients from the CoreValve US Extreme and High-Risk trials with LVEF ≤40% were evaluated. Early LVEF recovery was defined as an absolute increase of ≥10% in ejection fraction at 30 days.$^{28}$ One-year outcomes were compared between patients with and without early recovery.$^{28}$ Early LVEF recovery occurred in 62% of patients, generally before discharge. By 30 days, LVEF increased >17% compared with baseline in the early recovery group with minimal increase in the no early recovery group (48.9% ± 8.8% vs 31.5% ± 6.9%, respectively; $P < .001$).$^{28}$ One-year all-cause mortality was numerically (but not statistically) higher in the no early recovery group (24% vs 12%; $P = .07$). Absence of previous myocardial infarction and baseline mean gradient ≥40 mm Hg were identified as predictors of early LVEF recovery.$^{28}$

**High-Risk Surgical Patients With STS PROM <7%**

The CoreValve US Pivotal High-Risk Trial evaluated patients with an STS PROM of 7% or less who had nontraditional risk factors, including indices of frailty, disability, and comorbidities.$^{29}$ Two-year all-cause mortality was lower in patients treated with self-expanding TAVR (15%) than in patients treated with surgery (26.3%; log-rank $P = .01$). The 2-year rate of stroke was numerically but not statistically lower with self-expanding TAVR (11.3% vs 15.1% in surgery patients; log-rank $P = .50$).$^{29}$ Quality of life by the KCCQ-
OS showed significant and equivalent increases in both groups at 2 years.\textsuperscript{29} These findings suggest that self-expanding TAVR compares favorably with surgery in high-risk patients who were previously considered intermediate risk using traditionally risk scores.\textsuperscript{29}

**Self-Expanding TAVR for Surgical Valve Failure**

Proper positioning of the self-expanding bioprosthesis improves the hemodynamic result in patients undergoing TAVR in surgical valve failure.\textsuperscript{30} In an analysis of 292 consecutive patients, of whom 157 were treated to CoreValve Evolut, optimal implantation depth was defined as a depth of 0 to 5 mm. A high implantation was associated with a significantly lower rate of elevated gradients in comparison with low implantation (15% vs 34.2%, respectively; $P = .03$). Lower gradients were seen in patients treated with the CoreValve Evolut (vs balloon-expandable prostheses; $P = .02$) and regurgitation as the failure mode (vs stenosis/mixed etiologies; $P = .002$). There may be particular advantages of a supra-annular, self-expanding TAVR device in the subset of patients with surgical valve failure.

**Angulated or “Horizontal” Aortas**

An aortoventricular angle $>70^\circ$ has been an exclusion criterion for treatment with the CoreValve self-expanding TAVR. An analysis of 3578 patients with less severe angulation found no significant correlation in the frequencies of device success or procedural success, frequencies of moderate or greater aortic regurgitation at 30 days, number of valves implanted, or need for balloon after dilation or new pacemakers with increasing degrees of aortoventricular angulation (Fig. 44-8).\textsuperscript{31} These results have been attributed to the use of “best practice” techniques, such as use of co-planar aortography, alignment of the delivery catheter along the greater curvature of the aorta using stiffer guidelines (eg, SuperStiff Amplatz or Lunderquist 0.035-inch guide wires), stabilization of the delivery catheter using gentle forward force on the delivery catheter guide wire positioned in the left ventricular apex, alignment of the delivery catheter marker to allow visualization of the inflow of the prosthesis in a co-axial alignment, slow deployment and controlled annular contact to stabilize the valve frame, avoidance of deeper implantation by forward tension on the delivery guide wire and retraction on the catheter,
and careful assessment of the hemodynamic and echocardiographic results after deployment.\textsuperscript{31}

\begin{figure}
\centering
\includegraphics[width=\textwidth]{image}
\caption{Effect of aortoventricular angle and outcomes with self-expanding transcatheter aortic valve replacement (TAVR). A. A horizontal line is drawn in the coronal plane at the level of the annulus, and a second line is drawn along the axis of the aortic annulus. The 50° angle in this case is defined by the intersection of these 2 lines. B. Relationship of aortoventricular angulation and residual aortic regurgitation after TAVR. (Adapted from Zorn GL 3rd, Little SH, Tadros P, et al. Prosthesis-patient mismatch in high-risk patients with severe aortic stenosis: a randomized trial of a self-expanding prosthesis. \textit{J Thorac Cardiovasc Surg}. 2016;151:1014-1022, Copyright © 2016, with permission from The American Association for Thoracic Surgery.)}
\end{figure}

**Bicuspid Aortic Valve Disease**

Bicuspid aortic valve disease is a common cause of aortic stenosis in younger patients, and a number of classification systems have been proposed.\textsuperscript{32,33} Selection of the appropriate transcatheter size has been challenging in these patients.\textsuperscript{34} In a series of 139 patients with bicuspid valve disease, patients were treated with self-expanding and balloon-expandable TAVR.\textsuperscript{34} The patients had Sievers type 0 bicuspid disease in 26.7%, Sievers type 1 bicuspid disease in 68.3%, and Sievers Type 2 bicuspid disease in 5.0%.\textsuperscript{34}

Postimplantation aortic regurgitation grade >2 occurred in 28.4% of patients (19.6% balloon-expandable THV vs 32.2% self-expandable THV; \(P = .11\)) but was prevalent in only 17.4% when multislice CT (MSCT)-based transcatheter aortic valve sizing was performed (16.7% balloon-expandable THV vs 17.6% self-expandable THV; \(P = .99\)).\textsuperscript{34} MSCT sizing was
associated with reduced aortic regurgitation on multivariate analysis (odds ratio [OR], 0.19; 95% CI, 0.08-0.45; \( P < .0001 \)). \(^{34}\) Thirty-day device safety, success, and efficacy were noted in 79.1%, 89.9%, and 84.9% of patients, respectively, and 1-year mortality was 17.5%. \(^{34}\) Unique sizing algorithms may be useful in this subset of patients that incorporate a supra-annular measurement of sinus dimensions that allows appropriate sizing of the prosthesis in patients with bicuspid aortic valve disease.

### Aortic Regurgitation

A number of series have evaluated the outcome of patients undergoing TAVR of severe aortic regurgitation. \(^{35,36}\) In a series of 43 patients who underwent self-expanding TAVR for native valve aortic regurgitation, eight patients (18.6%) required a second valve during the index procedure for residual aortic regurgitation; notably, all second valves were required in patients without valvular calcification. \(^{36}\) Postprocedure aortic regurgitation grade 1 or lower was present in 34 patients (79.1%). At 30 days, the major stroke incidence was 4.7%, and the all-cause mortality rate was 9.3%. \(^{36}\) At 12 months, the all-cause mortality rate was 21.4% (6 of 28 patients). \(^{36}\) In another series of 26 patients (1.6%) who presented with aortic regurgitation, patients with aortic regurgitation were significantly younger, more frequently had New York Heart Association Class III/IV heart failure, and had a higher incidence of severe pulmonary hypertension compared with patients with aortic stenosis. Valve Academic Research Consortium-2 (VARC-2)–defined device success was lower in the aortic regurgitation group (79% vs 96%; \( P = .006 \)). \(^{37}\) At 1 month, patients treated for aortic regurgitation had a higher overall mortality (23% vs 5.9%; OR, 4.22; 95% CI, 3.03-8.28; \( P < .001 \)) and cardiac mortality (15.3% vs 4%; OR, 4.01; 95% CI, 2.40-7.66; \( P < .001 \)). Results were consistent at 12 months (overall mortality: 31% vs 19%; HR, 2.1; 95% CI, 1.5-4.41; \( P < .001 \); and cardiac mortality: 19.2% vs 6%; HR, 3.1; 95% CI, 2.09-8.22; \( P < .001 \)). \(^{37}\) Self-expanding TAVR in patient with aortic regurgitation may be considered when there are limited surgical options.

**PREDICTING OUTCOMES WITH SELF-**
EXPANDING TAVR

Due to the limitations of conventional risk scores in predicting outcome with TAVR, the CoreValve US Pivotal Trial and Registries examined the importance of nonconventional risk factors, including frailty, disabilities, and comorbidities. In an analysis of 3687 patients treated with self-expanding TAVR, patients were divided 2:1 into derivation and validation cohorts. The overall mortality rate was 5.8% at 30 days and 22.8% at 1 year. Thirty-day mortality was predicted by home oxygen use, assisted living, albumin levels <3.3 g/dL, and age >85 years, and 1-year mortality was predicted by home oxygen use, albumin levels <3.3 g/dL, falls in the past 6 months, STS PROM score >7%, and severe (≥5) Charlson comorbidity. A simple scoring system created on the basis of these multivariable predictors effectively stratified risk at 30 days and 1 year into low-risk, moderate-risk, and high-risk subsets and showed a 3-fold difference in mortality rates for the low-risk and high-risk subsets at 30 days (3.6% and 10.9%, respectively) and 1 year (12.3% and 36.6%, respectively). The 1-year mortality model was more stable than the 30-day model (C-statistics: 0.79 vs 0.75).

BEST PRACTICE SELF-EXPANDING BIOPROSTHESIS IMPLANTATION

The positive results of the US CoreValve Clinical Trials were due to a number of important contributing factors, detailed in the following sections.

Preprocedural CT Angiography

Multidetector CT is useful for determining the appropriate THV size in patients undergoing self-expanding TAVR. In an analysis of 1023 patients with severe aortic stenosis deemed high or extreme risk for surgery and treated with the CoreValve bioprosthesis, a sizing algorithm was evaluated and used based on the perimeter-derived diameter (Table 44-1). A device annular sizing ratio (DAR) was also calculated based on the native annulus perimeter and perimeter of the selected THV. Higher DARs were associated with lower rates of moderate or severe aortic PVR (DAR ≤10%, 17.6%; DAR
10% to 15%, 9.9%; DAR 15% to 20%, 6.3%; and DAR >20%, 4.9%; \( P < .001 \). There was no increase in clinical events associated with higher DARs.

### Vascular Access

Multidetector CT imaging of the vascular access for self-expanding TAVR has been invaluable for determination of minimal lumen diameters, vessel calcification, and tortuosity. Historically, an 18-Fr sheath was comparable to the CoreValve bioprostheses requiring iliofemoral diameters >6.0 mm in the absence of calcification and 6.5 to 7.0 mm in the presence of severe calcification in the iliofemoral vessels. A balloon-expandable sheath has also been used with iliofemoral diameters <5.5 mm with the larger CoreValve devices.\(^{39}\) The newer generation of Evolut R with its 14-Fr Enveo delivery system has allowed treatment of iliofemoral diameters of 5.0 mm or larger.

### Optimal Implantation

Self-expanding bioprosthesis positioning requires a precise knowledge of the aortovalvular complex at the time of implantation. Traditionally “best practice” recommendations are reviewed during a preprocedural planning meeting that includes the selection of a co-planer view that aligns the basal planes of the 3 coronary sinuses (Fig. 44-9). The co-planar view can be estimated with the use of a multidetector noncontrast CT scan and confirmed with aortography at the time of the procedure. The co-planar view is then used to identify the noncoronary sinus for placement of the injection pigtail catheter for contrast injection during implantation. The noncoronary sinus is critical at it represents the most inferior position of the valve leaflets that are used for proper implantation.
Establishment of co-planar view. Alignment of the 3 coronary sinuses is performed to identify the noncoronary sinus (arrow) and left coronary sinus for self-expanding transcatheter aortic valve replacement.

**Wire Positioning**

With the early CoreValve bioprosthesis, there was a tendency for downward migration into the left ventricular during implantation. This force can be countered by using the left ventricular guide wire to provide a counterforce but required optimal position and shaping to avoid left ventricular perforation (Fig. 44-10A). In the initial CoreValve series, 0.035 Extra Support or Lunderquest wires were preferred but have now largely been replaced by preshaped left ventricular guide wires such as the Confida (Fig. 44-10B) or Safari wires.
**FIGURE 44-10** Optimal position of left ventricular guideline during CoreValve deployment.  

**A.** Hand-shaped 0.035” extra support guide wire with a 1-cm floppy tip. The guide wire is shaped such that there are no transition zones that would result in left ventricular perforation with forward force on the guide wire. This forward force on the ventricular guide wire stabilizes the position of the CoreValve device during deployment.  

**B.** The Confida preshaped left ventricular guide wire with a transition zone remote from the tip that lessens right of left ventricular perforation.

**Predilatation**

Based on the extent of annular and valvular calcification, balloon valvuloplasty may be useful in fracturing the restrictive annulus and allowing full bioprosthesis expansion. However, the avoidance of rapid ventricular pacing may be of particular use in patients with reduced LVEF and patients who have lesser degrees of calcification.\(^{40}\)

Another important component of self-expanding implantation is the lining up of the marker at the distal delivery catheter tip to allow co-axial biosprothesis release (Fig. 44-11). In the co-planar aortography projection, this is generally a caudal angulation that elevates the right coronary sinus to ensure coverage.

![Alignment of the delivery catheter marker. Left Panel: The CoreValve delivery catheter is positioned along the lesser curvature, and the delivery catheter marker is not in plane. Right Panel: The catheter is now located along the greater curvature of the aorta by forward pressure on the left ventricular guide wire, and the gantry has been rotated caudal to provide a “co-axial” alignment of the delivery catheter marker.](image)

**Depth of Implantation**

A key component to optimal self-expanding TAVR is a slow and gentle deployment with incremental rotation of the microknob to secure the position of the CoreValve. Once there has been annular contact with the inflow
portion of the frame, there is generally a drop in the systolic arterial pressure. Fast (up to 110 bpm) ventricular pacing during deployment may help stabilize the valve in the setting of systolic hypertension. Once the sheath has been fully retracted, the tension on the wire is removed and the valve is released or repositioned. In addition, the angle of the CoreValve frame can be determined to understand whether forward or withdrawal pressure is needed at the end of the procedure. The optimal implantation depth is 3 to 5 mm with the Evolut R bioprosthesis and 4 to 6 mm with the CoreValve bioprosthesis (Fig. 44-12).\textsuperscript{41}

\textbf{Recapture and Positioning}

An advantage of the Evolut R system is that it can be recaptured and repositioned if it is not in optimal position (Fig. 44-13).
**FIGURE 44-13** Placement of an Evolut R with recapturing and repositioning. A. Positioning of the Evolut R 4 mm below the noncoronary sinus. B. Annular contact of the Evolut R. C. Retraction of the delivery catheter sheath to the prerelease position. D. The inflow is now located at 2 mm below the annular plane. E. Because the prerelease position is deemed to be too close to the sinus of Valsalva, the Evolut R is recaptured. F. The Evolut R is appropriately positioned at 4 mm below the noncoronary sinus. G. Final aortography showed the Evolut R at 4 mm below the noncoronary sinus without paravalvular regurgitation.

**Concordance of Postprocedural Imaging**

Multiple modality imagining is performed at end of the procedure, with an assessment of hemodynamics, aortography, and echocardiography. Hemodynamic evaluation is a critical component of the postprocedural assessment. Optimal implantation demonstrates a wide separation between the aortic and left ventricular end-diastolic pressures (Fig. 44-14).  

**FIGURE 44-14** Hemodynamics after self-expanding valve placement. Simultaneous determination of left ventricular end-diastolic pressure (*blue line*) and diastolic blood pressure in the aorta (*red line*) in a patient without paravalvular regurgitation (PVR) (A) and a patient with moderate PVR (B). (Adapted from Sinning JM, Hammerstingl C, Vasa-Nicotera M, et al. Aortic regurgitation index defines severity of peri-prosthetic regurgitation and predicts outcome in patients after transcatheter aortic valve implantation. *J Am Coll Cardiol*. 2012;59:1134-1141, Copyright © 2012, with permission from American College of Cardiology Foundation.)

**Balloon Postdilation**

Balloon postdilation is performed in approximately 20% to 25% of cases of self-expanding TAVR, most commonly for residual PVR and less commonly...
for residual transaortic gradients. In an analysis of 3532 patients treated with self-expanding TAVR, 22% of patients underwent postdilation. Male sex ($P < .0001$), larger aortic annular diameters ($P < .0001$), lower device-to-annular ratios ($P < .0001$), and higher grades of baseline aortic regurgitation ($P < .05$) were more common in the patients who underwent balloon postdilation. Thirty-day and 1-year clinical event rates, including stroke, were similar in the 2 groups. One case of valve migration and 3 cases of fatal annular rupture occurred following balloon postdilation likely due to balloon oversizing. As a result, in the setting of significant left ventricular outflow tract (LVOT) calcification, the minimal lumen diameter is used to select a compliant balloon, and 1 mm less than the LVOT minimal lumen diameter is selected for a noncompliant balloon. In the absence of LVOT calcification, a balloon sized to the mean diameter of the annular is selected for a compliant balloon, and 1 mm less than the mean diameter is used for a noncompliant balloon. Care must be taken to avoid crossing the guide wire through the self-expanding frame cells prior to postdilation.

**COMPLICATIONS WITH SELF-EXPANDING TAVR**

**Stroke**

Neurologic events are uncommon after self-expanding TAVR. In patients enrolled in the CoreValve US Extreme Risk and High-Risk Pivotal Trials or Continued Access Studies, the 1-year stroke rate after TAVR was 8.4%. Analysis of the stroke hazard rate identified an early phase (0-10 days; 4.1% of strokes) and a late phase (11-365 days; 4.3% of strokes). Baseline predictors of early stroke included National Institutes of Health stroke scale score $>0$, prior stroke, prior transient ischemic attack, peripheral vascular disease, absence of prior coronary artery bypass surgery, angina, low body mass index ($<21$ kg/m$^2$), and falls within the past 6 months. Significant procedural predictors were total time in the catheterization laboratory or operating room, delivery catheter in the body time, rapid pacing used during valvuloplasty, and repositioning of the prosthesis. Predictors of stroke
between 11 and 365 days were small body surface area, severe aortic calcification, and falls within the past 6 months. There were no significant imaging predictors of early or late stroke.

**Paravalvular Regurgitation**

There are a number of potential mechanisms for PVR after TAVR (Fig. 44-15). Appropriate self-expanding bioprosthetic sizing using multidetector CT imaging is the most important factor in reducing the frequency of significant post procedural PVR. Occasional, incomplete frame expansion occurs due to excess calcification of the LVOT (Fig. 44-16). Ventricular and aortic placement can be managed with recapturing and repositioning.
aortic valve implantation. Paravalvular leaks with consecutive periprosthetic aortic regurgitation result from underexpansion of the prosthesis stent frame, which might be caused by calcifications of the annulus or the cusps of the native valve (A), valve malposition with too shallow (B) or too deep (C) implantation depth of the prosthesis, and/or annulus-prosthesis size mismatch (D). (Adapted from Sinning JM, Hammerstingl C, Vasa-Nicotera M, et al. Aortic regurgitation index defines severity of peri-prosthetic regurgitation and predicts outcome in patients after transcatheter aortic valve implantation. J Am Coll Cardiol. 2012;59:1134-1141, Copyright © 2012, with permission from American College of Cardiology Foundation.)

**FIGURE 44-16** Extensive calcification of the left ventricular outflow tract. **Upper Left Panel:** Extensive calcification of the aortic valve in cross-section. **Lower Left Panel:** Volume rendering shows the calcification extending into the mitral annulus. **Right Panel:** Extensive left ventricular outflow tract calcium.

A smaller randomized study of 120 patients who received a balloon-expandable TAVR and 120 patients assigned to a self-expandable TAVR found that device success, defined as successful vascular access and deployment of the device and retrieval of the delivery system, correct position of the device, intended performance of the heart valve without moderate or severe regurgitation, and only 1 valve implanted in the proper anatomic location, was higher in the balloon-expandable valve group (95.9%) than the self-expanding group (77.5%; \( P < .001 \)).\(^{49}\) This was primarily due to
a significantly lower frequency of residual more-than-mild aortic regurgitation in the balloon-expandable TAVR group (4.1% vs 18.3% in the self-expanding TAVR group; \( P < .001 \)) and the less frequent need for implanting more than 1 valve with balloon-expandable TAVR (0.8% vs 5.8% with self-expanding TAVR; \( P = .03 \)). Despite these findings, there were no differences in clinical outcomes between the 2 devices.

One unique feature of the self-expanding bioprosthesis is that an improvement in aortic valve hemodynamics and a reduction in PVR may occur in some patients over time. The US CoreValve Extreme Risk Study showed an improvement in the rate of moderate or severe PVR in over 80% of patients between 30 days and 1 year. Serial analysis of echocardiograms in this study showed that aortic valve velocity, mean gradient, and effective orifice area further improved significantly from discharge to 1 month and that this improvement was sustained to 1 year. PVR was moderate or severe in 9.9% of patients, and 83% of patients improved by at least 1 grade of regurgitation by 1 year. Oversizing was associated with an improvement in PVR over time (Fig. 44-17). PVR can also be treated with transcatheter closure devices.

(Adapted from Oh JK, Little SH, Abdelmoneim SS,

Significant PVR has been associated with high rates of early\(^5,53,54\) and late mortality\(^5,54,55\) after self-expanding TAVR. Predictors of PVR after self-expanding TAVR are the degree of calcification and undersizing of the self-expanding prosthesis.\(^56\) Although the VARC-2 Working Group has classified residual PVR[CD2] as none, mild, moderate, and severe, a more granular classification including trace, mild-moderate, and moderate-severe may provide more incremental prognostic valve.\(^57,58\)

**Conduction Abnormalities**

Due to the proximity of the origin of the left bundle branch in the LVOT at the location of the noncoronary and right coronary sinuses, implantation of a self-expanding bioprosthesis has been associated with the development conduction abnormalities,\(^59\) including new left bundle branch block (33%-38%)\(^59,60\) and atrioventricular block or bradycardia (20%). Conduction abnormalities have been associated with presence of preexisting conduction disorders and depth of implantation.\(^60\) The frequency of the need for a new permanent conduction system disturbance was lower in the US Pivotal Trials (20%) than in prior studies. Baseline conduction system disturbances such as right bundle branch block and left anterior fascicular hemiblock were predictors of the need for a permanent pacemaker. Although intermediate-term mortality has not been affected by the use of permanent pacemaker placement,\(^51\) longer term studies with larger numbers of patients are needed.

The ADVANCE-II Registry was designed to evaluate “best practice” implantation technique on the occurrence of conduction disturbances in 194 patients after self-expanding TAVR.\(^62\) Optimal implantation was defined as an implant at an optimal depth ≤6 mm below the aortic annulus.\(^62\) An optimal implantation depth was achieved in 43.2% of patients, and the overall rate of permanent pacemaker implantation was 18.2%.\(^62\) The rate of permanent pacemaker placement was nonsignificantly lower in patients with depths ≤6 mm versus depths >6 mm (13.3% vs 21.1%, respectively; \(P = .14\)).\(^62\) New-onset left bundle branch block and first-degree atrioventricular block occurred in 45.4% and 39.0% of patients, respectively, and resolved
spontaneously within 30 days in 43.2% and 73.9% of patients, respectively.\textsuperscript{62} In patients with new proton pump inhibitor, the rate of intrinsic sinus rhythm increased from 25.9% at 7 days to 59.3% at 30 days ($P = .004$).\textsuperscript{62}

**Leaflet Thickening and Valve Thrombosis**

Serial imaging using multidetector CT imaging has shown that a minority of patients treated with both transcatheter and surgical bioprostheses may show leaflet thickening and valve thrombosis.\textsuperscript{63-65} In rare circumstances,\textsuperscript{65} these may result in elevated gradients that can be treated with oral anticoagulation.\textsuperscript{63,64} The clinical implications are uncertain,\textsuperscript{66} and a 400-patient multidetector CT substudy including 200 patients treated with transcatheter and surgical aortic valve replacement will be part of the Evolut R low-risk randomized clinical trial.

**Other Complications**

Coronary occlusion is a rare complication after self-expanding TAVR\textsuperscript{67} and can be mitigated by careful preprocedural assessment of the sinus of Valsalva width and coronary heights. Annular ruptures are also rare\textsuperscript{68} and are most often due to oversizing balloons used for postdilation. Vascular complications are infrequent due to the smaller vascular access diameters (6 mm) needed for the 18-Fr CoreValve system that will accommodate all sizes of THV up to 31 mm. The vascular access diameter is further reduced with the Evolut R to a true 14 Fr (not expandable 14 Fr), and access diameter is reduced to 5 mm in the iliofemoral vessels. Endocarditis is a rare complication.\textsuperscript{69}

**EVOLUT R SELF-EXPANDING BIOPROSTHESIS**

Design improvements of transcatheter bioprostheses have focused on reducing procedural complications by decreasing delivery catheter profile, improving annular sealing, and providing the ability to reposition the transcatheter valve during deployment (Fig. 44-18). The fourth-generation
Evolut R self-expanding bioprosthesis addresses these issues; it includes a 14-Fr equivalent EnVeo R Deliver Catheter System (Medtronic, Minneapolis, MN) (Fig. 44-19), a modified nitinol design at the annulus that optimizes radial expansive force, a longer porcine pericardial sealing skirt, and a nitinol delivery catheter capsule that allows resheathing and recapturing during deployment. A recent modification of the Evolut R 34XL includes annular diameters of 30 mm and the EnVeo Delivery catheter of 16 Fr equivalent, which was approved for commercial use in the United States.

**FIGURE 44-18 Evolut R bioprosthesis.**
The Evolut R was first evaluated in a single-arm, multicenter pivotal study in 60 high- or extreme-risk patients with symptomatic aortic valve stenosis. Patients were older (mean age, 82.8 ± 6.1 years; STS PROM, 7.0% ± 3.7%) and underwent self-expanding TAVR via the transfemoral route in 98.3%, using a 29-mm valve in 68.3% of patients. No death or stroke was observed up to 30 days. The VARC-2 overall device success rate was 78.6%. PVR after TAVR was mild or less in 96.6%, moderate in 3.4%, and severe in 0% of patients at 30 days.

The Evolut R US Study included 241 patients who were at high or extreme risk for surgery. Patients were elderly (mean age, 83.3 ± 7.2 years) and had high surgical risk (STS PROM, 7.4%). Resheathing or recapturing was performed in 22.6% of patients; more than 1 valve was required in 3 patients (1.3%). Thirty-day outcomes included all-cause mortality (2.5%), disabling stroke (3.3%), major vascular complications (7.5%), life-threatening or disabling bleeding (7.1%), and new permanent pacemaker (16.4%). Aortic valve hemodynamics were markedly improved at 30 days: the mean aortic valve gradient was reduced from 48.2 ± 13.0 mm Hg to 7.8 ±
3.1 mm Hg (\(P < .001\)), and aortic valve area was increased from 0.6 ± 0.2 cm\(^2\) to 1.9 ± 0.5 cm\(^2\) (\(P < .001\)).\(^{41}\) Moderate residual paravalvular leak was identified in 5.3% of patients and was related to the degree of oversizing (Fig. 44-20).

**FIGURE 44-20 Relationship of oversizing to paravalvular regurgitation.**

**FUTURE PERSPECTIVES**

Additional design iterations are ongoing with the Evolut 2.0 (Pro), which will contain a thin pericardial skirt on the outside of the frame that will increase the surface area contact with the annulus to reduce PVR. The 1200-patient Evolut R Low-Risk Study will randomly assign patients with severe aortic stenosis and an estimated 30-day surgical risk of <3% to either self-expanding TAVR or surgery. The primary end point for the study is all-cause mortality or major stroke at 2 years. These studies and others will further expand the spectrum of patients who will benefit from the use of self-expanding bioprostheses in the future.

Pulmonary Balloon Valvuloplasty and Percutaneous Pulmonary Valve Implantation

Mike Saji
D. Scott Lim

INTRODUCTION

Since percutaneous balloon pulmonary valvuloplasty (BPV) for pulmonary valve stenosis (PS) was first successfully performed by Rubio-Alverez and Limon-Lason\(^1\) using a ureteral catheter in 1950s, it has become the standard of care for treatment of isolated PS over surgical valvotomy.\(^2,3\) In 2000, based on these experiences, the percutaneous pulmonary valve implantation (PPVI) was first performed by Bonhoeffer et al\(^4\) in a patient with a dysfunctional of right ventricle–to–pulmonary artery conduit. In 2010, the Melody valve (Medtronic, Minneapolis, MN) became commercially available in the United States under a humanitarian device exemption protocol and, more recently, was awarded postmarket approval by the US Food and Drug Administration. Since then, PPVI has been performed in over 4500 patients in more than 30 countries worldwide. In this chapter, we will review BPV and PPVI with particular focus on the indication, technical aspect, clinical outcomes, and potential complications.
Isolated PS is a relatively common disorder, accounting for approximately 10% of all congenital heart defects, and it varies in regard to severity of obstruction to the pulmonary orifice size, leaflet morphology (eg, dome-shaped, unicommissural, bicuspid, or dysplastic tricuspid valve), and annulus (eg, hypoplastic or enlarged annulus). Other congenital cardiac defects that may be associated with PS include atrial septal defect, ventricular septal defect, tetralogy of Fallot, transposition of the great arteries, double-outlet right ventricle, and ventricular inversion. Significant obstruction may lead to an inability to augment pulmonary blood flow during exertion, resulting in exercise-induced fatigue, syncope, or chest pain. Physical examination reveals a systolic ejection murmur with maximal intensity at the left upper sternal border, and transthoracic echocardiography is key to determining the severity and morphologic diagnosis. Once a severe PS is diagnosed, cardiac catheterization is performed in order to provide appropriate therapy.

Given the relative low risk and high likelihood of a long-standing good result, the generally accepted indication of BPV is more than moderate degree of PS (echocardiographic peak instantaneous pressure gradients ≥50 mm Hg or mean Doppler pressure gradients ≥30 mm Hg for symptomatic patients and peak Doppler pressure gradients ≥60 mm Hg or mean pressure gradients ≥40 mm Hg for asymptomatic patients) with less than moderate pulmonary valve regurgitation. BPV provides an immediate reduction of pulmonary valvular gradients and modest increase of pulmonary pressure and cardiac index. Improvement in right ventricular dysfunction frequently results in reduction of tricuspid regurgitation and right-to-left shunt if it exists. Patients with mild (gradient <30 mm Hg) stenosis are contraindicated for intervention, as natural history studies have demonstrated the benign natural history of mild PS at follow-up. Even in the asymptomatic patient, severe PS should be treated to prevent myocardial damage associated with long-term right ventricular pressure overload. Exercise testing may induce abnormal hemodynamic response due to low cardiac output in these patients.
Technique

BPV is performed most commonly under local anesthesia with procedural sedation, with continuous noninvasive heart rate, pressure, and oxygen saturation monitoring. Although transfemoral venous access is commonly preferred, transaxillary, transjugular, or transhepatic venous access can be successfully performed as well.\textsuperscript{13-15}

A balloon wedge catheter (Arrow International Inc., Reading, PA) is usually used for right-sided pressure measurements, obtaining right ventricular and then pulmonary artery pressures. If a simultaneous gradient is required, a dual lumen catheter can demonstrate simultaneous gradient across the pulmonary valve. Simultaneous recording of the right ventricular pressure and femoral arterial pressure also helps in assessing the severity of the pulmonary valve; right ventricular peak systolic pressure $\geq 75\%$ of peak systolic systemic pressure is considered significant as well, particularly in younger patients. After gradient evaluation, right ventriculogram is performed in the right ventricle with left lateral projection (Fig. 45-1A). A straight anteroposterior view helps to assess the right ventricular size and ejection fraction, whereas the left lateral view, which is perpendicular to the pulmonary valve annulus, helps to determine the single plane assessment of valvular annular dimension. Left-sided catheterization and angiography are usually not warranted. After crossing the catheter through the pulmonary valve, 0.035-inch exchange length wire is passed to the pulmonary artery (left pulmonary artery is preferable) through the catheter already in place, and then the catheter is removed. If the size of the femoral venous sheath does not accommodate the selected balloon catheter, the sheath may be upsized to an appropriate size at this point. The selected balloon angioplasty catheter is advanced and positioned at the pulmonary valve. Tyshak II balloons (NuMed, Inc., Hopkinton, NY) are usually preferred due to their low-profile cross-sectional area for introduction. Landmarks from the previous ventriculogram or balloon indentation on fluoroscopy may help in positioning the balloon during inflation. The balloon is inflated with diluted contrast material ($\sim 15\%$) using a syringe and hand inflation. The balloon is rapidly inflated until the disappearance of the sharp part of the balloon waist and no greater than the burst pressure of the balloon (Fig. 45-1B-C). Conservative balloon sizing is important to avoid the creation of significant pulmonary regurgitation and rupture of pulmonary annulus. The current recommendation
is to use a balloon diameter 1.2 to 1.3 times the pulmonary annulus based on follow-up data,\textsuperscript{16,17} except for pediatric patients with a dysplastic pulmonary valve, in whom it is recommended to use a diameter 1.4 to 1.5 times the pulmonary annulus.\textsuperscript{18} Use of balloon diameters more than 1.5 times the pulmonary annulus may result in annular injury.

**FIGURE 45-1** A. Right ventriculogram is performed to evaluate the pulmonary valve stenosis. B. The balloon is inflated slowly until the waist is seen (arrow) to adjust the positioning of the balloon. C. If the waist is seen at the center of the balloon, the balloon is fully inflated until that waist is eliminated.

For larger annuli, the double-balloon technique may be considered if the largest single balloon is inadequate. The following formula is used to calculate the effective balloon size:\textsuperscript{17} \[\text{effective balloon diameter} = \frac{D_1 + D_2 + \pi (D_1/2 + D_2/2)}{\pi}.\] \(D_1\) and \(D_2\) are the diameters of each balloon used. This formula has been further simplified,\textsuperscript{19} as follows: \[\text{effective balloon diameter} = 0.82 (D_1 + D_2).\] The double-balloon technique produces less hypotension during the procedure because it allows right ventricular output in between the balloons during inflation. However, single-balloon valvuloplasty is currently preferred due to its ease and simplicity, with usually excellent outcomes compared to the double-balloon technique.\textsuperscript{20}

Following balloon valvuloplasty, repeat hemodynamic measurements are undertaken to assess the results of the valvuloplasty. If the result is not satisfactory (gradient in excess of 30 mm Hg), a repeat dilatation with a larger balloon is considered. Once the catheter and guide wire are removed, a right ventriculogram is performed to evaluate for any complication, such as tricuspid regurgitation or pulmonary annular injury.
The patient is observed overnight with heart rate, blood pressure, and pulse oximetry monitoring for any late complications. Clinical reevaluation at least once using echocardiography is generally recommended for follow-up.

**Clinical Outcomes and Potential Complications**

The Valvuloplasty and Angioplasty of Congenital Anomalies Registry reported mortality of 0.24% (mostly neonate and young infant) and major complication of 0.35% from 822 BPV procedures from 26 sites. Major acute complications were inversely related to age and mostly associated with cardiac catheterization as follows.

Injury of the right ventricular outflow tract occurs in 0.1% of patients undergoing BPV. Because the right ventricular infundibulum is lacking in elastic fibers as compared with the pulmonary trunk, it is susceptible to tearing and dissection. An oversized balloon, especially in neonatal patients with a narrowed infundibulum, may result in myocardial injury and thereby increase the risk of right ventricular perforation. The uncommon but feared complication of “suicidal right ventricle” may result after BPV in which muscular spasm after relief of valvar PS occurs. Patients with significant infundibular gradients that develop after valvuloplasty may benefit by acute administration of fluids to expand the right ventricle or administration of β-blocker medications to slow the heart rate.

Pulmonary regurgitation is less common and less severe following balloon valvuloplasty than following open surgical valvotomy. However, if one includes milder degrees of pulmonary regurgitation, it has been reported in approximately 60% to 90% of cases, and the degree of pulmonary regurgitation may increase with time. Although most patients do not require surgical intervention for increased pulmonary regurgitation, clinical follow-up is recommended in patients with more than mild pulmonary regurgitation to identify the small number of patient with late development of severe pulmonary regurgitation and right ventricular dysfunction in whom pulmonary valve replacement would be warranted. This cohort may now be considered for PPVI as well, and this will be discussed later in this chapter. See also the section titled “Percutaneous pulmonary valve implantation.”

The complication of severe tricuspid regurgitation has been demonstrated to occur in 0.2% of patients, although it is primarily confined to neonatal
patients due to the tricuspid papillary muscle rupture being caused by the proximal part of the inflated balloon.\textsuperscript{22}

Other potential complications are arrhythmia (eg, complete heart block, right bundle branch block, ventricular tachycardia), pulmonary thromboembolic events, and acute pulmonary edema. In the younger patient with severe PS, the pulmonary vascular bed may have been exposed to long-standing hypoperfusion and remodeling. As such, it may not be able to adapt to acute increases in pulmonary blood flow after resolution of the valvar stenosis, which can result in acute pulmonary edema. Fortunately, such acute pulmonary edema is frequently transient in nature.

Late complications at follow-up include femoral vein stenosis or occlusion, which occurs in approximately 7% to 19% of patients (more likely in infants) but is mainly asymptomatic. Restenosis of the pulmonary valve is uncommon but can be detected by follow-up echocardiography in about 8% to 10% of patients.\textsuperscript{21,28} Repeat BPV is first considered; however, subsequent surgical intervention is reported in 10% to 16% of cases at 10 years.\textsuperscript{28,29} The risk factors of recurrence identified in previous studies are primarily a balloon–to–pulmonary valve annulus ratio $<1.2$ and immediate postvalvuloplasty gradient $>30$ mm Hg.\textsuperscript{26,30} A small annulus due to dysplasia and postsurgical or complex PS were also found to be a predictive factors for restenosis,\textsuperscript{28} and surgery may be generally recommended in these patients.

**Comparison With Surgery**

In surgical series for open approaches to PS, mortality rates vary from 3% to 14%, and recurrence rate range from 0% to 8%.\textsuperscript{28} Due to baseline differences between patient populations, it is difficult to compare directly the effectiveness of BPV and surgical valvotomy. However, in the present era, BPV has become the initial standard of care due to the far less invasive nature with less mortality and comparable relief of obstruction with less regurgitation compared to open surgery.\textsuperscript{31}

**Aneurysmal Poststenotic Dilation**

Poststenotic dilation of the pulmonary artery is relatively common in congenital PS, but the natural history remains unclear, although it is likely
benign in most cases. Typical poststenotic dilation diameter involves the main and left pulmonary arteries. BPV serves to relieve the stenosis and may prevent further poststenotic dilation. Rarely, the left pulmonary artery dilatation after BPV may be due to traumatic injury from a long and large balloon. Recommended modifications include using a smaller initial balloon ratio and using shorter balloons to minimize risk of injury to the left pulmonary artery.

PERCUTANEOUS PULMONARY VALVE IMPLANTATION

Clinical Indications and Patient Selection

Dysfunction of a surgically placed pulmonary valve, manifesting as some combination of stenosis or regurgitation, is a common problem after surgical repair of right-sided congenital heart disease. Surgical pulmonary valve replacement using a valved conduit or tissue valve has been a long-standing therapy that has been performed with low mortality. However, dysfunction of the bioprosthetic valve occurs in more than half of the patients by 10 years postoperatively. As a result, the majority of such patients have been faced with the prospect of multiple repeat open-heart surgeries during their life. Therefore, patient management strategy has been based on delaying surgical intervention for as long as possible, so that the number of open-heart surgeries performed on any individual patient is kept to a minimum. However, this approach bears the risk of delaying surgery beyond a theoretical point of limited return when right ventricular dysfunction and impaired exercise capacity might be irreversible.

Previous studies have shown that late surgical pulmonary valve replacement did not lead to normalization of right ventricular dimensions as assessed by magnetic resonance imaging (MRI). The impact of timing of pulmonary valve replacement on right ventricular function, exercise performance, and long-term survival remain undefined, and the clinical decision making regarding timing of intervention in these patients is still complicated. However, the less invasive therapy of PPVI has led to a shift toward earlier pulmonary valve replacement, although the optimal timing has
still yet to be clearly determined. The following are the criteria commonly used in recent years in the United States for patients with right ventricle–to–pulmonary artery conduit, native right ventricular outflow tract (RVOT) obstruction, and failing bioprosthetic valve:

1. Symptomatic patients with severe RVOT obstruction and exercise intolerance related to symptoms with continuous wave Doppler velocity >3.5 m/s by echocardiography
2. Asymptomatic patients with severe RVOT obstruction, peak continuous wave Doppler velocity >4.0 m/s, or RVOT obstruction with right ventricular systolic pressure greater than two-thirds of systemic systolic pressure
3. Patients with severe pulmonary regurgitation and right ventricular end-diastolic volume index >150 cm/m² by cardiac MRI

On the other hand, the European Society of Cardiology/Association for European Pediatric Cardiology guidelines for the management of adults with congenital heart disease include the following indications in patients with right ventricular–to–pulmonary artery conduits:

1. Symptomatic patients with right ventricular systolic pressure >60 mm Hg (tricuspid regurgitation [TR] velocity >3.5 m/s; may be lower in cases with reduced flow) and/or moderate to severe pulmonic regurgitation
2. Asymptomatic patients with severe right ventricular outflow tract obstruction and/or severe pulmonic regurgitation when at least 1 of the following criteria is present:
   • Decrease in exercise capacity on cardiopulmonary exercise testing
   • Progressive right ventricular dilation
   • Progressive right ventricular systolic dysfunction
   • Progressive TR (at least moderate)
   • Right ventricular systolic pressure >80 mm Hg (TR velocity >4.3 m/s)
   • Sustained atrial/ventricular arrhythmias

In addition to the clinical indication, patients have to fulfill the anatomic criteria in regard to 2 crucial factors: coronary position relative to the
intended landing zone for the PPVI and a suitable landing zone for the intended pulmonary valve implant.

Interventions on the RVOT and pulmonary trunk expose the risk for coronary artery compression due to expansion of the RVOT. The ostium of the left coronary artery usually runs close to the pulmonary artery in patients with tetralogy of Fallot. Postoperatively, the right ventricle–to–pulmonary artery conduit may run in close proximity and directly over the left main coronary artery. It is essential to assess the course of the coronary artery in relation to the RVOT/pulmonary trunk prior to PPVI. Tomographic imaging (computed tomography [CT] or MRI) allows the determination of coronary proximity to the intended landing zone of the PPVI. Alternatively, selective coronary angiography during balloon dilation of the patient’s conduit can determine the risk for functional compression prior to stented valve implantation (Fig. 45-2). Contrast-gated CT (Fig. 45-3) allows a multiplanar reformatting of the image to determine the distance from the coronary to the landing zone in the pulmonary outflow. Cardiac MRI can also be helpful. CT scanning also allows for accurate measurement of the pulmonary annular size. Of the 2 available transcatheter valves for pulmonary implantation, the Melody valve has a potential diameter of 18 to 22 mm to replace the dysfunctional RVOT. The SAPIEN XT valve (Edwards Lifesciences, Irvine, CA) comes in diameters of 23, 26, and 29 mm and covers ranges from 18 to 28 mm (annular areas of 340-680 mm²). Certain patients, particularly those with a transannular patch after tetralogy of Fallot repair, may have quite large RVOT diameters, potentially exceeding the currently available transcatheter valve sizes. Older patients with failing bioprosthetic valves in the pulmonary position also are potential candidates for either a Melody or SAPIEN valve implanted valve-in-valve.
In complex congenital heart disease, it is essential to assess the course of proximal coronary arteries in relation to the right ventricular outflow tract/pulmonary trunk prior to percutaneous pulmonary valve implantation. Coronary angiography is performed with the pulmonary balloon inflated. A. Right anterior oblique. B. Left anterior oblique. There is no evidence of coronary artery compression (arrow) in either view.
FIGURE 45-3 Multidetector computed tomography shows that the left coronary artery runs in close to the pulmonary artery (PA; arrow) in a patient considered for percutaneous pulmonary valve implantation.

**Device Design and Technique**

PPVI may be performed under procedural sedation or general anesthesia. Femoral access is preferred because it allows for an easy working position in the catheterization laboratory. Transjugular access can also be performed safely, particularly if the angles for delivery from the inferior vena cava are suboptimal.

The commercially available valves for PPVI are the Melody valve and the SAPIEN series valves (SAPIEN, SAPIEN XT, and SAPIEN 3 valves; Edwards Lifesciences). The Melody valve is composed of a balloon-expandable stent and valved bovine jugular venous conduit (Fig. 45-4A). The stent comprises 6 rows of circumferential struts, each of which is fashioned
from a length of platinum-iridium wire that is welded at the ends and formed to have 8 crown “zigs.” Each strut is welded together at the crowns with gold-brazed to increase their strength. The stent measures 34 mm in length when in expanded configuration and 28 mm in length when expanded to 18 mm in diameter. The most important design characteristics that make this stent appropriate for use in the Melody valve platform are its relative malleability, which is felt to be important for facilitating conformation to irregular RVOT conduits; easy crimping on a balloon delivery catheter; and its ability to expand well beyond the expected working diameter of the valve without shortening to a degree that would distort the valve leaflets. However, this is also a potential disadvantage because the low radial strength of the stent materials can lead to stent fracture as the valve is compressed between the sternal table and the water-hammer effect of the aorta. Stent fracture has been associated with early valve failure, necessitating prestenting of the landing zone to protect the subsequently implanted Melody valve. Another advantage of the Melody’s venous valve is its relatively deep commissures, which allow for valve competence in a range of sizes, thereby providing for a single valve that can be dilated up to approximately 24 mm. The valve sheath tissue is sutured to the frame at each stent node with a separate interrupted suture between the stent and venous conduit. Blue suture is used at the distal end of the valve to ensure proper orientation of the valve on the Ensemble transcatheter delivery system (Medtronic), which has a blue nose cone on the end.
The Ensemble delivery system (Fig. 45-4B-C) consists of a balloon-in-balloon system and is mounted within a Teflon sheath that is 22-Fr in outer dimension at its distal portion, where it covers the valve, and 16-Fr along most of its length. The delivery system is manufactured with outer balloon diameters of 18, 20, or 22 mm, and the inner balloon is half the outer balloon diameter and shorter than the outer balloon. The tip of the balloon catheter is equipped with a blue nose cone, which tapers distally to act as a vascular introducer, and has a proximal end that engages within the distal end of the sheath to create a smooth contour. The delivery system is identical among the different balloon sizes.

The Melody valve is crimped manually onto the balloon of the appropriate-sized Ensemble delivery system, and the covering portion of the capsule is advanced over the mounted Melody valve. Once the valve is covered, the system is introduced into the vein over a stiff guide wire and advanced to a proper position in the RVOT (Fig. 45-5). After withdrawing the sheath to expose the valve, the inner and outer balloons of the balloon-in-balloon system are inflated in succession to deploy the valve. Once the valve is implanted successfully, the balloons are deflated and the entire delivery system is removed over the guide wire. As mentioned, it is important to prestent the landing zone prior to the Melody valve implantation to prevent the stent fracture. Stent fracture occurs due to the pulmonary conduit valve being compressed by the water-hammer effect of the aorta posteriorly and the sternal table anteriorly. Stent fracture has been linked to early valve failure. 39,42
FIGURE 45-5 A. Angiogram (left anterior oblique projection) demonstrates the recoil of the stent implanted 3 months ago in 16-mm homograft that showed significant stenosis. B. Angiogram shows distance between main pulmonary artery and left main coronary artery (*asterisk*). C and D. Additional stent was implanted to open the recoil. E. Additional inflation was performed to gain the inner diameter. F. Acceptable opening of the homograft was achieved. G and H. Melody valve was positioned and implanted in the double stent. I. The final angiogram demonstrates good valvular competence and good acceptable opening of the homograft.
The SAPIEN series valves are made of bovine pericardium and affixed within a short stent frame (stainless steel in the SAPIEN and cobalt-chromium in the SAPIEN XT and SAPIEN 3 valves). The stent frame is of relatively high radial strength and has not been found to date to develop stent fractures when implanted in the pulmonary position. The SAPIEN series valves come in 20-, 23-, 26-, and 29-mm diameters and, therefore, have been used in pulmonary landing zones of 18 to 28 mm in diameter. The first-generation SAPIEN valves are mounted on the delivery balloon and have delivery system sheath requirements of 22- and 24-Fr inner diameters. The second- and third-generation SAPIEN valves are mounted on the shaft of the delivery catheter and then advanced up onto the balloon once inside the vasculature. This has allowed downsizing of the delivery system to facilitate its introduction via 16- to 20-Fr expandable sheaths. The third-generation SAPIEN valve has an outer skirt of polyethylene terephthalate designed to minimize paravalvular leak.

The actual procedure to implant the SAPIEN series valves in the pulmonary position is similar to that for the Melody valve. Although prestenting may not be as needed to protect the SAPIEN valve from stent fractures, it does provide a longer landing zone as well as prevent inflow and outflow obstruction when the shorter valve is implanted in longer narrowed conduit segments.

**Outcomes and Follow-Up**

PPVI results in significant reduction in right ventricular systolic pressure in previous studies, and pulmonary systolic pressure has also been shown to increase after deployment, indicating restoration of valvular competence. Systemic systolic pressures increase significantly after PPVI, which is a reflection of increased cardiac output. Significant paravalvular leak is rare. Patients have been demonstrated to have a significant improvement in New York Heart Association functional class after PPVI as well, regardless the pathology. However, there is a different functional response after PPVI between patients with predominantly stenotic versus predominantly regurgitant pathology in terms of ventricular remodeling as assessed by MRI and exercise capacity data. In patients with PS, an improvement in peak oxygen uptake after PPVI is seen, with the reduction in RVOT gradient being the only predictor of improved exercise capacity. As assessed by MRI, the
relief in right ventricular afterload by the RVOT gradient reduction leads to a reduced right ventricular end-systolic volume and increased right ventricular ejection fraction. In contrast, in patients with primarily pulmonary regurgitation, excise capacity remains unchanged, and PPVI does not improve the right ventricular ejection on MRI findings. The hypothesis is that pulmonary regurgitation is reduced to a minimum at peak exercise and therefore is not a limiting factor for cardiac output augmentation during exercise due to increased systemic venous return, shortening of diastole, and a reduction in pulmonary vascular resistance.

**Potential Complications**

Mortality and major complications have been reported in 0% to 5% and 3% to 11% of cases, respectively, predominantly due to intraprocedural complications.

Significant blood loss due to RVOT/conduit rupture occurs in 2% of cases. Bleeding generally drains into the pleural space rather than pericardium. Acutely, fluoroscopy can identify the pleural location of bleeding and provide for rapid drainage to reestablish the hemodynamic stability. Conduit or RVOT rupture can often be treated by placement of the Melody valve or another covered stent, and small ruptures can self-seal. Emergent surgical intervention for catastrophic rupture is rarely required.

Significant damage to the tricuspid valve occurs in less than 1% and, in most cases, it can be prevented by localizing the stiff guide wire to the center of the valve as it crosses the tricuspid annulus. Balloon-tipped floating catheters may minimize the risk of entrapment of the delivery system in either the chord or subvalvular apparatus of the tricuspid valve.

Cardiac and vascular injury due to the stiff guide wire occurs in 1% of cases. Although a stiff guide wire is required to provide sufficient support for advancement of the delivery system, the distal end may lead to injury of a branch pulmonary artery. The operator has to make sure that the guide wire is in the stable position in one of the distal pulmonary artery branches. Additionally, if the stiff guide wire is shaped by hand, care should be taken to create a smooth curve along its length, because acute bends can be traumatic to the right ventricle.

Other complications reported are uncommon and include device dislodgement, acute pulmonary edema, compression of the left coronary
artery, arrhythmia (ventricular tachycardia, complete heart block), and endocarditis.

**Stent Fracture**

The most commonly noted problem following PPVI with the Melody valve is stent fracture that can lead to loss of the functional integrity of the valve. Although it may occur with the Melody valve, it has not yet been reported following implantation with the SAPIEN series valves. It is classified into 3 types: type I, in which there are 1 or more strut fractures without loss of structural integrity; type II, in which there are strut fractures with loss of integrity; and type III, in which there is fragmentation or embolization of stent fragment.\(^4\) Data from the initial US trial on the Melody valve demonstrated a stent fracture rate of 28% in patients in whom prestenting of the RVOT was not performed,\(^47\) whereas the stent fracture rate with prestenting was 5% to 20%.\(^38,48,49\) Non-prestented status is the strongest predictor for stent fracture and restenosis, which is the most common reason for reintervention. The freedom from valve dysfunction rate was 87% and freedom of reintervention rate was 92% to 95% at 1 year.\(^39,48\) Other risk factors for stent fracture are chest wall contact, higher early Doppler gradient in the RVOT, absence of conduit calcification, and asymmetry of the Melody valve following implantation.

**SAPIEN SERIES VALVES IMPLANTED IN THE PULMONARY POSITION**

Since the first reports of using the SAPIEN series valves in the aortic position, investigators have reported small numbers implanted in the pulmonary position, which is in contrast to the tens of thousands reported for aortic applications. Although all reported patients underwent prestenting prior to SAPIEN valve implantation, there have been no reports of SAPIEN valve stent fracture.\(^50-53\) SAPIEN valves were implanted in conduits of diameters from 16 to 30 mm, with acute complication rates of 0% to 21%. These same reports characterized high acute implant success rates (95%-100% in case series of 72 total reported patients), with <5% reintervention rates at short-
and intermediate-term follow-up.

**SUMMARY**

Since the first percutaneous pulmonary valve was approved for commercial use in 2010, a significant number of patients have benefited from this therapeutic approach. Factors limiting its early success have included early valve failure due to stent fracture as well as size and deliverability of the valve to the pulmonary position. Both of these issues have been significantly improved upon with procedural as well as device modifications, such that the procedure has become generally accepted as first-line therapy in the field. Indications for PPVI have been set out in multispecialty guidelines, although issues related to functional assessment of pulmonary valve dysfunction remain, as do correlation with long-term outcomes. However, it appears that transcatheter pulmonary valve implantation will undergo further maturation and remain the primary therapeutic modality in pulmonary valve conduit dysfunction.

INTRODUCTION

The MitraClip (Abbott Laboratories, Chicago, IL) device offers a novel, percutaneous, transvenous, transcatheter approach for patients suffering from severe mitral regurgitation, despite maximal medical therapy, in whom surgery is not an option. This chapter serves to describe mitral valve anatomy in the context of regurgitant pathology, provide a detailed description of the MitraClip procedure along with practical “pearls” to optimize deployment, and finally outline the current evidence base for MitraClip through a brief review of published literature.

MITRAL VALVE ANATOMY

The mitral valve apparatus is an elegantly complex structure that is comprised of the mitral valve leaflets, annulus, annular attachment at the atrioventricular junction, chordae tendineae, and the papillary muscles, all of
which work synchronously throughout the cardiac cycle to deliver blood to the left ventricle.

The valve itself is composed of the aortic and mural leaflets, more often clinically referred to as the anterior and posterior leaflet, respectively.\textsuperscript{1,2} The anterior leaflet of the mitral valve is broader than the posterior leaflet and comprises one-third of the annular circumference. This semicircular anterior leaflet shares a fibrous continuity with the left and noncoronary cusps of the aortic valve and between the aortic cusps adjacent to the membranous septum. This region of continuity is referred to as the intervalvular fibrosa or aortic-mitral curtain. The motion of the leaflet defines an important boundary between the inflow (during diastole) and outflow (during systole) tracts of the left ventricle. In contrast to the anterior leaflet, the posterior leaflet is narrower and extends two-thirds around the left atrioventricular junction within the inlet portion of the ventricle. The posterior leaflet is commonly described as having 2 clefts that separate the leaflet into 3 scallops along the free edge. The Carpentier nomenclature describes the most lateral scallop as P1, adjacent to the anterolateral commissure; the central scallop as P2; and the most medial as P3, adjacent to the posteromedial commissure.\textsuperscript{1,2} The anterior leaflet is divided into 3 regions, named A1, A2, and A3, which correspond to the opposing scallops of the posterior leaflet (Fig. 46-1). Often, the free edge of the anterior leaflet is continuous and without indentation, making the distinction between different regions of the anterior leaflet somewhat challenging.
The primary purpose of the MitraClip procedure is to perform a percutaneous edge-to-edge repair and effectively create a double mitral orifice, based on the original “Alfieri stitch” surgical approach. Accordingly, due to the central location within the valvular complex, A2 and P2 pathology generally provides the ideal anatomy for procedural success. Commissural regurgitant jets pose a technical challenge, due to difficulty delivering the clip and grasping tissue at the ends of the free edge of each leaflet.

The mitral annulus gives a point of attachment for the mitral valve and separates the left atrium from the left ventricle (LV). The anterior, or aortic, aspect of the annulus is fibrous and less prone to dilatation. The posterior aspect...
annulus is a dynamic, nonrigid, oval-shaped structure that alters shape throughout the cardiac cycle. The posterior, or mural, aspect of the annulus is muscular and therefore often subject to dilatation and calcification.

**MitraClip Implantation Pearl**

Following grasping, care must be taken to ensure that adequate tissue from both leaflets has been captured and there is not excessive tension placed on 1 or both leaflets that may lead to leaflet tear or, worse, clip detachment.

The chordae tendineae are fan-shaped chords that arise from the papillary muscles (PM) and insert into the mitral leaflets. The anterolateral and posteromedial PM arise from the mid to apical segments of the LV at the anterolateral and posterior walls, respectively. The posteromedial PM gives chords to the medial aspect of both leaflets (A3, P3, and half of A2 and P2), while the anterolateral PM chords attach to the lateral aspect of the leaflets (A1, P2, and half of A2 and P2).

**MitraClip Implantation Pearl**

Awareness of the chordal structures is important as the clip passes below the valve as entanglement may occur. This risk increases when additional clips are used, as these are passed through the mitral valve in a closed position and opened below the valve in the LV. Risk of chordal entanglement can be minimized by ensuring a coaxial advancement of the clip into the LV.

**PATHOPHYSIOLOGY**

Mitral regurgitation (MR) is the ejection of blood from the LV back into the left atrium during ventricular systole. This is due to failure of the leaflets to adequately coapt (close/seal) or appose (come together and overlap). There are numerous classification systems that describe the etiology of the
regurgitation, which has relevant implications for therapeutic intervention. One such classification divides the etiologies into either primary or functional, also known as secondary, MR (Fig. 46-2). Primary MR is a consequence of valvular pathology, while secondary MR is due to anatomic distortions or functional impairment of the LV. In primary MR, the standard treatment is repair or replacement of the affected valve. In functional MR, therapy involves management of the underlying LV dysfunction or attempted restoration of normal annular size and shape. For select patients in whom optimized medical therapy is unsuccessful, surgical or percutaneous intervention may be pursued.

**FIGURE 46-2** Primary mitral regurgitation (MR) versus functional MR. A. Normal mitral valve function. B. and C. Primary (degenerative) mitral regurgitation. D. Functional (secondary) mitral regurgitation.

**Primary Mitral Regurgitation**

The most prevalent etiology of primary MR is valvular degeneration that causes morphologic changes to the valve, including leaflet thickening and stretching of leaflet tissue. This accounts for approximately 60% of MR cases. The severity of these changes can be limited to focal involvement of 1 leaflet or can range to severe involvement of both leaflets in their entirety. For example, fibroelastic deficiency may account for the single, localized prolapsing segment, which is often normal in appearance. This prolapse is due to focal chordal elongation with or without rupture. Barlow disease, on the other hand, occurs in the setting of extensive myxomatous changes to both leaflets and is associated with chordal thinning and elongation.
Accordingly, segments of both leaflets prolapse into the left atrium. A more severe manifestation is a flail leaflet, characterized by complete eversion of the leaflet edge into the left atrium. A flail may be present in the event of primary chordal rupture and may result in severe mitral regurgitation.

**MitraClip Implantation Pearl**

Actions that may increase the success rate of adequate leaflet grasp include the following:

1. Control heart rate. The more bradycardic, the easier it is to time the clip positioning to ensure optimal grasp into the MitraClip arms.
2. MitraClip arm angle. Usually the clip arm angle is decreased to a 120° angle and pulled back in order to grasp the leaflets. Occasionally, a more obtuse angle may be needed to ensure adequate leaflet capture if the leaflet separation is too wide for capture.

Other less common causes of primary mitral valve disease include infective endocarditis, deep clefts, congenital mitral cleft, and rheumatic mitral disease. As a result of earlier and more effective treatments for rheumatic fever in the developed world, this disease process is decreasing in prevalence and accounts for approximately 12% of MR. This acquired valvulopathy often leads to commissural fusion of the leaflets and results primarily in mitral stenosis with associated regurgitation. Progressive inflammation leads to leaflet and chordal thickening. Over time, the leaflets may calcify and restrict leaflet motion, with subsequent malcoaptation during systole resulting in regurgitation.

**Secondary (Functional) Mitral Regurgitation**

Functional MR occurs in the context of morphologically normal leaflets and subvalvular apparatus, on a background of an underlying dilated cardiomyopathy or ischemic cardiomyopathy secondary to coronary artery disease. This accounts for approximately 25% of MR. The regurgitation is due to geometric perturbations of the LV, which may or may not be associated with dilatation. Regional or generalized wall motion abnormalities
of the LV can distort the position of the papillary PMs during systole, resulting in chordal tension and leaflet restriction. Ventricular dilatation causes subsequent annular dilatation, resulting in failure of leaflet coaptation or inadequate apposition.

**MitraClip Implantation Pearl**

There are currently no commercial indications for the MitraClip in secondary MR.

In functional MR, there are 2 important elements to consider during the MitraClip procedure.

1. Patients with severe LV dilatation will have a larger coaptation gap.
2. The zone of coaptation is lower in functional MR patients than in primary MR patients. Thus, the site of transseptal puncture must be slightly lower in the functional MR cohort.

**NATURAL HISTORY AND PROCEDURAL INDICATIONS FOR MITRAL REGURGITATION**

The clinical course of MR is usually indolent and progressive, except for the rare perimyocardial infarction complication of acute MR due to PM rupture. The posteromedial PM is more prone to rupture compared to the anterolateral PM due to single versus dual blood supply, respectively. The insidious nature of the disease in the majority of patients is a consequence of cardiac compensation for increasing regurgitant volume, initially through enlargement of the left atrium and by increasing LV systolic function as a measure to increase stroke volume and maintain cardiac output. As the valvular regurgitation progresses, the heart loses its ability to compensate for the increased regurgitant volumes and cannot maintain physiologic demands. The LV eventually dilates, with evidence of diastolic dysfunction, elevated pulmonary artery pressures, and ultimately systolic dysfunction, which may
progress to decompensated heart failure. The presence of LV dilatation and attenuated systolic function, particularly in the context of symptoms or functional impairment, heralds a very poor prognosis if left untreated. Annual mortality rates with optimal medical therapy in patients age 50 years or older are approximately 3% for moderate MR and approximately 6% for severe MR.\textsuperscript{4,5}

Until recently, surgical valve repair and replacement were the only treatments proven to improve symptoms and prevent heart failure. Current American College of Cardiology (ACC)/American Heart Association (AHA) and European Society of Cardiology (ESC) guidelines recommend surgical intervention in symptomatic patients with chronic severe primary MR and in asymptomatic patients with chronic severe primary MR with evidence of systolic dysfunction or LV dilatation.\textsuperscript{6,7} MV repair is the preferred method of surgical correction and has been shown to be superior to MV replacement in terms of morbidity and mortality.\textsuperscript{8-10} Mortality has been shown to decrease by approximately 70% in such patients. As expected, the best outcomes are obtained in asymptomatic patients treated in high-volume advanced repair centers with low operative mortality (<1%) and high repair rates (>80%). These results highlight the importance of early detection, assessment, and management of MR by experienced physicians and surgeons.

Patients with secondary MR carry higher preoperative mortality compared to their primary MR counterparts, attributable to severe comorbidities of the latter patient population.\textsuperscript{9,10} Accordingly, the ACC/AHA and ESC guidelines recommend surgery for patients with severe secondary MR and preserved systolic function only when undergoing coronary artery bypass grafting or aortic valve replacement.\textsuperscript{6,7}

Although surgery is the gold standard for treatment, there remains a cohort of patients who are either at prohibitively high risk for surgery or who may not benefit from a valve surgery, particularly those with functional MR. There is scant clinical evidence to demonstrate reduction in mortality following surgical repair in patients with systolic dysfunction and ventricular dilatation. Accordingly, treatment of such patients is debatable. The application of the MitraClip in such patients is the subject of an ongoing clinical trial.
THE MITRACLIP DEVICE

The complete device apparatus is composed of (1) a steerable guide handle attached to the steerable sleeve and the clip delivery system, (2) the clip, (3) the delivery catheter handle, and (4) the delivery catheter (Fig. 46-3).

![MitraClip device](image)

**FIGURE 46-3 MitraClip device.**

The MitraClip device is delivered using a 24-Fr catheter guide with a mobile steerable tip to precisely position the clip. The clip is a 4-mm wide and 8-mm long chrome-cobalt clip with 2 articulated arms that open from 0° (closed position) to 240° (open position), which facilitates grasping and drawing together the anterior and posterior leaflets. The inner parts of the clip’s arms are grippers, lined with small frictional elements that promote more effective grasping of the leaflets once the device has been deployed and is ultimately closed. The outer aspect of the clip is covered in a polyester mesh to promote epithelialization and tissue growth to facilitate a fibrous tissue bridge between the leaflets (Fig. 46-4). The clip delivery system has 2 knobs that control the anterior-posterior and medial-lateral steering of the catheter tip. The delivery catheter handle is composed of: (1) 2 levers to lock/unlock the clip and to lift/depress the gripper lines, respectively; (2) a knob to facilitate the opening and closing of the clips; and (3) a screw to enable release of the clip from the shaft of the delivery catheter.
Procedure

The MitraClip procedure is performed under general anesthesia, primarily to enable pauses in ventilation, which facilitates precise clip positioning and deployment. The additional advantage of general anesthesia is comfort to the patient, particularly in the context of a potentially lengthy procedure (which is contingent on operator experience and valvular anatomy) as well as extended periods of transesophageal echocardiography (TEE) evaluation.

One of the key advantages of the MitraClip procedure is that it is performed via venous access. It is recommended to use a micropuncture needle for veinotomy, in order to minimize vascular complications and ensure optimal sheath placement. Two sites of venous access are required. The first site is the jugular or femoral vein for right heart catheterization at the commencement of the procedure and immediately following release of the clip, which provides some indication of the efficacy of the intervention. A second venous sheath is placed in the femoral vein for eventual passage of the 24-Fr MitraClip apparatus. A Perclose ProGlide suture can be placed in a “pre-close” fashion to achieve hemostasis at the conclusion of the case. Alternatively, a figure of 8 suture can be applied at the end of the case to provide local external hemostasis.
MitraClip Implantation Pearl

As opposed to arterial closure, deployment of the Perclose suture may be performed with much less tension on the sutures and still result in adequate venous stasis. Avoidance of overtightening may decrease risk of venous stenosis.

Cardiac imaging with visualization of the interatrial septum (IAS) and the mitral valve apparatus is vital to the success of the MitraClip procedure. Operators should be able to obtain and interpret echocardiographic views to guide transseptal puncture, device positioning, and clip deployment. Furthermore, operators should be aware of the parameters used to assess the success of clip deployment based on echocardiographic interrogation, including but not limited to an immediate decrease in 2-dimensional color Doppler regurgitant jet, decrease in proximal isovelocity surface area, reduction in regurgitant volume, and improvement of pulmonary venous flow. Repeat hemodynamic assessment should demonstrate improvement of pulmonary pressures with decrease of V wave and reduction in left atrial pressure. At our institution, TEE is performed by a cardiac anesthesiologist or cardiologist experienced in MitraClip procedures, with an understanding of the expectations and requirements of the operator. Effective communication between the echocardiogram operator and the interventional cardiologist is imperative to facilitate an efficient and effective procedure.

MitraClip Implantation Pearl

Periprocedural planning is imperative to the success of the MitraClip deployment. A multidisciplinary heart team approach is recommended to confirm the etiology of the MR, assess for presence of significant baseline stenosis, and determine the most effective site of clip placement to ensure resolution of the regurgitation.

Arguably, the transseptal puncture is the most critical step of the procedure. If the puncture is inaccurate, subsequent device maneuverability
and clip positioning are made difficult, often resulting in failed or, at best, unsatisfactory clip deployment position reflected by minimal or no improvement in MR. Furthermore, poor clip position may actually worsen the degree of MR or create a mitral stenosis gradient. Accordingly, great care must be taken to ensure precise transseptal puncture, repeating the process if necessary to ensure an optimal starting position. The transseptal puncture is performed under both fluoroscopic and TEE guidance using standard equipment and technique.

To perform transseptal puncture, simultaneous viewing of a short-axis biatrial image for anteroposterior positioning and a bicaval image for superoinferior positioning is recommended. The optimal site for puncture is located slightly inferior and posterior on the septum (Fig. 46-5). Once this position is located, obtain a 0°, midesophageal, 4-chamber view to measure the “device distance,” defined as the distance of the septal puncture from the mitral annulus. Ideally, this distance should be 4.0 to 4.5 cm above the mitral annulus as measured perpendicular to the plane of mitral valve coaptation during systole (Fig. 46-6).

**FIGURE 46-5** Transseptal puncture.
MitraClip Implantation Pearl

Transseptal puncture may be facilitated by placing a bend on the BRK needle. With left atrial enlargement, a BRK-1 needle should be considered. If difficulty is encountered puncturing the septum, such as in the case in a thickened or fibrotic septum, focal cautery orization of the septum may be used to facilitate entry.

Once the needle is across the septum, the entire system is advanced into the left atrium and heparin is administered for anticoagulation with a target activated clotting time of >250 seconds. The 24-Fr Abbott MitraClip delivery steerable system is then advanced over a superstiff wire into the left atrium. The superstiff wire is then removed and the baseline left atrial pressure recorded. Next, the MitraClip device is carefully advanced into the left atrium through the device deployment sheath under fluoroscopy and TEE guidance. From the plane of entry into the left atrium, parallel to the mitral annulus, the clip delivery system should first be steered toward the valve using the
medial-lateral steering knob to turn the device 90°. By turning the guide clockwise, the clip is aligned perpendicular to the annulus. Once the device reaches just above the leaflets, an assessment of the position of the clip in a mediolateral and anteroposterior plane is made, using bicommissural (midesophageal view, approximately 50-75°) and LV outflow tract (midesophageal, approximately 115-145°) echocardiographic views, respectively (Fig. 46-7).

FIGURE 46-7 Bicommissural and left ventricular outflow tract views.

The trajectory of the clip is optimized by moving the delivery catheter handle up and down while assessing the direction of the delivery shaft. Adjustments in the medial or lateral direction are made in the bicommissural view either by moving the entire system or by adjusting the M knob. Adjustments in the anterior or posterior direction are made in the LVOT view by rotating the guide handle counterclockwise or clockwise, respectively. Once an ideal position is achieved, the clip is opened to 180°, and a 3-dimensional enface “surgeon’s view” of the mitral valve is obtained to assess for orientation of the clip arms relative to the leaflets (Fig. 46-8). Any adjustments are made by rotating the delivery catheter handle in the desired direction and then transmitting the torque by moving the handle up and down.
rapidly. Once the clip is perpendicular to the leaflets, the clip is advanced in the open position through the valve. The orientation of the clip is then reconfirmed, followed by closure of the clip to 120°. Next, the delivery catheter handle is retracted slowly to grasp both leaflets into the semi-opened clip. Once leaflet capture is confirmed, the grippers are pushed down, and the clip is completely closed. TEE interrogation is then performed in multiple views to ensure leaflet capture with adequate tissue grasp, reduction in MR (assessed by regurgitant volume, size of MR proximal isovelocity surface area, and pulmonary vein Doppler), and absence of a significant stenosis gradient (Fig. 46-9). If these procedural goals have been met, the clip is released. If these goals are not met, and significant MR persists without significant stenotic gradient (<6 mm Hg), the clip can be opened and repositioned or additional clips can be positioned and deployed. These are deployed in the previously described manner with 1 key difference: subsequent clips are passed through the valve in a closed position "then opened below" the valve in the ventricle. Placement of additional clips carries a risk of worsening MR due to deformation of the leaflets, clip interaction with potential instability, and/or significant stenosis. An inherent advantage of the MitraClip device is the ability to remove a clip following closure and subsequent assessment. If the operator is dissatisfied with the result of an additional clip, this can simply be opened, detached from the leaflet, brought back into the guide, and removed from the body.

**FIGURE 46-8** A. Checking orientation in 3-dimensional (3D) enface view. B. Correcting orientation in 3D enface view.
FIGURE 46-9 Predeployment check. A. Leaflet insertion. B. Reduction in regurgitation (i) preprocedure and (ii) postprocedure. C. Pulmonary vein assessment (i) preprocedure and (ii) postprocedure. D. Mitral stenosis (i) preprocedure and (ii) postprocedure.

**MitraClip Implantation Pearl**

It is technically more challenging to place multiple clips. Due to a lack of adequate clearance between the septum and the valve plane, if there is any expectation or consideration for multiple clips, it may be helpful to place the first clip in the more medial position with all subsequent clips placed laterally.

The MitraClip procedure is generally safe and well tolerated. Aside from the risks associated with general anesthesia, those specific to the procedure
include femoral venous complications; transseptal trauma resulting in an atrial septal defect (significant shunts may require closure) or left atrial perforation (care must be taken to manipulate the guide catheter away from the posterior wall of the left atrium prior to removal); clip detachment and embolization (clip stability must be assessed fluoroscopically and via echocardiography prior to final release of the clip); and endocarditis. The overall rate of such adverse events in experienced centers is less than 1%.

**CLINICAL OUTCOMES FOR THE MITRACLIP**

Table 46-1 summarizes the relevant clinical studies. Procedural success was achieved in the majority of patients with reduction of MR from 4+ to <2+ in all of the listed studies. Additionally, these results were attained with an excellent safety profile without significant rates of adverse procedural outcomes.

Abbreviations: DMR, degenerative mitral regurgitation; FMR, functional mitral regurgitation; MR, mitral regurgitation; NA, not applicable; STS, Society of Thoracic Surgeons.

The EVEREST trial16 early cohort investigated the MitraClip, and 1-year clinical outcomes were published in 2009. This was a prospective, multicenter study evaluating the feasibility, safety, and efficacy of MitraClip in patients with moderate-to-severe (3+) or severe (4+) MR with a class I
surgical indication. In total, 107 patients were enrolled, which included 55 from the EVEREST I cohort and 52 from the prerandomization phase of EVEREST II, with a mean follow-up of nearly 2 years. This very early experience demonstrated the feasibility and safety of the MitraClip device. There was a very low periprocedural complication rate, with 30-day and 1-year mortality rates of 0.9% and 4.1%, respectively. In addition, this study demonstrated a meaningful reduction of MR in up to two-thirds of a carefully selected group of patients.

The subsequent landmark study was EVEREST II in 2012. This was a multicenter randomized clinical trial designed to compare the efficacy and safety of percutaneous treatment with MitraClip as compared to conventional surgical MV repair or replacement. From a total of 279 patients, ultimately 170 were assigned to the MitraClip group and 80 to the control group. Compared to surgery, the MitraClip had a lower 30-day complication rate. At 1 year of follow-up, surgery was more effective in reduction of MR, but there was equivalent improvement of symptoms, functional class, and favorable LV remodeling in both groups. Furthermore, these symptomatic improvements were sustained after 4 years, as evidenced by persistent reductions in New York Heart Association (NYHA) functional class. The 4-year follow-up results reported no mortality difference between the MitraClip and surgical cohorts, a low rate of subsequent MV surgery in the MitraClip repaired group beyond the first 6 months of therapy, and a low rate of adverse events from 1 to 4 years in both groups.

The EVEREST II High-Risk Registry (HRR) was a substudy from the EVEREST II cohort that included patients with moderate-severe or severe MR with an estimated surgical risk of 12% or greater, based on the Society of Thoracic Surgeons risk score or as estimated by the surgical team. Enrollment of patients has continued as part of the REALISM Registry, which has 2 arms: high-risk patients and non–high-risk patients. The combined REALISM and EVEREST II HRR demonstrated an impressive 30-day mortality of less than 5% with significant improvement in patient-reported symptoms, reduced rate of hospitalization, and improved LV remodeling at 1 year. These trials also support that after the learning curve is overcome with more procedural experience, better outcomes are to be expected as compared to the statistics reported in the initial trials.

Based on the outcomes from EVEREST II, the AHA/ACC guidelines state
that the MitraClip intervention should only be considered for high-risk or nonoperable patients with chronic primary MR who remain severely symptomatic with NYHA class III to IV heart failure symptoms despite optimal heart failure therapy. Similarly, the ESC guidelines recommend that MitraClip may be considered in patients with symptomatic severe primary MR who fulfill the echocardiographic criteria of eligibility, are judged inoperable or at high surgical risk by a heart team, and have a life expectancy greater than 1 year. Uniquely, however, based on experience from the EVEREST trials and observational studies, ESC guidelines suggest that MitraClip is feasible at low procedural risk in patients with secondary MR in the absence of severe tethering and may provide short-term improvement in functional condition and LV function. In 2013, the ACCESS-EU trial supported this recommendation as this patient cohort was comprised of a predominantly functional MR “real-world” population, yet had favorable results showing the effectiveness and safety of the procedure. While the AHA/ACC guidelines acknowledge that MitraClip provides a safe, less invasive, effective alternative to surgery, the procedure is not yet approved for clinical use for secondary MR in the United States.

The currently enrolling COAPT trial is a randomized, parallel-controlled, multicenter clinical evaluation of the MitraClip device for the treatment of clinically significant secondary (functional) MR in symptomatic heart failure subjects who are treated per standard of care with optimal medical therapy but have been deemed ineligible for MV surgery. Eligible subjects will be randomized in a 1:1 ratio to the MitraClip device or to no MitraClip device (control group). The primary outcome measures include the primary safety end point (composite of single leaflet device attachment, device embolizations, endocarditis requiring surgery, mitral stenosis requiring surgery, and any device-related complications requiring nonelective cardiovascular surgery) and the primary effectiveness end point (recurrent heart failure hospitalizations). The conclusion and results of this investigation are eagerly anticipated and will likely frame the guidelines for the safety and efficacy of MitraClip in patients with functional MR.

**CONCLUSION**

The mitral valve apparatus is a complex anatomic structure with numerous
components that must work in concert for the valve to function. The most common cause of MR is primary MR, which has traditionally been remedied with surgical valve repair or replacement. Recently, the MitraClip device has emerged as a safe and effective alternative approach to treat high-risk patients with severe MR with proven durability and clinical improvement. The excellent safety profile for the procedure can be attributed to 2 key elements. First, this percutaneous repair is completed via transvenous access, which limits the significance of vascular complications compared to an open surgical approach. Second, the transseptal approach is a far less invasive method of accessing the mitral valve compared to surgical access via the left atrium whether by sternotomy or with minimally invasive or robotic surgery. In the United States, current US Food and Drug Administration approval for the MitraClip device is only for treatment of high-risk, nonoperable patients with primary MR. The currently enrolling randomized COAPT study is expected to address the additional information of the safety and utility of this device in the setting of secondary, or functional, MR compared with medical therapy alone. Short- and intermediate-term follow-up have further supported the use of the MitraClip as a safe minimally invasive therapy for severe MR, but additional investigations must be pursued to evaluate the long-term risks and benefits of this intervention.

REFERENCES

**MULTIPLE CHOICE QUESTIONS**

1. Which of the following is NOT a characteristic of the anterior leaflet?
   A. It is broader than the posterior leaflet.
   B. It is also known as the mural leaflet.
   C. It comprises one-third of the annular circumference.
   D. It shares a fibrous continuity with the left and noncoronary cusps of the aortic valve.

2. The MitraClip is based off of what surgical technique?
   A. Mitral valve annuloplasty
   B. David’s technique
C. Feikes technique  
D. Alfieri stitch

3. How can you minimize risk of chordal entanglement with the MitraClip?  
A. By using multiple clips  
B. By making the majority of positioning adjustments after the clip is advanced into the ventricle  
C. By making the majority of positioning adjustments when the clip is within the valve leaflets  
D. By ensuring coaxial advancement of the clip prior to moving into the left ventricle

4. Which of the following statements is true regarding strategies to minimize complications with transseptal puncture?  
A. Adjunctive imaging techniques rarely provide additional information or utility compared to fluoroscopy alone.  
B. After transseptal puncture, slight counterclockwise rotation of the transseptal needle may be helpful to avoid puncturing the posterior wall of the left atrium (LA).  
C. After transseptal puncture, slight counterclockwise rotation of the transseptal needle may be helpful to avoid puncturing the aorta.  
D. The optimal site for puncture is located anterior and superior on the septum.

5. Which of the following conclusions about the EVEREST II trial are correct?  
A. There was a lower 30-day complication rate compared to surgery.  
B. At 1 year, surgery was more effective in reducing mitral regurgitation with no clinical differences in terms of symptoms, functional class, and LV remodeling.  
C. Four-year follow-up showed no mortality difference between MitraClip and surgery.  
D. A and B  
E. B and C  
F. A and C  
G. All of the above
ANSWERS

1. B

The valve is also known as the aortic leaflets, which share a continuity with the aortic valve (left and noncoronary cusps) that is often referred to the intervalvular fibrosa or aortic-mitral curtain. All the other answers are characteristics of the anterior leaflet.

2. D

The Alfieri stitch is an edge-to-edge repair/plication. Percutaneous mitral annuloplasties are currently under investigation but use a different technique for valvular intervention. David’s technique is a surgical technique that preserves the anterior leaflets and its chordal attachments by excising a central trapezoidal segment of the anterior leaflet and resuspending the residual leaflet to the anterior annulus. In the Feikes technique, the anterior leaflet is incised in the midline and the incision is extended sideways, then the 2 segments of the anterior leaflet are turned backward and sutured to the posterior mitral annulus.

3. D

Multiple clips and positional changes when in the left ventricle (LV) increase the risk of entanglement. The manipulation of the valve at the level of the valve does not increase entanglement into the chords; however, it is not advisable. The best way to minimize risk of entanglement is to perform the majority of the positioning adjustments when the clip is in atria, prior to inserting into the LV. Minor changes and fine adjustments can be made in the ventricle with caution and visualization on transesophageal echocardiography (TEE) and fluoroscopy to ensure the clip does not tangle.

4. B

TEE is essential to the MitraClip procedure; without it, the procedure would not be possible. TEE accurately and reliably identifies the inferior-posterior location that is usually the optimal site of puncture. B is correct; slight counterclockwise rotation of the transseptal needle may be helpful to avoid
puncturing the posterior wall of the LA. Clockwise rotation is needed if the needle is pointed toward the aorta.

5. G

All of the above are true statements.
Percutaneous Left Atrial Appendage Closure

Maurice Buchbinder

INTRODUCTION

Atrial fibrillation (AF) is the most common cardiac arrhythmia in adults with a current prevalence estimated at 1.5% to 2% of the general population. With the aging population in the United States, AF prevalence is projected to increase steadily from approximately 6 million cases in 2010 to 15.9 million by 2050. AF is a major cause of stroke, being responsible for 15% of all strokes and 30% of strokes in patients over age 80. Unfortunately, stroke is the leading cause of long-term disability and the fourth leading cause of death in the United States. The presence of AF is associated with a 4- to 5-fold risk of ischemic stroke, and the incidence increases significantly with advancing age. Moreover, strokes associated with AF are more severe; AF-related stroke victims have a 50% greater likelihood of becoming disabled or handicapped and a >50% likelihood of death. Accordingly, stroke prevention with anticoagulation is one of the main pillars of AF management, and guidelines for anticoagulation have become more stringent recently. The Canadian Cardiovascular Society had lowered their threshold for recommending oral anticoagulation (OAC) for CHADS\textsubscript{2} (congestive heart failure, hypertension, age 75 years, diabetes mellitus, stroke) score $\geq$1, the
European Society of Cardiology (ESC) for CHA$_2$DS$_2$-VASc (congestive heart failure, hypertension, age $\geq$75 years, diabetes mellitus, stroke/transient ischemic attack, vascular disease, age 65-74 years, sex category) score $\geq$1, and the American College of Cardiology (ACC) for CHA$_2$DS$_2$-VASc score $\geq$2.$^{1,8-10}$

**Anticoagulation for AF and Limitations**

Several randomized placebo-controlled trials have demonstrated that OAC is highly effective in preventing thromboembolism with AF, and landmark meta-analysis with warfarin demonstrated a 64% relative stroke reduction and 26% relative mortality reduction.$^{11,12}$ Although OAC is the current gold standard for AF stroke prevention, a significant proportion (30%-50%) of eligible patients do not receive therapy due to absolute contraindications or perceived risks of bleeding.$^{13,14}$ Furthermore, OAC increases the incidence of major bleeding despite the use of novel OAC (NOAC); a recent meta-analysis of all 4 NOAC trials showed major bleeding rates of 6.2% with warfarin and 5.3% with NOAC.$^{15}$ Even though the risk of intracranial hemorrhage is consistently lower with NOAC, overall major bleeding is not diminished with dabigatran or rivaroxaban compared with warfarin.$^{16,17}$ Apixaban and edoxaban were the only 2 agents that lowered major bleeding compared to warfarin.$^{18,19}$

There are also other concerns with OAC therapy, including patients with renal and liver dysfunction (excluding use with NOAC), high risk of falls, noncompliance, and patients requiring dual antiplatelet therapy after stent placement. For warfarin, there are additional issues with drug and diet interaction, the need for anticoagulation monitoring, and narrow therapeutic window, with time in therapeutic range of only 50% to 60% in community practices.$^{20,21}$ There are also high discontinuation rates with OAC even in the setting of clinical trials, with discontinuation rates of 16% to 34% for warfarin and 21% to 37% with NOAC at the end of study follow-up.$^{16-19}$

Therefore, even though OAC is effective for thromboembolic prevention, there remains a large proportion of eligible patients not on therapy for a multitude of reasons. Moreover, there is a residual stroke risk of 2% to 5% annually despite optimal OAC.$^{22}$ These challenges have led to the investigations of device-based therapies for nonvalvular AF. In fact, the ESC
recently gave a Class IIB recommendation for percutaneous left atrial appendage (LAA) closure for patients with high stroke risk and contraindications to long-term OAC.\textsuperscript{9}

**Rationale for LAA Occlusion**

In the presence of AF, the left atrium loses active contraction, leading to decreased blood velocity in the LAA, which results in stasis and increased risk of thrombus formation.\textsuperscript{23} Abnormalities in the thrombosis cascade in overloaded LAA may additionally increase the risk of thrombus formation with AF.\textsuperscript{24} Transesophageal echocardiography (TEE), autopsy, and surgical reports confirmed that >90% of nonrheumatic AF-related left atrial thrombi were isolated to or originated from the LAA.\textsuperscript{25} Atrial thrombi are detected on TEE in approximately 15% of AF patients not receiving long-term OAC.\textsuperscript{26} The presence of LA thrombus, spontaneous echo contrast, and low LAA velocities (≤20 cm/s) are independent predictors of stroke and thromboembolism on TEE.\textsuperscript{27-29} Thus, local mechanical approaches to exclude the LAA from systemic circulation to limit embolization in nonvalvular AF patients have been developed. Early attempts of surgical removal or ligation of LAA developed over 60 years ago were limited by the invasiveness of major cardiac surgery and by significant rates of incomplete exclusion that were associated with increased risks (~2.5-fold) of stroke.\textsuperscript{30,31} Minimally invasive percutaneous approaches have since been developed over the past 2 decades and can be broadly divided into endocardial and epicardial devices (Table 47-1). This chapter reviews contemporary percutaneous LAA closure, with in-depth discussions of the available leading devices with regard to procedural techniques and clinical outcomes.

**INDICATIONS FOR PERCUTANEOUS LAA CLOSURE**
The current most commonly adopted indication for percutaneous LAA closure is for patients ineligible for long-term OAC, although this practice varies geographically. In Europe, the majority of LAA closures are done according to the ESC recommendation for patients with high stroke risk and contraindications to long-term OAC. However, there are high-volume centers (eg, in Switzerland and Germany) where LAA closures may be performed for anticoagulation-eligible patients, and this is likely related to the full reimbursement of this procedure in these countries. In Canada, LAA closure is generally restricted to patients with high stroke risk and contraindications to long-term OAC. In the United States, LARIAT (SentreHEART, Redwood City, CA) and WATCHMAN [Boston Scientific, Natick, MA] received approval by the US Food and Drug Administration [FDA]) and may be performed for patients with high stroke risk with or without contraindications to OAC.

**CURRENTLY AVAILABLE DEVICES FOR PERCUTANEOUS LAA OCCLUSION**

**WATCHMAN**

The WATCHMAN device was the second dedicated LAA device manufactured after PLAATO (Appriva Medical, Sunnyvale, CA), which was the first device manufactured but was subsequently removed from the market for commercial reasons. WATCHMAN was originally designed and manufactured by Atritech (Plymouth, MN) and was acquired by Boston Scientific in 2011. The current second-generation WATCHMAN LAA Closure Technology is constructed of a self-expanding nitinol frame covered by a permeable 160-μm polyethylene terephthalate (PET) membrane (Fig. 47-1). There are 10 fixation anchors at the perimeter of the nitinol frame that are designed to engage the LAA tissue for device stability. The PET membrane covers approximately 50% of the proximal outer aspect of the nitinol frame, which blocks thrombus embolization from the LAA and promotes endothelialization. The spherical contour of WATCHMAN can
accommodate most LAA anatomy. There are 5 device sizes available (21, 24, 27, 30, and 33 mm), and all are delivered through dedicated 14-Fr sheaths (double curve, single curve, and anterior curve). The fourth-generation device was evaluated in a European registry, and the fifth-generation (WATCHMAN-FLEX) device is awaiting first-in-man evaluation. The WATCHMAN received Conformité Européene (CE) mark in 2005 and FDA approval in March 2015. To date, >10,000 WATCHMAN devices have been implanted worldwide.
FIGURE 47-1 A. The WATCHMAN device. B. The double-curve and single-curve 14-Fr access sheaths. There are 3 radiopaque marker bands (33, 27, and 21 mm) on the distal sheath, which should be aligned to the left atrial appendage (LAA) “ostium” according to the size of the device used.

Amplatzer Cardiac Plug and Amulet

The Amplatzer Cardiac Plug (ACP) (St. Jude Medical, Plymouth, MN) is the third dedicated LAA device to be manufactured and is specifically designed to occlude the proximal segment of the LAA. In Europe, operators initially used nondedicated Amplatzer devices for LAA closures in a small series of patients. However, the incidence of embolization was high (12% in the 32-patient series in Bern), and these nondedicated devices are no longer used for this indication.

This device consists of a self-expanding nitinol mesh, which forms a lobe and a disc connected by a central articulating waist (Fig. 47-2). The lobe is intended to be implanted at 10 mm inside the orifice (proximal neck of LAA) and, along with the 6 pairs of stabilizing wires at the distal lobe, serves as the key anchoring mechanism. The disc is intended to be deployed in the left atrium and pulled in under traction against the LAA orifice by the central waist, which helps seal the orifice. Both the lobe and disc have polyester mesh sewn in manually. The ACP comes in 8 different sizes according to the lobe dimension accommodating LAA diameters of 12.6 to 28.5 mm (Fig. 47-3). The second-generation ACP device, Amulet, is similar in design but has a wider lobe, longer waist, recessed proximal end screw, and more stabilizing wires. These features improve device stability and may theoretically reduce the risk of thrombus formation on the atrial side of the device. Amulet comes in 8 different sizes and can accommodate larger LAA (up to 32 mm diameter). The ACP device has to be manually loaded onto the delivery cable, but Amulet comes preloaded on the delivery cable for ease of setup. ACP/Amulet is delivered through the TorqueVue 45 × 45 sheath (see Fig. 47-2), which has a 3-dimensional distal tip allowing anterior and superior angulation for coaxial positioning at the landing zone. The TVLA1 and TVLA2 sheaths are no longer being manufactured. The access sheath size varies according to device size (see Fig. 47-3).
FIGURE 47-2 Amplatzer Cardiac Plug device showing the 2 key components of the lobe and disc and the recommended TorqueVue 45 × 45 sheath.

FIGURE 47-3 Device characteristics of Amplatzer Cardiac Plug (left) and Amulet (right).
The ACP received CE mark approval in December 2008, and the Amulet was approved in January 2013. The delivery system of Amulet has been redesigned, and the updated system will be relaunched in the latter half of 2014. To date, >10,000 ACP/Amulet devices have been implanted worldwide.

**LARIAT**

The LARIAT LAA closure system requires both an endocardial and epicardial approach for implantation. LARIAT has FDA and CE mark approvals for suture and knot tying during surgical applications but is not approved specifically for stroke reduction with AF. There was a prior surge in interest and procedural volume in the United States before the approval of WATCHMAN, due to the availability of this device for patients who were not candidates for anticoagulation. LARIAT consists of a snare with a pretied suture that is magnetically guided over the LAA in the epicardium. The device consists of 3 components: (1) 15-mm compliant occlusion balloon catheter (EndoCATH), (2) 0.025- and 0.035-inch magnet-tipped guide wires (FindrWIRZ), and (3) 12-Fr LARIAT suture delivery device.\(^{34}\)

**WaveCrest**

The WaveCrest occluder by Coherex Medical (Salt Lake City, UT) is made of a nitinol frame with retractable anchors to enable optimal device positioning. The occluder is covered by a polytetrafluoroethylene (PTFE) membrane on the left atrial side of the device and a foam substrate on the inside surface to minimize peridevice leak. In contrast to other devices, the anchoring system can be operated independently of the lobe, allowing repositioning before anchoring. Contrast can be injected through the delivery sheath or on the appendage side of the occluder to evaluate occlusion. It comes in 3 sizes (22, 27, and 32 mm) and can be implanted through 4 different 15-Fr delivery sheaths. The device was first implanted in June 2012, and CE mark was obtained in 2013.

**IMPLANTATION TECHNIQUES FOR**
WATCHMAN, ACP/AMULET, AND WAVECREST

**Preprocedural Imaging**

Baseline TEE is important to exclude preexisting LAA thrombus and to assess LAA anatomy for device closure suitability. A full 0° to 180° sweep of the LAA is useful to appreciate the anatomy and for accurate widest and deepest dimension measurements. For WATCHMAN, the widest LAA ostium (from the level of the circumflex artery to ~2 cm within the pulmonary vein ridge) is measured at 0°, 45°, 90°, and 135°, and the available depth (from ostium to apex of LAA) is also measured at the same angles (Fig. 47-4). For ACP, measurements at both the short-axis (30-60°) and long-axis (120-150°) angles of the landing zone and orifice are performed. The LAA orifice for ACP/Amulet is measured from the pulmonary vein ridge to the circumflex artery. The landing zone is measured at 10 mm inside the orifice for ACP (~13-18 mm for Amulet), at an angle that is perpendicular to the neck axis. The LAA depth is measured from the orifice to the back wall along the axis of the neck. The LAA measurements are usually wider at the long axis (corresponding to caudal projection on fluoroscopy) compared to the short axis (corresponding to right anterior oblique [RAO] cranial).
Preprocedural cardiac computed tomography angiography (CCTA) is also useful given its superior spatial resolution and 3-dimensionality as a noninvasive alternative to or in addition to TEE. CCTA has excellent sensitivity for ruling out LAA thrombus. Although the specificity and negative predictive value for LAA thrombus have traditionally been suboptimal with CCTA due to difficulty differentiating thrombus from inadequate contrast mixing (eg, spontaneous echo contrast), additional protocols using double contrast injections, delayed imaging, dual energy, and prone positioning have optimized the results.\textsuperscript{35} CCTA also offers superior anatomic visualization and measurements of the LAA compared to TEE. Patients do not need to be fasting prior to CCTA; furthermore, saline infusion is typically administered before scans, providing more accurate measurements at euvoletic states. Thus, CCTA may become a preferred alternative to TEE in experienced CCTA centers and is increasingly being used.
performed routinely prior to LAA closures.

**Procedural Imaging**

Procedural TEE is the routine standard in the majority of centers and is typically accompanied by general anesthesia. There are a few centers adept at procedural intracardiac echocardiography (ICE) to guide LAA closure, obviating the need for general anesthesia. However, obtaining adequate ICE LAA images can be challenging, and proceduralists may overcome this problem by advancing the ICE probe into the left atrium through another transseptal puncture. Although a few centers rely on fluoroscopy alone during LAA closure, this is not advised for the average operator.

**Transseptal Puncture**

Venous access is preferred through the right femoral vein for more direct transseptal access. Access site subcutaneous tissues should be well prepared and separated with scalpel and forceps to ease advancement of large 13- to 14-Fr sheaths. Manual compression, “figure-of-8” suture, and preclosing with 6-Fr Perclose (Abbott Vascular, Chicago, IL) are commonly used for venous hemostasis.

The preferred location for transseptal puncture is inferior and posterior at the fossa ovalis for all endocardial LAA devices. This position is gauged well with the bicaval and short-axis TEE view, respectively. ICE is a good alternative to guide transseptal puncture. It is generally advised not to use a patent foramen ovale as the access, but instead to perform a separate transseptal puncture inferoposteriorly to provide more direct vector orientation to access the LAA, which arises anteriorly and superiorly. Intravenous heparin is administered before or immediately following transseptal puncture to maintain an activated clotting time (ACT) >250 seconds. Adequate mean left atrial pressure (10-15 mm Hg) should be attained with fluid bolus for accurate LAA measurements.

**Fluoroscopic LAA Measurements**

Following transseptal access, a 5-Fr marker pigtail may be advanced into the LAA and cineangiograms taken in multiple projections to ascertain the LAA
anatomy and measurements. RAO caudal projections usually provide better visualization of the mid-distal LAA for WATCHMAN, whereas RAO cranial projections better visualize the ostium and proximal LAA for ACP/Amulet. Multiple angiographic views are often taken and can be predicted by baseline CCTA for angle selection. For WATCHMAN, it is common to start with RAO (20-30°) caudal (20-30°), posteroanterior (PA) caudal (20-30°), and RAO (20-30°) cranial (10-20°) projections. For ACP, we usually start with RAO (30°) cranial (10°), RAO (30°) cranial (30°), and PA caudal (20-30°) projections.

**Access Sheath Advancement**

To cross the interatrial septum with the access sheath safely, a long (260-cm) J-tipped stiff 0.035-inch wire (eg, Amplatz Super Stiff J-tip 3-mm curve) should be advanced into the left upper pulmonary vein (LUPV) as a rail support. The appropriately sized access sheath can then be safely advanced to the LUPV ostium on the stiff wire. To ease sheath access, the venous access and subcutaneous tissue should be dilated well, and the sheath should be gently rotated during advancement to achieve coaxial approach when crossing the septum. To advance the sheath into the LAA, it is best to use a pigtail (5-6 Fr) to seek the LAA orifice and then use it as a rail to safely navigate the sheath into the LAA.

For WATCHMAN, the 14-Fr access sheath is advanced deep into the LAA until the corresponding radiopaque marker band for the device size (see Fig. 47-1B) is aligned with the LAA ostium. Once in position, the pigtail is removed, and often some catheter torque is required to maintain sheath position in the distal lobe.

For ACP/Amulet, the appropriately sized sheath/dilator is usually advanced to the LUPV orifice over the stiff J-wire, and then the sheath is withdrawn slightly and counterclocked to fall into the LAA ostium. Alternatively, a J-wire or pigtail may be used to facilitate engaging the LAA to minimize traumatizing the thin left atrium.

**WATCHMAN Sizing and Implantation Steps**

WATCHMAN sizing is based on the widest LAA ostium diameter, which should be 17 to 31 mm to accommodate available devices. The instructions
for use recommend oversizing by 9% to 25%, which generally corresponds to 2 to 4 mm oversizing based on widest dimension. The depth of the LAA should be roughly as deep as the device diameter chosen. The delivery system containing the compressed device should be prepped and de-aired and then introduced into the access sheath. The delivery system is advanced until both distal marker bands of the delivery system and access sheath are aligned; the sheath unit is then “locked” in place. The device is then unsheathed slowly by withdrawal of the access sheath, preferably inducing apnea in intubated patients to allow stable deployment. Once the device is fully unsheathed, it may still be partially recaptured if the device is implanted too distally and then redeployed more proximally by withdrawal of the sheath. If the device is too proximal or if the sizing or position is suboptimal, the device can be fully recaptured and removed. A new device and delivery system can then be reintroduced through the existing 14-Fr access sheath.

The PASS criteria should be met before device release: position (device distal to or at LAA ostium; small protrusion of shoulder by <5-7 mm is acceptable), anchor (a tug test to assess stability by retracting the deployment knob and letting go), size (widest device shoulder should be compressed 8%-20% of original size on TEE), and seal (assess for any residual flow on TEE; must be <5 mm before release). When these criteria are met, the device may be released by counterclockwise rotation of the cable for 3 to 5 turns. Final angiography and TEE assessment are then performed.

**ACP/Amulet Sizing and Implantation Steps**

ACP sizing is based on the widest landing zone diameter on fluoroscopy or TEE. A standard recommendation is to upsize the device by 3 to 5 mm for ACP and 2 to 4 mm for Amulet. This degree of oversizing improves stability of the device; however, caution should be exercised if the landing zone is very elliptical to avoid dramatic oversizing in the narrowest dimension, which often results in the lobe jumping out of the LAA.

The prepped device is advanced to the tip of the access sheath, which is positioned at the landing zone of the LAA (10 mm from the orifice for ACP and 13-18 mm for Amulet). The first step of device deployment is unsheathing by withdrawal of the delivery sheath to deploy the “ball.” Once the “ball” is formed, the system can be relatively safely advanced or withdrawn within the LAA to achieve optimal position. The remainder of the
lobe is then deployed by a “push-pull” maneuver, which often requires counterclockwise rotation of the sheath to allow coaxial expansion of the lobe for full contact against the LAA neck. Adequate positioning of the lobe is assessed on cineangiogram and TEE before deploying the disc. This step requires slight traction of the delivery cable during unsheathing of the disc to separate the lobe from the disc and to ensure that the disc is deployed in the left atrium. If the position is unsatisfactory at any point prior to release, the disc and lobe can be resheathed into the “ball” configuration, ensuring that the 2 platinum markers on the lobe do not enter the radiopaque band on the sheath (which marks the location of the stabilizing wires at the tip of the sheath). If a different device size is required, the device can be completely withdrawn, but the sheath would need to be replaced before introducing the new device.

Five criteria should be met before releasing the ACP/Amulet device: (1) tire-shaped lobe (which ensures adequate compression of the lobe and engagement of stabilizing wires); (2) separation of the lobe and disc (ensuring that the disc is pulled in against the LAA orifice with good seal); (3) concavity of the disc (indicating traction of the disc from the lobe with good seal); (4) axis of the lobe (should be perpendicular to the neck axis at the landing zone, which ensures proper contact of lobe and stabilizing wires against the LAA); and (5) lobe is adequately within the circumflex artery on TEE (the width of the lobe should be two-thirds or greater within the circumflex). If there is uncertainty about device stability, a gentle tug test by slight pulling of the disc may be performed, but vigorous wiggle testing should be avoided. Alternatively, the device can be observed for several minutes to assess for any device movement prior to release. The presence of residual leak is assessed on TEE, and contrast injection is performed through the delivery sheath to assess optimal positioning. If satisfactory position is achieved, the device is released with counterclockwise rotation of the delivery cable.

IMPLANTATION TECHNIQUES FOR LARIAT

For the LARIAT procedure, a preoperative CCTA is necessary to exclude
large (>40 mm) appendages and other anatomic contraindications (eg, posteriorly rotated LAA under the pulmonary artery, pericardial adhesions), which may occur in up to 20% of cases. TEE is also performed before the procedure to exclude LAA thrombus and during the procedure to verify the anatomic position of the EndoCATH (SentreHEART) balloon at the LAA ostium.

The procedure requires pericardial and transseptal access, advancement of the endocardial magnet-tipped guide wire to the apex of the LAA, connection of the epicardial and endocardial magnet-tipped guide wires, and snare capture of the LAA with closure confirmation before release of the pretied suture for LAA ligation. Pericardial access requires an anterior approach through the subxiphoid area with a 17-gauge epidural needle. A 0.035-inch guide wire is then advanced and left in the pericardial space while the transseptal puncture is performed. The EndoCATH with the magnet-tipped 0.025-inch endocardial guide wire is advanced to the LAA apex through the transseptal catheter. The epicardial access is then sequentially dilated to insert the 14-Fr guide-cannula, and the epicardial magnet-tipped guide wire is then directed toward the LAA to connect with the endocardial magnet. With the EndoCATH balloon inflated at the LAA ostium, the LARIAT suture is then looped over the LAA to snare it along the epicardial magnet. The snare is closed and cut after confirmation on TEE and left atrial angiogram. A pigtail catheter is usually left in the pericardial space for several hours or overnight after procedure. Colchicine has been routinely used to reduce pericarditis related to this procedure.

**CLINICAL TRIALS EVALUATING SAFETY AND EFFICACY OF LAA OCCLUSION**

Only 2 randomized trials on percutaneous LAA closure have been published to date. There are several registries that have evaluated the efficacy and safety of various LAA occlusion devices, although the majority are early experience registries.
WATCHMAN

WATCHMAN was evaluated in the multicenter PROTECT-AF (Watchman Left Atrial Appendage System for Embolic Protection in Patients With Atrial Fibrillation) study. In this study, 707 patients with nonvalvular AF and CHADS\textsubscript{2} score $\geq$ 1 were randomized to WATCHMAN (n = 463) or warfarin (n = 244) in a 2:1 ratio. Technical success was 90.9\% with WATCHMAN. Warfarin was continued for 45 days with WATCHMAN in 86\% of patients, and switched to clopidogrel (until 6 months) if there was no leak $>5$ mm on TEE at 45 days. At 6 months, 92\% of patients were off warfarin. Aspirin was continued lifelong after implant. WATCHMAN was noninferior to warfarin for the composite primary efficacy end point of stroke, systemic embolism, and cardiovascular death event rates at 1065 and 1588 patient-years of follow-up. The primary procedure-related adverse event and major bleeding rate was higher with WATCHMAN (5.5\% vs 3.6\% annually; relative risk [RR] 1.53; 95\% confidence interval [CI], 0.95-2.70; Table 47-2). At the 45-month (2621 patient-years) follow-up, the primary efficacy end point was significantly lower with WATCHMAN (2.3 vs 3.8 events per 100 patient-years; RR, 0.6), meeting both the noninferiority and superiority criteria (presented at the Heart Rhythm Society meeting in 2013). Hemorrhagic stroke (RR, 0.15), cardiovascular death (RR, 0.4), and all-cause mortality (HR, 0.66) were also significantly lower with WATCHMAN.

Table 47-2 WATCHMAN Studies
Due to early safety concerns in PROTECT-AF, the FDA mandated a second randomized trial to confirm the late PROTECT-AF and CAP (Continued Access Protocol) registry safety results of WATCHMAN. Thus, the PREVAIL study (Prospective Randomized Evaluation of the WATCHMAN LAA Closure Device in Patients With Atrial Fibrillation vs Long-Term Warfarin Therapy) was conducted, which randomized 407 patients to WATCHMAN or warfarin in a 2:1 ratio (see Table 47-2). Technical success improved to 95.1%. The safety end point met the prespecified noninferiority criterion and had significantly improved compared to PROTECT-AF. At 18 months, the first primary efficacy event rate (composite of stroke, systemic embolism, and cardiovascular/unexplained death) was 0.064 with WATCHMAN versus 0.063 with warfarin (rate ratio, 1.07; 95% CI, 0.57-1.89), which did not achieve the prespecified noninferiority criteria. The rate for the second primary efficacy end point (stroke or systemic embolism >7 days after randomization) was 0.0253 versus 0.0200 (risk difference, 0.0053; 95% CI, –0.0190 to 0.0273), achieving noninferiority. Overall, the efficacy event rates were low and numerically comparable in both arms. In the warfarin arm, the incidence of ischemic stroke was surprisingly low at 0.7 per 100 patient-years, which was much lower than comparative contemporary NOAC trials.
and probably contributed to the failure of meeting the first noninferiority end point.

The ASAP (Aspirin Plavix Feasibility Study With Watchman Left Atrial Appendage Closure Technology) study evaluated 150 patients with nonvalvular AF and CHADS\textsubscript{2} score $\geq 1$ who were ineligible for warfarin.\textsuperscript{40} Patients underwent WATCHMAN implantation and were treated with thienopyridine for 6 months and lifelong aspirin thereafter. The mean duration of follow-up was 14 months, and the all-cause stroke and systemic embolism rate was 2.3% per year. The observed ischemic stroke rate was 77% lower than expected based on the CHADS\textsubscript{2} score of 2.8. The ASAP-TOO study will be a large multicenter randomized controlled trial comparing WATCHMAN to single antiplatelet therapy in patients who are ineligible for OAC; this study is anticipated to launch toward the end of 2016.

The CAP registry showed lower procedure-related events compared to PROTECT-AF, with a procedural stroke rate of 0% and serious pericardial effusion rate of 2.2% with WATCHMAN.\textsuperscript{37} The subsequent CAP2 registry stopped enrolling patients in the United States in early 2014.

There is a definite learning curve with WATCHMEN implantation, with improvement in technical success and procedural safety with increasing experience. The implant success rate improved from 90.9% in PROTECT-AF to 94.3% in the CAP registry and to 95.1% in PREVAIL.\textsuperscript{39} There was a significant reduction in procedural time (56 vs 50 minutes; $P < .001$) from PROTECT-AF to the CAP registry. There was also a significant decline in procedural safety event rates when comparing the first and second halves of PROTECT-AF and CAP, with 10.0%, 5.5%, and 3.7% of patients, respectively, experiencing events within 7 days of procedure ($P = .006$).\textsuperscript{37}

**Amplatzer Cardiac Plug**

The ACP was evaluated in several small retrospective registries (Table 47-3), mostly involving single-center experience worldwide.\textsuperscript{33,41-50} In aggregate, >1100 patients were included in these registries, showing good safety profile (serious pericardial effusion, $\sim 1.7$%; device embolization, $\sim 1.1$%; ischemic stroke, $\sim 0.4$%) and procedural success ($\sim 96.4$%).

Table 47-3 **Procedural Success and Complications in ACP Registries**
Recently, Tzikas et al\(^{51}\) published a pooled ACP retrospective registry of 22 European and Canadian centers including 1047 patients. The mean age was 75 years, the CHA\(_2\)DS\(_2\)-VASc score was 4.5, and the HAS-BLED (hypertension, abnormal renal/liver function, stroke, bleeding history or predisposition, labile international normalized ratio, elderly, drugs/alcohol concomitantly) score was 3.1. Twenty-nine percent of patients were on OAC prior to implant. Technical success rate was 97.3%, and in 93.3% of patients, the first device selected was implanted. With follow-up TEE, the closure rate (<3 mm residual flow) was 97.6%. The rate of periprocedural major adverse events of 7-day death, ischemic stroke, systemic embolism, and procedure- or device-related complications requiring major cardiovascular or endovascular intervention was 4.97%. Mortality was 0.76%, pericardial tamponade 1.2%, device embolization 0.8%, and stroke 0.9%. The observed annual stroke rate was 2.3%, which was 59% lower than the expected 5.6% stroke rate based on CHA\(_2\)DS\(_2\)-VASc score. This reduction was similar to that observed in other smaller registries.\(^{33,46,48}\)

The US pivotal ACP trial was initiated in early 2013 and randomized nonvalvular AF patients with CHADS\(_2\) score ≥2 to ACP versus anticoagulation (warfarin or dabigatran) in a 2:1 ratio. However, due to slow enrollment and anticipated FDA approval of WATCHMAN, this study was discontinued in December 2013 after enrollment of approximately 80 patients. A new randomized Amulet study is being planned and will involve noninferiority comparison to WATCHMAN.

**LARIAT**
The first published study with LARIAT was a single-center experience of 89 patients in Poland.\textsuperscript{34} The mean age was 62 years, CHADS\textsubscript{2} score was 1.9, and CHA\textsubscript{2}DS\textsubscript{2}-VASc score was 2.8. Technical success was 96%. There were a few procedural complications (1 right ventricular puncture, 1 superficial epigastric artery laceration, 1 hemopericardium) and postprocedural adverse events (2 cases of severe pericarditis, 1 late pericardial effusion, 2 unexplained sudden deaths, and 2 late strokes). Of the 65 patients who underwent TEE at 1 year, complete LAA closure was observed in 98%.

More recently, Price et al\textsuperscript{52} reported the multicenter retrospective US LARIAT experience of 151 patients. The procedure duration was 76.6 minutes, technical success was 93%, but procedural success (without procedural complication) was only 86%. Major adverse in-hospital events were relatively high, including significant pericardial effusion (requiring intervention) in 10%, major bleeding requiring transfusion in 4.6%, and emergency cardiac surgery in 1.3%. At median 133 days of follow-up, there were 3 deaths (2.3%), 3 strokes or transient ischemic attacks (2.3%), and 3 pericardial effusions (2.3%). TEE follow-up was performed in 60 patients and showed residual leak $\geq$5 mm in 7%, <5 mm in 15%, and no leak in 78%; thrombus was seen in 5% of patients after LARIAT. This study brought to light the potential high complications with LARIAT and the need for prospective randomized studies with this device.

**COMPLICATIONS WITH PERCUTANEOUS LAA CLOSURE**

The acute complications with the WATCHMAN and ACP devices appear comparable. With increased operator experience, the procedure can be performed with a low periprocedural ischemic stroke risk of $<0.5\%$, serious pericardial effusion of 1\% to 2\%, and device embolization of 0.5\% to 1\%. Ischemic strokes may occur due to procedural air embolism from inadequate device preparation or poor technique, or from thrombus in the LAA or on equipment. Baseline imaging to exclude preexisting LAA thrombus, adequate procedural anticoagulation (keeping ACT $>250$ seconds), and meticulous techniques are important to minimize thromboembolism. The risk of pericardial effusion can be minimized by careful wire, sheath, and device
manipulations in the left atrium and LAA. Using a relatively atraumatic pigtail to guide sheath advancement into the LAA can minimize such risks. Pericardial tamponade requires emergent pericardiocentesis and possibly even pericardial window or surgical intervention for cardiac perforation. Pericarditis related to LARIAT is often managed with nonsteroidal anti-inflammatory drugs, colchicine, or steroids. Device embolization can usually be managed by percutaneous retrieval if feasible. A large arterial sheath that is ≥2-Fr larger than the implanting access sheath is often required to retrieve the embolized device, in conjunction with loop snares and even bioptome. Embolized devices trapped in the left ventricle, left atrium, and aorta have been successfully retrieved. However, surgical removal may be required if the device is trapped by tissues (eg, papillary muscles or trabeculations) or if the device cannot be fully retracted into the large sheath.

Longer term issues with percutaneous LAA closures include thrombus formation on the atrial side of devices and residual leaks. Follow-up TEE or CCTA at approximately 3 to 6 months after procedure should be routinely performed, and sometimes, it should be repeated at 1 year. Device thrombus formation may occur in 2% to 5% of cases with these devices, which tends to occur on nonendothelialized device protrusions such as the threaded insert with WATCHMAN and the proximal end screw with ACP, especially if implants are too deep. Thus, deep implantations resulting in uncovered trabeculations and recesses should be avoided. Newer device designs may also be less thrombogenic; for example, Amulet has a recessed proximal end screw that allows faster and/or more complete endothelialization. Although there is no consensus on management, device thrombus is usually managed with anticoagulation (OAC or low-molecular-weight heparin) for 8 to 12 weeks, with repeat TEE to assess for thrombus resolution before discontinuing anticoagulation. Reported thromboembolic stroke event rates related to device thrombus are low at 0.3% to 0.7%.37,40

Residual leak may occur with a significant proportion of WATCHMAN implants. In the PROTECT-AF study, some degree of leak was seen in 32% of cases at 12-month follow-up (36.8% >3 mm and 63.2% ≤3 mm). However, residual leak was not associated with higher risk of thromboembolism,53 although the number of events was low, and this finding was inconclusive. Residual leak with ACP has been reported to be lower; leak >5 mm has not been documented, leak of 3 to 5 mm occurs in 0% to 1% of cases,48 and leak <3 mm occurs in 0% to 16% of cases.42,44,46 The ACP’s low incidence of
leak is presumably related to the lobe-disc design, with fabric in both components. Residual leak has also been demonstrated with LARIAT, with variable reported incidence of 2% to 22% on follow-up TEE. With any of these devices, if there are residual leaks >5 mm, patients should probably be continued on long-term OAC, or alternatively, repeat LAA closure with a different device may be attempted.\textsuperscript{54}

CONCLUSION

In summary, several devices for percutaneous LAA closure are CE marked and available in many countries. The WATCHMAN device has the most supportive data and received FDA approval in early 2015 for warfarin-eligible patients. Data from PROTECT-AF, PREVAIL, and CAP have shown good procedural safety after the initial learning curve. Furthermore, superiority of primary efficacy end points with WATCHMAN was demonstrated at long-term follow-up in the PROTECT-AF study, together with reduction in cardiovascular and all-cause mortality. The large randomized controlled ASAP-TOO study with WATCHMAN for warfarin-ineligible patients will be launched imminently. For ACP, there has also been a good deal of real-world experience to date, and a recent large multicenter registry of almost 1000 patients revealed a good safety profile. A randomized trial comparing the ACP to WATCHMAN is being launched. LARIAT has also gained interest lately; however, early studies were concerning for relatively high complication rates of serious pericardial effusion and major bleeding. Further prospective studies are necessary to evaluate the safety and efficacy of LARIAT. There are also several other percutaneous LAA devices under clinical investigation, and future randomized trials comparing them to WATCHMAN are anticipated.

Percutaneous Closure of Atrial Septal Defect and Patent Foramen Ovale

David P. Lee
Stanton B. Perry

Over the course of the past decade, there has been a burgeoning interest in closing septal defects percutaneously. To date, there are now percutaneous closure devices available for the intended closure of ostium secundum atrial septal defects (ASDs) as well as patent foramen ovale (PFO). With the increased interest in these percutaneous procedures, the interventional cardiologist now has an additional set of procedures to master outside the coronary vasculature. This chapter will review the current techniques and devices employed during these specialized procedures.

ATRIAL SEPTAL DEFECT

ASDs are the most common adult congenital cardiac abnormality, occurring in about 8% of the adult congenital heart disease population with a slight female predominance (3:2). They are classified by the anatomic location as well as their associations with other local anatomic structures. ASDs can be classified as follows: (1) ostium primum, in which the defect is located inferiorly and is often associated with tricuspid and or mitral valve abnormalities as well as a ventricular septal defect; (2) ostium secundum, in which the defect is related to persistent separation at the midatrial level due to failed fusion during cardiac development; and (3) sinus venosus, in which
there is partial anomalous pulmonary venous return due to the septal defect extending superiorly along the atrial septum to include the incoming pulmonary veins. Of these 3 types of ASDs, transcatheter repair is tenable at this time only with the secundum-type defect.

In general, the threshold for closure is dictated by hemodynamic findings. Historical data, largely from the surgical literature, suggest that ASD closure is warranted in patients with a pulmonary/systemic flow ratio (Qp/Qs) of 1.5 or greater. Closure may also be warranted if pulmonary hypertension or early echocardiographic evidence of right ventricular enlargement and/or failure is present. A paradoxical embolus may also be considered to be an indication for closure. Clinically, patients often present with dyspnea on exertion or evidence of right-sided heart failure. It is generally rare to see a cryptogenic neurologic event with an ASD, given that most of the flow early in the process involves left-to-right shunting; as the right heart fails, however, the shunting becomes mixed and even reversed in late-stage disease, with predominantly right-to-left shunting. An electrocardiogram showing incomplete right bundle branch block is common in patients with secundum ASD.

A transesophageal echocardiogram (TEE) is critical in defining the anatomy of the ASD and is useful in determining the potential success of percutaneous closure of a secundum-type defect. An adequate (≥1 mm) anterosuperior aortic rim is important to allow adequate anchoring of the ASD closure device. In addition, the size of the defect and an estimate of the shunt fraction may be helpful in determining the eligibility for closure as well as appropriate balloon sizing. Right ventricular enlargement of at least a mild degree is usually observed. Other important features revolve around the definition of the type of defect and the relationship of the mitral valve annulus to the ASD. An investigation of the left atrial appendage to rule out thrombus and a bicaval view to assess inflow into the atrium are important to exclude a sinus venosus–type defect. A multifenestrated secundum ASD is noted in about 10% of all secundum ASDs, and imaging to assess for this is important because it could have an influence on planning for device closure. Finally, other defects such as anomalous pulmonary venous return should also be excluded with TEE or computed tomography (CT).

**Percutaneous ASD Closure**
Percutaneous closure of a secundum ASD has been performed for many years in both pediatric and adult populations. The first attempt at transcatheter ASD closure was in 1974 by King and Mills. The techniques have been refined over time, and there are now a number of commercially available devices outside the United States. Within the United States, one device, the Amplatzer Septal Occluder (AGA Medical, Golden Valley, MN), has received approval from the US Food and Drug Administration for secundum ASD closures (Fig. 48-1).

**FIGURE 48-1** The Amplatzer Septal Occluder (AGA Medical, Golden Valley, MN) is composed of 2 nitinol disks covered by polyester. It is approved for use in the United States for appropriate secundum-type atrial septal defects.

The Amplatzer Septal Occluder (ASO) consists of 2 attached circular disks—a larger left atrial disk separated by a small space on top of a smaller right atrial disk. These disks are made of polyester fabric encasing a wire
mesh made of a nitinol. The device is screwed onto a delivery cable and delivered via a long sheath. In the typical ASO, the left atrial disk is 6 to 8 mm larger than the right atrial disk, and a central space (“waist”) consists of a small mesh tube, which also promotes self-centering. The device is sized per the right atrial disk.

Screening for potential percutaneous closure candidates consists of the tests noted earlier to diagnose and confirm a secundum-type ASD. In addition, tests to exclude concurrent infection, pregnancy, and a hypercoagulable state should be performed prior to closure. It is important to also administer intravenous (IV) antibiotics at the time of closure to prevent any potential infectious risk. This is performed usually just prior to obtaining venous access. The procedure in the catheterization laboratory is relatively straightforward and has recently been reviewed.3

Two venous sheaths are placed in the right femoral vein. Unfractionated heparin (100 U/kg) is then administered IV with an aim to keep an activated clotting time of greater than 200 seconds. To confirm the hemodynamic significance of the ASD, a saturation run with pressure measurements should be performed prior to the planned closure. Once the shunting has been confirmed, one of the sheaths can be replaced with an 8- or 10-Fr sheath to allow the passage of a 10-MHz intracardiac echocardiography (ICE) probe (AcuNav; Siemens Medical Solutions, Malvern, PA; Fig. 48-2), which allows direct visualization of the atrial chambers and atrioventricular valves during closure. An alternative is to use TEE during the procedure, but studies have suggested a greater benefit for using ICE over TEE.4,5 Once the probe has been guided into the right atrium at the level of the ASD, a 6-Fr multipurpose diagnostic coronary catheter is directed over a 260-cm J-tipped (Rosen) wire to the right atrium. Alternative choices of catheter include an Amplatzer Left-1, but this may direct the wire toward the coronary sinus. Some operators prefer an Amplatzer (stiff) guide wire. The catheter is then manipulated toward the ASD, and the wire is guided across the ASD into the left atrium and anchored within the pulmonary veins, preferably the left superior pulmonary vein. Once the wire is anchored, the catheter is removed. Using the ICE and previous TEE data as a guide, a 24- or 34-mm sizing balloon (St. Jude Medical, Saint Paul, MN) can be guided across the ASD and its position confirmed by ICE and/or fluoroscopy. Typically, the stretched diameter of the ASD is 30% larger than the unstretched diameter. The sizing balloon is then inflated with a 1:4 mixture of contrast and saline, and a balloon “waist”
appears fluoroscopically as well as on the ICE. This “waist” is then measured as the stretched diameter of the ASD using predefined markers on the balloon catheter for calibration (Fig. 48-3). To avoid oversizing, a “stop-flow” technique has been developed in which the balloon is gently inflated while color Doppler echo visualizing the shunt flow is used on ICE or TEE. The “stop-flow” measurement is the point at which flow across the shunt is fully occluded by the balloon. Once the stop-flow ASD size is confirmed, the balloon is then deflated and removed.

**FIGURE 48-2** AcuNav intracardiac echocardiographic catheter. It images at 10 MHz and is 10-Fr sheath compatible. (Siemens Medical Solutions. Used with permission from Siemens Healthineers.)
FIGURE 48-3 Sizing balloon used in the measurement of septal defect size. In this photograph, the sizing balloon has been inflated to reveal the atrial septal defect size when stretched, allowing appropriate sizing for a septal occluder device. Markers on the sizing balloon allow accurate estimation of defect size.

Typically, the chosen ASD closure device size with the ASO is 1 to 4 mm larger than the stretched diameter. Because of the variety of ASD closure device sizes (4-40 mm), the delivery sheath size may vary. For example, for a 22-mm ASO, a 9-Fr delivery sheath is adequate, whereas a 36-mm ASO requires at least a 12-Fr delivery sheath. Once the proper delivery sheath size is chosen, the femoral sheath is exchanged for a long (80 cm) curved delivery sheath. The introducer should be placed into the pulmonary vein and then removed along with the wire once the sheath has been anchored within the pulmonary vein. Great care should be taken to expunge any air from the
sheath by carefully removing fluid and potential air from the sheath and then gently flushing with saline.

The ASO is screwed in a clockwise fashion until tight onto the delivery cable. A 180-degree counterclockwise turn is then used to slightly loosen the device and prevent locking of the ASO onto the delivery cable. A small introducer sheath included in the packaging should then be used to expunge any air from the delivery cable and device while pulling back in a pool of saline. This short sheath with the ASO on the distal end of the delivery cable is then connected onto the proximal end of the delivery sheath and pushed into the delivery sheath with care taken to avoid kinking of the cable or sheath. It is common to experience some mild initial resistance with the introduction of the ASO into the delivery sheath.

Fluoroscopy can then be used to visualize the delivery cable and ASO within the sheath as it approaches the tip of the delivery sheath. When the device is at the tip of the sheath, the entire system is then retracted back into the upper portion of the left atrium. When this is accomplished, the sheath is gently retracted from the delivery cable, and the left atrial disk should be deployed (Fig. 48-4). Under ICE and fluoroscopic guidance, the left atrial disk, delivery cable, and sheath are then retracted as a unit until the left atrial disk is flush against the left atrial side of the ASD. Once this is established, the sheath is then further retracted to allow deployment of the right atrial disk (Fig. 48-5). The device should be well-seated across the atrium with both respective atrial disks fully expanded on either side of the septum. A gentle but firm to-and-fro motion ("Minnesota wiggle"\(^6\)) can be used to gauge the positional stability of the ASO while using ICE or TEE. This can be confirmed with ICE and Doppler imaging of the ASD on either side of the device. Contrast or bubbles may be injected through the delivery sheath to image the right atrium and detect contrast across the ASD with the device, still held in place by the delivery cable, in the defect. If these methods detect minimal or no leakage, the device is then detached from the delivery cable by attaching the rotator knob on the back end of the delivery cable and using a counterclockwise rotation of the knob. It is imperative to maintain a very slight and gentle constant traction on the device as the knob is rotated until the device is released. The device may “jump” or slightly reorient/recenter itself as the device is released (Fig. 48-6).
FIGURE 48-4 Fluoroscopy (top panels) showing the left atrial disk of an Amplatzer Septal Occluder being used. Intracardiac echocardiography (bottom) shows the left atrial disk used within the left atrium.
FIGURE 48-5 Deployment of the right atrial disk under fluoroscopy and intracardiac echocardiographic (ICE) guidance. The ICE imaging also shows the Doppler signal at the aortosuperior rim of the device.
FIGURE 48-6 (A) Immediate result of device release (left) compared with the final result (right). Please note the orientation change of the Amplatzer Septal Occluder after it has settled into position. This is considered normal and can be further investigated with intracardiac echocardiography, seen in panel B, which shows excellent device placement and apposition.

Prior to release, if positioning is unsatisfactory, the sheath can be readvanced into the left or right atrium to recover the right and/or left atrial disk, and the deployment process can begin again. If the deployments remain unsatisfactory, some operators have advanced a second catheter to help better align the device as it is deployed by using a constant upward pressure on the device and/or sheath as it is deployed across the ASD. This obviously requires another venous sheath to be placed. For larger ASDs, a novel
technique has recently been described in 14 patients using the sizing balloon inflated within the right atrium to help support large ASOs as they are deployed.

Once the device has been released, ICE should be used to scan along the atrium from the superior vena cava (SVC) to the inferior aortic border to confirm the positioning of the device as well as the elimination of the shunt itself by Doppler (Fig. 48-7). In addition, a scan of the atrioventricular valves should be performed to exclude impingement on either of these structures. Alternatively, some operators inject bubbles through the now empty venous delivery sheath and image as the bubbles are in the right atrium to see if any bubbles are able to cross the ASD. Residual shunting through the device is not uncommon immediately after release. Significant residual shunting is rare and usually suggests device malposition or a second defect. A second device can be used depending on the size and location of the defect. If there are significant bubbles or Doppler-detected flow across the ASD on either side of the device, a second device can be placed by recrossing the ASD with a multipurpose catheter and stiff J-wire and eventual deployment of a smaller second ASO without the use of a sizing balloon. Alternatively, some operators who have noted moderate persistent defects on one end of the device have used coronary catheters to “adjust” the positioning along the end of the device with a persistent residual shunt. Once the final result has been deemed to be satisfactory, the sheaths are removed.
Before the availability of a large device designed to cover fenestrated defects, the general approach was to use multiple devices if the defects were 7 mm or further apart along the atrial septum, with the first device used to cover the largest defect. Currently, the preferred method is to use 1 device, and the Amplatzer Multifenestrated Septal Occluder, also known as the cribriform device, is the most common device used in the United States for these types of defects. This device differs from the ASO by harboring 2 fixed-distance polyester-covered nitinol circular disks with a central space (“waist”) of 4 mm. The right atrial disk is thicker than the left atrial disk, but both have the same diameter. Available sizes in the United States are 18, 25, 30, and 35 mm, measured as a diameter of the disks.

Device deployment for the cribriform device is similar to the ASO but with a few differences: the device should be delivered through the largest defect, with calculation of the distance from the main defect to the aortic rim measured on TEE or ICE used as the basis for device sizing.

Another device, the Gore Helex device (W. L. Gore & Associates, Inc., Flagstaff, AZ), is also available in the United States for secundum ASD closure. This device consists of a single nitinol wire acting as a looped frame.
with an ePTFE covering, which allows for acute mechanical closure and eventual endothelialization. The device comes in 15- to 35-mm diameter sizes with 5-mm increments. The device sizing choice is based on at least a 2:1 ratio of device-to-defect size per stop-flow ultrasound imaging. The device has islets to allow for fluoroscopic visualization and device alignment with the defect. It may also be used for multifenestrated defects.

The Helex delivery sheath with the premounted device may be directed into the left atrium either alone or with a guide wire used as a monorail system. The left atrial disk is then released at the end of the catheter and slowly pulled back toward the septum with a pull-stabilize-pull technique; as the device approaches the septum, the second loop is released, covering the left side of the atrium and SVC. The right atrial loop is then opened with gentle tension and fully released to allow the device to settle along the defect on both sides. The radiopaque islets are visualized to make sure the device is aligned and centered both by fluoroscopy and ultrasound imaging, and the device may then be released (unlocked) with final detachment of the release cord.

In addition, clopidogrel is administered after device closure, with a loading dose of 300 to 600 mg in the laboratory, with plans for a maintenance dose of 75 mg once a day for at least 1 month with concomitant aspirin. The aspirin should be continued for 6 months after closure. Currently, no data have been published, but ticagrelor or prasugrel may be used as an alternative for patients who are sensitive to clopidogrel. A small study has suggested that platelet activity is enhanced in the presence of ASD and largely reversible after defect closure.

The issue of thrombus formation and its significance is interesting and controversial. The devices are thought to acutely close septal defects by mechanical obstruction of the defect as well as thrombosis with long-term closure secondary to endothelialization.

**Postprocedural Care**

In addition to the postprocedure administration of aspirin and clopidogrel for 3 to 6 months, our standard of practice in the hospital has been to continue IV antibiotics (cefazolin 1 g IV every 8 hours; for penicillin-sensitive patients, vancomycin 1 g IV every 12 hours) through the course of the hospitalization after the procedure.
The patient is usually discharged on the following morning after a transthoracic echocardiogram (TTE) with contrast. This is done for 2 reasons: (1) to reconfirm proper device positioning (Fig. 48-8), and (2) to establish the degree of shunting, if any, across the device. In addition, an anteroposterior and lateral chest x-ray is taken. The ultrasound imaging studies are repeated at 1, 6, and 12 months, and then as needed. The use of contrast during the TTE follow-up studies is reserved for patients with persistent residual shunts. Chest x-rays are performed only as indicated.

**FIGURE 48-8** Transthoracic echocardiogram image of a large Amplatzer Septal Occluder 1 day after placement across a secundum defect.

The patient should allow at least 4 weeks for complete endothelialization of the device. In our program, no lifting of objects that weigh more than 20 pounds is recommended for the first month after procedure. Gentle walking is allowed immediately after procedure and until the patient returns for follow-up at 1 month. An important reminder involves the prevention of device infection: the patient should follow American College of Cardiology/American Heart Association guidelines for bacterial endocarditis prophylaxis for 6 months after procedure.

**Complications**
The delivery of a septal defect closure device has a particular set of complications of which every operator should be aware. Beyond the rare complication of vascular access issues, there are a number of unique potential complications related to these devices. These include transient bradyarrhythmias and tachyarrhythmias, ST-segment elevation, device embolization, device erosion, thrombosis and embolism, and pericardial effusion.

The incidence of bradyarrhythmias, such as complete heart block, is rare. In a review, 10 patients underwent percutaneous ASD closure. Periprocedural atrioventricular (AV) block was noted in 3 patients (1.9%). During the postprocedure follow-up at 1 week, an additional 7 patients developed AV block. Four of these 10 patients had first-degree AV block. All had no symptoms or hemodynamic compromise. All patients with higher degree AV block completely recovered within 6 months. Two patients had residual first-degree block at 12 and 33 months after the procedure. Interestingly, patients with a larger defect and hence larger shunt fraction and ASO (>19 mm) had a much higher incidence of AV block. In a series from Italy, 11 the incidence of AV block was 1 of 417 patients (0.2%). In this patient, complete heart block developed, and the operators then removed the device with complete cessation of the AV block. One year later, the patient underwent an uneventful percutaneous ASD closure. In another study, 9 of 41 patients (22%) exhibited nonsustained supraventricular tachycardia; no patients had atrial fibrillation or other atrial tachycardias. Five of 199 patients (2.5%) in the study by Wang et al 14 experienced supraventricular tachycardia, but all of these events were terminated with administration of IV adenosine.

Tachyarrhythmias, such as atrial tachycardia and atrial fibrillation, have also been reported. In a recent series from the Mayo Clinic 13 using ICE-directed ASD or PFO closure, the incidence of atrial tachyarrhythmia was 4.3% (4 of 94 patients). Three of these patients had atrial fibrillation, whereas 1 had a supraventricular tachycardia. Two of these 4 patients recovered spontaneously, whereas the other 2 were cardioverted without incidence. There were no cases of ventricular arrhythmias. In another study, 9 of 41 patients (22%) exhibited nonsustained supraventricular tachycardia; no patients had atrial fibrillation or other atrial tachycardias. Five of 199 patients (2.5%) in the study by Wang et al 14 experienced supraventricular tachycardia, but all of these events were terminated with administration of IV adenosine.

ST-segment elevation is an interesting development during and after ASD
closure. This usually occurs in the inferior leads, and the mechanism postulated has been inadvertent air embolism during device deployment. It is usually transient and resolves spontaneously within 20 minutes. Clinically, the patient may complain of chest discomfort and nausea, but this usually subsides in a short period.

Device dislodgement and embolization is a known complication of ASD closure. This is an operator-driven error and can be the result of many possible errors, most commonly incomplete attachment to the delivery cable, sizing and device error, malpositioning, and premature device release. In an Italian series of ASD closure\textsuperscript{11} with a variety of devices, 1 patient (0.2\%) had device embolization. In a more generalized survey of ASO operators by Levi and Moore,\textsuperscript{15} a 0.6\% incidence of device embolization was noted. In general, larger devices are thought to be associated with a higher incidence of device embolization because of the inadequacy of a rim to anchor the device in a large defect. Indeed, in several series,\textsuperscript{11,14-16} larger (or undersized) devices were shown to be more prone to malpositioning and dislodgement/embolization. Device embolization was noted in 7 of 417 Italian patients (1.7\%) and 1 of 191 patients (0.5\%) in the Taiwanese experience.

Techniques to retrieve the ASO vary, but all involve a gooseneck snare and the use of an oversized venous sheath. The review by Levi and Moore\textsuperscript{15} in which they surveyed a number of experienced ASO operators suggests that a stiffer sheath with a beveled tip may be advantageous when recapturing a dislodged ASO. The technique to retrieve a device involves snaring the right atrial disk screw and pulling the device back into a sheath (Fig. 48-9). A bioptome generally cannot sufficiently “grab” a device by its right atrial screw for removal. In some cases, however, a bioptome may be used to pull the device into the inferior vena cava (IVC) with the snare holding the right atrial disk screw. Once there, a stiff J-wire can be advanced across the device in the IVC to stabilize its position.\textsuperscript{17} The ASO can then be pulled more easily into the retrieval sheath and removed. In their survey, 15 of 21 (71\%) device embolizations were successfully retrieved via a percutaneous route from a total cohort of 3824 patients. The other 6 patients underwent surgical removal. Chessa et al\textsuperscript{11} successfully retrieved 4 of 11 embolized or malpositioned devices. The other 7 patients underwent successful surgical retrieval and closure.
FIGURE 48-9 Retrieval of an Amplatzer Septal Occluder after embolization into the right atrium. The arrow shows the location of the snare around the screw-type interface between the original delivery catheter and device. The snare is used to grab (A) and retract the device back into the capture sheath. Note that the right atrial disk is first collapsed (B) and withdrawn into the sheath (C), followed by the left atrial disk. Eventually, the entire device is captured within the sheath (D) and removed.

There is a growing interest in the thrombosis rate for any septal defect closure device. In the case of the ASO, this has been examined in a small
study by Anzai et al.\textsuperscript{18} In their study, 66 patients underwent septal defect closure with either a CardioSeal, an Amplatzer PFO occluder, or an ASO. TEE was performed in 50 patients 1 month after closure, and the incidence of detectable thrombus in the 27 patients with the Amplatzer devices was 0%. A recent review by Krumsdorf et al.\textsuperscript{19} of the incidence of thrombosis induced by septal closure devices (including both ASD and PFO devices) in 1000 patients undergoing septal defect closure suggested that the mean incidence of thrombosis in the 407 ASD closure cases, using a variety of devices, was 1.2% (5 of 407 patients). The incidence of thrombosis in those receiving an Amplatzer device was 0%. These thrombi were detected at the planned 30-day and/or 6-month follow-up, which included a TEE. Interestingly, 14 of 221 ASD patients (6.3%) had a coagulation disorder; in these patients, there was a higher incidence of a precedent embolic event prior to closure. In addition, of the 326 Amplatzer devices used in this study, there were no cases of detected thrombus by echocardiographic imaging. This reduced incidence of detectable thrombosis in the Amplatzer patients may be due to the covering of the nitinol mesh with polyester. Other devices, because of a difference in the covering, may be more prone to thrombus formation. However, a recent review and meta-analysis of 17 reports found 54 patients with device thrombosis, and no device was spared from this complication.\textsuperscript{20} Predictors of thrombus formation include hypercoagulability, presence of atrial fibrillation, and presence of a persistent atrial septal aneurysm in PFO patients. The presence or absence of a residual shunt does not appear to predict thrombus formation, nor does diabetes, hypertension, or concomitant coronary heart disease.\textsuperscript{19}

Overt cardiac rupture is heretofore unheard of, but the development of significant pericardial effusion leading to pericardial tamponade has been reported in a number of studies. The report by Chessa et al.\textsuperscript{11} included 2 pericardial effusions (0.5%), 1 of which required emergent surgical drainage in the catheterization laboratory because of a guide wire perforation. The other effusion resolved with medical therapy after 20 days. Four (2.0%) of the 199 patients in the series described by Wang et al.\textsuperscript{14} developed pericardial effusions, 1 of which required pericardiocentesis for relief of tamponade. In a recent registry review of ASO erosions, 28 cases (14 in the United States) were examined. All erosions were near the aortic root, and the large majority of these patients had a deficient aortic rim (89%) or superior rim. In addition,
oversizing of the defect with aggressive balloon sizing and a subsequent oversized device may have played a role in these perforations. Early recognition is the key to avoid any poor outcome. Serial echocardiograms are recommended for those patients who develop a pericardial effusion at the time of the procedure and early after the procedure.

**Results**

The results of percutaneous ASD closure\textsuperscript{6,11,14,21-24} are very encouraging. The earliest report of using the Amplatzer device for secundum ASD closure\textsuperscript{22} was a small pediatric study of 16 patients, and these procedures were performed without complication. An acute closure without residual shunting was achieved in 13 of the 16 patients (81%), and 2 of these 3 patients had no TEE-detectable shunt at 3 months, for an overall success rate of 94%. In another study of ASD closure,\textsuperscript{23} 200 patients were closed using the ASO device. At 3 months postprocedure, 98.1% of patients had no detectable shunt, with only trivial residual shunting noted in the remaining patients. In a review of 3580 ASD closures in 3535 patients, Omeish and Hijazi\textsuperscript{24} reported a 97.4% acute success rate for closure based on TEE findings of minimal or no shunt at the time of closure. At 3 months, the closure rate per the TTE was 99.2%, and at 3 years, it was 100%. There were no device-related deaths, and there was a serious complication rate of 0.3%. In a recent study from Taiwan,\textsuperscript{14} 197 patients underwent ASD closure with the Amplatzer device and the use of TEE. A deficient rim, defined as less than 5 mm, was noted in 114 patients, 113 of which were noted on the superior-anterior (aortic) portion of the atrial septum. Interestingly, the presence of a deficient rim was not associated with an increase in procedural failure. A total of 191 procedures were successful; repositioning (redeployment) of the device was needed in 28 patients. Of the 6 failures, 4 were in adults with an ASD stretched diameter of greater than 34 mm and 2 were in young children younger than 4 years of age with stretched ASDs of greater than 20 mm. Complications were noted in 3 patients; 1 had complete AV block that eventually resolved after 3 days, 1 experienced cardiac tamponade requiring pericardiocentesis, and 1 had embolization of the device and required emergent surgery after failed attempts to retrieve the device. The follow-up on these patients included TEE, and residual shunts were seen in 4% of patients at 2 years.
Summary

The development of a percutaneous device to close secundum ASDs has advanced the use of these devices in the adult cardiac catheterization laboratory. Experience with these devices is growing, and these devices have become common in many centers in the United States and around the world as a true alternative to surgical closure. The acute and medium-term (<10 years) experience has been very positive, and percutaneous ASD closure will continue to grow as the devices and operators improve. Early recognition of problems in ASD closure is important and may obviate the need for surgical intervention in a large number of complicated cases.

PATENT FORAMEN OVALE

PFO is a common congenital heart finding that can be an incidental finding in 10% to 30% of autopsies but can have a much higher incidence in patients with a neurologic event unascribed to another cause (“cryptogenic”). A PFO is a residual of a failed closure of the fossa ovalis, a remnant of the fetal circulation. In most people, the foramen ovale closes shortly after birth. In patients with a PFO, this closure fails to occur, and the heart is left with a persistent potential shunt between the right and left atrium (Fig. 48-10). In the large majority of patients with PFO, no neurologic events ensue. This is likely due to the adequacy of atrial flow and turbulence, which prevent thrombi from forming, and to the small chance of passage of embolic material through a small shunt.
Patients foramen ovale from a cadaver shows the probe patency from the right atrial (top) and left atrial (bottom) sides of the defect.

**Relationship of the PFO to Neurologic Events**

As noted earlier, a large percentage of the general population harbors a PFO. An evolving interest in PFO has been driven by the finding that 40% of ischemic stroke patients have no defined cause (“cryptogenic”). In many of
these patients, especially young patients, a PFO is discovered. The mechanisms postulated for the development of a cryptogenic stroke with PFO are (1) passage of thromboemboli from the right heart circulation across a PFO into the left atrium and thus into the cerebral circulation, and (2) in situ thrombosis across the PFO and thromboembolism from the PFO itself into the left atrium and subsequently into the cerebral circulation. Although there is no absolute proof that a PFO is a cause of cryptogenic neurologic events, there are several series suggesting that there is a higher incidence of PFOs in patients with cryptogenic stroke.\textsuperscript{25-28}

Mas et al\textsuperscript{29} performed a retrospective study of 132 patients with a cryptogenic neurologic event and a PFO and/or atrial septal aneurysm (ASA). The findings suggested that the annual rate of recurrent stroke was 1.2%, with a 3.4% annual rate for any neurologic event. The risk was highest for patients with both a PFO and ASA with an annual stroke recurrence rate of 4.4%. Another study by Nedeltchev et al\textsuperscript{30} examined 318 patients with a cryptogenic neurologic event (stroke or transient ischemic attack [TIA]) and PFO. A total of 159 patients underwent medical therapy; this consisted of vitamin K antagonists with a targeted international normalized ratio of 2.0 to 3.0 in 79 patients and platelet inhibitors (aspirin or clopidogrel) in 80 patients. At a mean follow-up period of 29 months, 21 patients (13.4%) had had a recurrent neurologic event (7 strokes, 14 TIAs). Based on this, the mean annual rate of stroke recurrence was 1.8% (5.5% for recurrent stroke or TIA). The Patent Foramen Ovale in Cryptogenic Stroke Study\textsuperscript{31} (PICSS) was a substudy of the 630-patient Warfarin-Aspirin Recurrent Stroke Study (WARSS), in which 203 patients had a documented PFO. In this medical therapy comparison, there was no difference in outcomes of recurrent stroke or death between warfarin or aspirin treatment, and the presence of a PFO did not affect outcomes. In addition, the size of the PFO or the presence of an ASA also did not affect outcomes. A meta-analysis of several studies\textsuperscript{32} in secondary prevention of recurrent neurologic events in PFO patients, however, suggested that warfarin is superior to aspirin and may be equivalent to surgical closure of a PFO.\textsuperscript{33}

Standard medical therapy has thus not been concretely defined but generally consists of warfarin with or without concomitant antiplatelet therapy. Within the neurology community, the actual “best practice” regarding medical therapy remains controversial\textsuperscript{34}; thus, patients may be
taking aspirin, aspirin and dipyridamole, clopidogrel with or without aspirin, or warfarin for secondary prevention of a cryptogenic stroke. With the development of devices for mechanical closure of a PFO, this has generated a great interest in mechanical closure of PFOs in patients with cryptogenic stroke.

**Special Interest: PFO and Migraine Headaches**

An interesting relationship, albeit not a proven causal one, has suggested that PFOs may be implicated in migraine headaches. From observational studies, it appears that patients with migraine headaches have about twice the incidence of PFOs, especially with ASA, than the general population. PFO closure may help alleviate the frequency of migraine headaches, as suggested by a study of migraine headache attacks in a population undergoing PFO closure for cryptogenic neurologic events. Based on these findings, a randomized clinical trial in the United Kingdom studying the role of PFO closure with the StarFlex device (NMT Medical, Boston, MA) in patients with migraine headaches (Migraine Intervention With StarFlex Technology [MIST]) without cryptogenic neurologic events was reported at the 2006 American College of Cardiology Scientific Sessions and published. In this important study, 147 patients were randomized to either device closure of their PFO or medical management with a sham procedure. The primary end point of the trial, complete cessation of migraine headaches, was achieved in 3 of 74 patients in the device group and 3 of 73 patients in the medical treatment (sham procedure) group. The device group had an improvement in their headache burden score (frequency × duration) and experienced a 50% or greater reduction in headache days, but neither of the predefined secondary end points were met. Controversy about MIST revolved around the echocardiographic data, and 1 of the co-primary investigators eventually was sued for libel by NMT, the company that made the StarFlex and sponsored the trial.

The PRIMA-PFO study using the Amplatzer PFO device was presented at the Transcatheter Cardiovascular Therapeutics (TCT) meeting in 2014. In this small study, 83 patients were randomized to device or best medical therapy and followed for 1 year with a primary end point of number of reduced migraine days. There was no significant difference between the 2 groups.

The PREMIUM PFO trial was also recently presented at the TCT 2015
meeting. The results of this trial suggested a small but nonsignificant statistical benefit regarding responders to therapy in patients receiving an Amplatzer device versus a sham procedure. A reduction in number of headache days per month was noted ($P = .03$) as part of a subgroup analysis, and there was a greater benefit in patients who experience an aura with their migraines, as shown by a treatment response in 49% of patients with the device versus 23% of patients in the sham group ($P = .015$) and complete remission in 10.8% of patients in the device group versus 1.5% of patients in the sham group ($P = .02$).

Based on these results, there has been diminished enthusiasm for PFO device–based treatment in migraneurs.

**Special Interest: PFO and Diving and High-Altitude Pulmonary Edema**

The interest in diving and PFO has persisted since the early 1960s when American naval physicians examined the incidence of decompression sickness (DCS) and relationship to the patient’s PFO status. Although the current indications do not include decreasing the risk of DCS, many operators believe that this is a valid medical indication for closure. The theory is that decompressive nitrogen gas bubbles forming in the venous circulation could cross the PFO and thus cause symptoms of DCS. There have been no randomized trial data to suggest benefit of PFO closure to prevent DCS, and there remains a debate as to whether divers should even be screened for a PFO in the absence of previous episodes of DCS. A recent guidance document suggests no need for screening, with a recommendation that if a PFO closure is undertaken, screening with a follow-up shunt study and completion of antiplatelet medications after closure should be done before allowing the diver to resume activities. In small studies, there is some evidence of a benefit in patients with PFO closure.

Similar concerns have been raised for mountain climbers and the incidence of high-altitude pulmonary edema. There has been a paucity of data regarding the role of closure in this situation, but some interesting physiologic studies show no difference in the incidence of PFO in high-altitude dwellers versus sea-level dwellers but some differences in physiologic response.
Finally, platypnea-orthodeoxia syndrome has also been linked to PFO in some patients in the generally postoperative condition in which positional changes can augment right-to-left blood flow across the PFO, leading to desaturation when sitting upright. Few anecdotal data have suggested benefit of closure.\textsuperscript{49, 50}

**The Decision to Close a PFO**

The decision to percutaneously close a PFO is often a difficult one. Currently, in the United States, there are no available devices specifically indicated for PFO closure. Outside the United States, there are a number of commercially available devices (Fig. 48-11). At present, the Gore Helex and Amplatzer PFO occluder (APO) are retrained by a Humanitarian Device Exemption (HDE) from the Food and Drug Administration (FDA). The HDE is specific in the indication for mechanical closure; it states that the device may be used under the HDE only for patients who have suffered a cryptogenic stroke and who have failed warfarin therapy. This has led to a difficult decision-making tree for many physicians, in part because of the widely held belief that mechanical closure is superior and in many cases preferable to medical therapy. In addition, patients may believe that they are at risk for a recurrent cryptogenic event while on warfarin therapy, which by itself may be objectionable because of the required monitoring. As a result, a number of closures are performed outside of the HDE ("off-label"), driven both by physician and patient preferences regarding mechanical closure and avoiding warfarin or other medical therapy. This is occurring despite the lack of concrete data suggesting that mechanical closure confers any advantage over medical therapy.
A variety of devices are available outside the United States for percutaneous closure of a patent foramen ovale. Within the United States, only the CardioSeal and Amplatzer Patent Foramen Ovale (PFO) Occluder have humanitarian device exemption from the US Food and Drug Administration for secondary prevention of cryptogenic stroke. (Images of Cardioform Septal Occluder © 2015 W. L. Gore & Associates, Inc. Used with permission.)

**Percutaneous PFO Closure**

Percutaneous PFO closure can be accomplished easily with either of the 2 previously approved devices in the United States. The APO differs from the ASO in that the APO has a larger right atrial disk than left atrial disk—
opposite that of the ASO—and the APO has a very thin, 3-mm long “waist” compared to the ASO (Fig. 48-12). The APO size is reported by the right atrial disk size, and the APO comes only in 18-, 25-, and 35-mm sizes. The 18-mm device is compatible with an 8-Fr sheath, whereas the 35-mm device requires a 9-Fr sheath. Similar to the ASO, the APO is retrievable while still on the delivery cable and may be redeployed to achieve a satisfactory closure.

![Image](image.png)

**FIGURE 48-12** The differences between the Amplatzer Septal Occluder (ASO; left) for secundum-type atrial septal defects and Amplatzer Patent Foramen Ovale Occluder (right) are evident with both devices oriented with the left atrial disk at the top: the ASO has a larger left atrial disk and a larger “waist” in the middle.

The technique for deploying the APO is very similar to the previously described technique using the ASO, with the exception that no right-sided heart catheterization is necessary and there is no need for a “stop-flow” technique. Instead, the sizing for PFO closure is based not on the stretched PFO diameter but rather on anatomic measurements. The proper APO size for PFO closure is based on the shortest distance of (1) the distance between the aortic root to the defect or (2) the distance between the defect and the SVC. In addition, the ASA length should be considered. For instance, a 9-mm PFO with a distance of 12 mm from the farther edge of the PFO to the aortic root and 14-mm SVC-PFO length would dictate an 18-mm device. For a 6-mm PFO, an aortic root–PFO distance of 15 mm, and SVC-PFO distance of 20 mm, the size should be 25 mm. If any of the measured distances are less than 6 mm, the device should not be used. In many US centers, the Amplatzer multifenestrated device has been used for “off-label” PFO closure given its mechanical similarity to the APO.

To be a candidate for closure, all cryptogenic stroke patients should have a thorough workup, including hypercoagulability studies, carotid and magnetic resonance imaging studies, and a TEE to diagnose and characterize the PFO.
and its surrounding anatomy. Once the decision to close the PFO has been reached, the patient should cease taking warfarin at least 3 days prior to the procedure. Just prior to starting the procedure, antibiotics should be administered.

In the catheterization laboratory, the sizing of the defect is identical to the procedure described in the earlier APO section. No right-sided heart catheterization is necessary, and ICE may be employed for imaging. Once the size of the PFO has been established, the choice of device size ensues, and this is dictated by the size of the defect.

**Postprocedure Care**

The postprocedure care does not differ from that of ASD closures (see above).

**Complications**

Complications associated with PFO closure are similar to those of ASD closure. In an earlier study, Windecker et al\(^5\)\(^1\) reported their experience in 80 patients, of whom 8 (10%) experienced a periprocedural complication. Air embolization occurred in 2 patients, resulting in a transient neurologic deficit in 1 patient and inferior ST-segment elevation in the other. An intraprocedural cerebrovascular accident (CVA) occurred in 1 patient, also presumed due to air embolism. Cardiac tamponade requiring pericardiocentesis after puncture of the right atrium by the delivery sheath was seen in 1 patient. Three device embolization events occurred, 2 of which were successfully retrieved by percutaneous method, and in 1, the device used was a reversed button device in which the occluder portion remained in the proper position in the PFO. In another report, Hung et al\(^5\)\(^2\) closed 63 PFOs using the Clamshell, CardioSeal, or Buttoned devices. The only periprocedural complication was 4 episodes of periprocedural or postprocedural new-onset atrial fibrillation, all of which resolved within the 2.6-year mean follow-up. In another series of 152 patients with PFO and cryptogenic neurologic events,\(^5\)\(^3\) 1 patient had a femoral artery laceration that necessitated surgery and eventual surgical PFO closure. Ten procedural complications were seen: device embolization in 4 patients, cardiac tamponade requiring pericardiocentesis in 1 patient, symptomatic air
embolism in 3 patients, and arteriovenous fistula at the puncture site in 1 patient. None of these 10 patients had any permanent disability due to the complications. Braun et al\textsuperscript{54} reported their findings in 276 patients, with 11 patients (4\%) suffering a periprocedural complication. Transient atrial fibrillation was seen in 2 patients, TIAs in 2 patients, reversible ST-segment elevation in 4 patients, and transient third-degree heart block in 1 patient. Device embolization occurred in 2 patients. The experience at the Massachusetts General Hospital\textsuperscript{55} in 110 patients revealed a periprocedural complication in 2 patients: pericardiocentesis was necessary in 1 case, and a device embolism occurred in another. A significant shunt or device malposition requiring a repeat procedure was needed by 4 patients (3.6\%) in this study. In a phase I trial with the APO in 50 patients,\textsuperscript{56} an arteriovenous fistula that required surgical treatment occurred in 1 patient. There were no APO-related complications.

Data from the large randomized CLOSURE-I (Evaluation of the Starflex Septal Closure System in Patients With a Stroke and/or Transient Ischemic Attack due to Presumed Paradoxical Embolism through a Patent Foramen Ovale)\textsuperscript{57} and RESPECT-PFO (Randomized Evaluation of Recurrent Stroke Comparing PFO Closure to Established Current Standard of Care Treatment)\textsuperscript{58} trials showed a relatively low rate of procedural complications, mostly clustered around vascular access. For instance, in the CLOSURE-I study, there was a 3.2\% major vascular complication rate (13 of 402 patients), which included 4 patients with a hematoma, 3 patients who received a transfusion, 1 patient who underwent a surgical vascular repair, 1 patient with left atrial perforation, 1 patient with peripheral nerve damage, and 3 patients retroperitoneal hematomas.

In RESPECT-PFO,\textsuperscript{58} there were a total of 22 adverse events in the 499 device-treated patients; among these events, there were 3 vascular events (2 bleeding and 1 hematoma), 2 cases of pericardial tamponade, and 1 cardiac perforation. There was also 1 patient with a right-sided thrombus noted periprocedurally, which led to procedure abandonment and no device deployment. Other adverse events were generally noted later in follow-up.

Taken together, the acute safety of the procedure remains very good, especially in the hands of well-experienced operators.

**Results**
PFO closure for the secondary prevention of neurologic events in patients with cryptogenic stroke has been generally positive. The incidence of an acute residual shunt after closure ranges from 17% to 55%\(^\text{51-56,59}\), a large majority of these are trivial or mild in grade. Larger shunts (moderate or greater in degree) had an incidence of 3% to 12%, with the general experience that most will close fully by 6 months. It is currently a topic of debate whether a residual shunt is related to a higher risk of recurrent neurologic events.

Windecker et al\(^\text{51}\) reported the 5-year follow-up on patients and found an annual risk of a recurrent TIA of 2.5%, 0% for CVA, and 0.9% for peripheral embolism. They also found that a residual shunt was a predictor for an event. The experience of Hung et al\(^\text{52}\) in Boston revealed 3 TIAs and 1 CVA in 63 patients at the mean follow-up of 2.6 years, for a 3.2% calculated annual risk of TIA or stroke after device placement.

In the study by Wahl et al,\(^\text{53}\) 9 patients (6%) in the 150-patient series had a neurologic event within a mean follow-up of 1.7 years after device placement. The risk of a neurologic event was significantly higher \((P = .02)\) in the 21% of patients with a residual shunt. In the United States, the small 18-patient study by Du et al\(^\text{59}\) showed acute complete closure in 12 patients (67%) and complete closure by 2 years. No neurologic events were seen within the mean follow-up of 2.2 years. In the study by Braun et al,\(^\text{54}\) 276 patients were followed for a mean of 15 months after PFO closure, and the annual risk of thromboembolic events was 1.7% for TIA, 0% for stroke, and 0% for peripheral emboli. There was no significant difference between patients with and without a residual shunt. Interestingly, 8 patients (2.9%) were noted to have thrombus adhering to the device; this prompted warfarin treatment, and follow-up TEE showed no thrombus in any of these patients. In yet another study\(^\text{53}\) involving 110 patients at a mean follow-up of 2.3 years, there was an annual neurologic event rate after PFO closure of 0.9%. The initial experience of Hong et al\(^\text{56}\) with the APO in 50 patients revealed no neurologic events after closure at a mean follow-up of 16.5 months.

The major weakness of the data generated had been the lack of a prospective randomized controlled trial of device versus medical therapy. A meta-analysis of several reports of closure or medical therapy\(^\text{60}\) included 10 studies of transcatheter closure and 6 studies of medical therapy, with 1355 patients undergoing device therapy and 895 patients treated medically for the
secondary prevention of cryptogenic neurologic events. The findings included an annual rate of recurrent neurologic events in the device group of 0% to 4.9%, whereas the medical group had an annual rate of 3.8% to 13.0%. The conclusion from this study was that transcatheter closure was safe and provided a benefit in the prevention of secondary neurologic events but that a firm recommendation about therapy could not be made in the absence of randomized controlled clinical trials comparing device and medical therapy. Indeed, a report from the American Academy of Neurology made the same recommendation regarding clinical trials to investigate the benefits of medical versus device therapy. This report noted that medical therapy itself was inconclusive as to whether warfarin or aspirin should be the recommended therapy for secondary prevention. In addition, the findings noted that PFO by itself did not increase the risk of a subsequent event in patients treated medically but that patients with a PFO and an ASA were possibly at a higher risk of subsequent events in patients treated medically.

As a result of the above recommendations and the desire to move beyond HDE status, 2 large randomized trials in the United States have examined outcomes after PFO closure for cryptogenic neurologic events. The first of these, the CLOSURE-I study, had planned to enroll 1600 patients in a randomized trial comparing device closure using the StarFlex device versus best medical therapy. In the end, 909 patients were enrolled, and there was no significant difference in events between the 2 groups in the 2-year composite end point of subsequent stroke, TIA, death at 30 days, or neurologic death between 31 days and 2 years. There were a number of interesting findings within this trial: (1) a large majority of neurologic events in both groups had no relation to the device or PFO; (2) atrial fibrillation was much more common in the device group (5.7%) versus medical therapy (0.7%); and (3) effective closure with the NMT device was 86%. The failed trial eventually led to a downfall of the company.

Results with the Amplatzer PFO device were reported in a similar randomized trial called RESPECT-PFO; the trial compared the APO against best medical therapy (antiplatelet or warfarin). In this important trial, 980 patients were enrolled and randomized to device or medical therapy with a primary efficacy end point that was a composite of recurrent nonfatal ischemic stroke, fatal ischemic stroke, or early death after randomization. The trial took 8 years to complete enrollment and was stopped after 25 primary end point events (9 in the device group and 16 in the medical therapy group).
In the intent-to-treat analysis, this difference was not statistically significant ($P = .08$), but the prespecified per protocol ($P = .03$) and as-treated analysis ($P = .007$) did show an advantage for the device group. There was no statistical difference in the incidence of atrial fibrillation (3.0% vs 1.5%). Five-year follow-up of the intent-to-treat analysis was recently presented in San Francisco at the TCT meeting and showed continued safety of the device and perhaps efficacy when compared to medical therapy ($P = .042$).

Subsequent large trials, such as a trial in Europe using the APO, again showed no significant advantage in PFO closure for cryptogenic neurologic events. As a result of these trials, there remains no FDA indication for percutaneous closure of PFO in the setting of a cryptogenic neurologic event.

**MULTIPLE CHOICE QUESTIONS**

1. A 32-year-old woman is referred to you because of an abnormal electrocardiogram (ECG) showing an incomplete right bundle branch block. She has mild exertional dyspnea, and an echocardiogram is ordered because you hear a widely split S₂ on examination and she reports a history of a “hole in her heart” when she was young. A transesophageal echocardiogram reveals a 12-mm secundum atrial septal defect (ASD) and mildly dilated right ventricle (RV), with an RV systolic
pressure estimated at 44 mm Hg. What do you tell her?
A. Her ASD is not clinically significant.
B. Her ASD should be closed percutaneously.
C. Her ASD should be closed surgically.
D. You need further review of the transesophageal echocardiogram (TEE) to determine the likelihood of success for percutaneous closure.

2. Recent data from trials involving patent foramen ovale (PFO) closure devices suggest which of the following?
A. For cryptogenic stroke or transient ischemic attack (TIA), closure is statistically superior to medical therapy.
B. Migraine headaches are easily treated with PFO closure.
C. There is no statistical benefit for PFO closure in cryptogenic stroke or TIA.
D. PFO closure is dangerous and should be avoided in all cases.

3. Which type of ASD can be safely and reliably closed using a percutaneous device?
A. Ostium primum with good rim
B. Ostium secundum with multiple fenestrations but with adequate rim
C. Ostium secundum with inferior rim of <1 mm
D. Sinus venosus with adequate rim

4. You are in the catheterization laboratory and in the midst of an ASD closure. You have crossed the defect, and you notice that the patient now has inferior ST-segment elevation on her ECG and is complaining of chest pain. What do you do next?
A. Obtain arterial access and perform a coronary angiogram
B. Withdraw the venous sheath from the pulmonary vein
C. Give oxygen and supportive care
D. Give a bolus of tissue plasminogen activator (tPA)

5. A scuba diver comes to see you because his friend recently went with him for a dive and developed decompression sickness (DCS). His friend was told he had a PFO and is in the midst of a decision with his physician regarding PFO closure. Your patient has never had DCS but is alarmed by
his friend’s recent events. What do you do?
A. Reassure him that his risk is low for DCS
B. Obtain a transesophageal echocardiogram with bubbles to rule out PFO
C. Obtain a screening transthoracic echocardiogram with bubbles
D. Obtain an ECG

ANSWERS

1. D
It is likely that her shunt is clinically significant, given her symptoms as well as the RV findings. Safe and successful percutaneous closure would require adequate rims to secure a device, and the TEE would need to be reviewed more closely. It could be closed surgically, but there are no data suggesting that surgical closure would be any better than percutaneous closure pending the anatomic review.

2. C
Data from several PFO closure trials (CLOSURE-I, RESPECT-PFO, PC) showed no statistical improvement in outcomes with PFO closure versus best medical therapy as dictated by a neurologist. Data regarding migraine headaches and PFO closure are mixed at best. PFO closure has been demonstrated to be relatively safe in these large trials.

3. B
Secundum ASD is the only defect that can be safely closed as long as there is an adequate rim.

4. C
This is a classic case of air embolus. Supportive care, including oxygen, will help with resolution of the ECG findings and symptoms. Answers A and D only add risk to the procedure and are unnecessary; answer B does not help and will only add extra effort to the eventual closure of the defect because you will have to recross the defect again.
5. A

In patients who scuba dive with no prior history of DCS, there is no indication to do testing for a PFO. Answer D does not address the suspicion of a PFO.
Alcohol Septal Ablation in Drug-Refractory Obstructive Hypertrophic Cardiomyopathy

John S. Douglas Jr.

SCOPE OF THE PROBLEM

Hypertrophic cardiomyopathy (HCM), defined clinically by the presence of hypertrophy of a nondilated left ventricle without loading conditions or other recognized causes of hypertrophy, occurs in 1 per 500 individuals in the general population, with approximately 700,000 cases in the US population. HCM, inherited with an autosomal dominant Mendelian pattern, is the most common familial heart disease and the most common cause of sudden death in athletes and adolescents. HCM is caused by 1 of more than 1500 different mutations of genes encoding sarcomeric proteins. This genetic heterogeneity and the diverse and unpredictable phenotypic expressions, clinical manifestations, and prognosis limit the value of genetic testing or projections based on affected family members. The vast majority of individuals who are genotype positive/phenotype positive are asymptomatic or minimally symptomatic and are undiagnosed. Heart failure is the most common clinical presentation of HCM in adults. Diagnosis may be difficult due to compensating adjustments in lifestyle that minimize symptoms and nonspecific physical and electrocardiogram (ECG) findings. Elevation of left atrial pressure results from diastolic dysfunction and mitral regurgitation.
Limitations of cardiac output in HCM resulting in fatigue, dyspnea, presyncope, and syncope are commonly related to left ventricular outflow tract (LVOT) obstruction and low end-diastolic volume because of diastolic dysfunction. LVOT obstruction (LVOT pressure gradient ≥30 mm Hg) is present in one-third of HCM patients at rest and in an additional one-third with provocation with Valsalva maneuver, nitroglycerin, post-extrasystolic potentiation, or exercise echocardiography, a preferred method of evaluating patients with no resting LVOT gradient but marked exercise tolerance. The presence of LVOT obstruction is a predictor of HCM-related progressive heart failure and heart failure death, and relief of obstruction surgically results in better survival than achieved by patients without this treatment. Relief of LVOT obstruction is a principle goal of both medical and septal reduction therapies.

PATHOPHYSIOLOGY: A 60-YEAR ADVENTURE

The cardiac surgeons Drs. Brock and Morrow coined the term functional aortic stenosis in the 1950s to describe the absence of expected LVOT obstruction in the cardioplegia-arrested heart during open heart surgery, and in the 1960s, Braunwald et al used the newly developed techniques of left heart catheterization to investigate the pathophysiology of obstructive HCM. These hemodynamic studies demonstrated highly variable LVOT obstruction depending on physiologic and pharmacologic maneuvers, which altered loading conditions and contractility (Fig. 49-1). The advent of echocardiography in the early 1970s introduced a powerful new tool for understanding the pathophysiology, diagnosis, and prognosis of HCM and for monitoring treatment of HCM (Figs. 49-2 and 49-3). LVOT obstruction results from several mechanisms, including narrowing of the LVOT by septal hypertrophy, anterior location of the mitral valve encroaching on the LVOT, and systolic anterior motion (SAM) of the anterior mitral valve leaflet leading to SAM-septal contact (see Figs. 49-2 and 49-3). The anterior leaflet of the mitral valve is longer in patients with HCM, and this favors its sail-like movement into the LVOT resulting in (1) a pressure gradient between the left ventricle (LV) and aorta and (2) a posteriorly directed jet of mitral
regurgitation (see Fig. 49-3C). In symptomatic patients without a resting LVOT pressure gradient, provocation with Valsalva maneuver (see Fig. 49-1B) or exercise echocardiography must be considered. LVOT obstruction adversely impacts long-term outcomes with respect to morbidity and mortality. Recently, cardiac magnetic resonance imaging (MRI) has become a valuable adjunctive imaging strategy, offering greater spatial resolution and detection of hard-to-see structures by echocardiography, including LVOT membranes, anomalies of the mitral subvalvular apparatus, focal segmental LV hypertrophy, and apical abnormalities. Contrast-induced MRI hyperenhancement techniques provide an estimate of myocardial fibrosis, with absence of hyperenhancement being associated with lower risk of sudden death (SD) and hyperenhancement of ≥15% of LV mass being associated with a doubling of risk of SD.¹
FIGURE 49-1 A. Simultaneous aorta–left ventricular pressure tracings show a bifid arterial waveform typical of obstructive hypertrophic cardiomyopathy (HCM) and a large left ventricular outflow tract (LVOT) pressure gradient of over 100 mm Hg. After a premature ventricular contraction, there is an augmentation of left ventricular pressure due to increased contractility and LVOT obstruction. Although subtle, there is also a decrease in aortic pulse pressure, the Brockenbrough sign. B. In a 65-year-old man with marked exercise intolerance, there was no LVOT gradient at rest but a >100-mm Hg gradient with Valsalva maneuver. Changes in contractility (A) and loading (B) can lead to marked changes in LVOT obstruction.

FIGURE 49-2 An M-mode echocardiogram (circa 1972) of the first obstructive hypertrophic cardiomyopathy patient seen by the author. A. At rest; note marked septal hypertrophy and minimal systolic anterior motion (SAM). B. After amyl nitrite, there was marked SAM-septal contact. C. Left anterior oblique–cranial view of the left ventriculogram showing SAM-septal contact.
FIGURE 49-3 Alcohol septal ablation procedure in a 65-year-old woman with obstructive hypertrophic cardiomyopathy (HCM), disabling angina, and effort dyspnea on optimal medical therapy. Basal septal thickness was 2.3 cm, and there was systolic anterior motion (SAM) with septal contact during systole (A). Left ventricular outflow tract (LVOT) gradient at rest was 67 mm Hg (B) and 110 mm Hg with Valsalva. LVOT turbulence was present, along with an eccentric posteriorly directed jet of moderate to severe mitral regurgitation (C). The first septal perforating artery was selected (D), and a 2.5 × 9 mm balloon catheter was introduced and inflated (E) through which agitated contrast solution was injected producing brightening of the basal septum at the SAM-septal contact point. With confirmation that the correct
septal artery had been selected and that there was no contrast solution reaching the LAD or other distant sites, 3 mL of alcohol was slowly injected over 10 minutes and allowed to “dwell” for 5 additional minutes. Following alcohol injection, there was no SAM (F), and the LVOT pressure gradient was reduced to 10 mm Hg at rest and 19 mm Hg with 100 μg of nitroglycerin plus Valsalva maneuver (G). There was also no LVOT turbulence and no mitral regurgitation (H). Coronary angiography revealed an occluded septal artery (I). The patient experienced relief of symptoms and, at last follow-up 3 years later, was asymptomatic. This patient had a left anterior descending artery stent placed several years earlier that bridged across the septal artery so entry into the septal artery was through stent struts.

TREATMENT OF OBSTRUCTIVE HCM

Treatment of patients with obstructive HCM is aimed at relief of symptoms and preventing SD (Table 49-1). Strategies to achieve the latter include abstaining from intense competitive sports and implantable cardioverter-defibrillator (ICD) implantation in high-risk patients,\(^5,6\) as well as treatment strategies to reduce LVOT obstruction. The 2011 American College of Cardiology (ACC)/American Heart Association (AHA) guideline statement “stand alone” Class I indications for ICD are prior cardiac arrest and sustained ventricular arrhythmias (ventricular fibrillation [VF] or ventricular tachycardia [VT]); Class II indications are SD in a first-degree relative, LV wall thickness ≥30 mm, and unexplained syncope.\(^5\) Other SD risk factors to be considered include nonsustained VT and abnormal blood pressure response to exercise. In a 2-center longitudinal study of 1000 patients with HCM presenting at 30 to 59 years of age, 5- and 10-year survival rates (confined to HCM death) were 98% and 94%, respectively, and were not different from the expected all-cause mortality in the general US population.\(^7\) This 0.5% per year mortality rate achieved by contemporary management strategies compares favorably to the 3% to 6% per year mortality rate reported in early HCM referral cohorts and the 1.5% per year mortality rate in the 1990s prior to utilization of current strategies. Although not included in the 2011 guideline statement,\(^5\) MRI-assessed myocardial fibrosis has begun to assume importance in risk stratifying patients.\(^7\) Late gadolinium enhancement was also a notable omission from the European Society of Cardiology (ESC) risk prediction model,\(^6\) which when applied to 35 incurred SD events in one study found that 21 (60%) failed to qualify for an ICD.\(^8\)
This and the absence of other potentially high-risk clinical entities (eg, apical aneurysm) suggested that the available guideline statements\(^5,6\) are outdated with respect to SD prevention by ICDs.

Relief of symptoms in patients with obstructive HCM is primarily accomplished by reducing LVOT obstruction by lifestyle changes and pharmacotherapy. Dehydration, the splanchnic pooling that accompanies a large meal, and alcohol consumption increase LVOT obstruction and should be avoided. β-Blockers are the drug of choice for treatment of symptomatic obstructive HCM and act by favorable negative inotropic and chronotropic effects. β-Blockers reduce LVOT gradient and are particularly effective in reducing provoked gradients such as those associated with exertion and have a class I indication in the 2011 guideline statement, which recommends titrating the dose to a resting heart rate of 60 to 65 bpm.\(^5\) Verapamil also has a Class I indication for symptomatic patients with HCM who do not respond to β-blockers or have contraindications to these drugs. Caution has been recommended in the use of verapamil in symptomatic patients with very large resting LVOT gradients because sudden hemodynamic collapse has been reported. Verapamil has negative inotropic and chronotropic effects similar to β-blockers. Patients with LVOT obstruction who remain symptomatic despite treatment with β-blockers and/or verapamil can be considered for treatment with disopyramide, a Class IA antiarrhythmic drug with negative inotropic
effects as well as anticholinergic side effects that hinder widespread usage. In addition, initiation of disopyramide therapy requires in-hospital cardiac monitoring for QT prolongation and arrhythmias (torsades de pointes). Disopyramide has a Class IIa indication in the 2011 guidelines.⁵

MANAGEMENT OF DRUG-REFRACTORY OBSTRUCTIVE HCM

For patients whose symptoms and LVOT obstruction prove refractory to optimal pharmacologic therapy, septal reduction therapies with myectomy or alcohol septal ablation are the currently recommended strategies.⁵,⁹ Dual-chamber pacing, which was widely used 20 years ago, was shown in 3 randomized crossover trials to produce a significant improvement in symptoms and exercise tolerance along with a decrease in LVOT gradients in <50% of patients. This led to a Class III indication for pacing as first-line therapy in drug-refractory patients.⁵ The observation that older patients were a subgroup that benefited most led to a 2011 guideline class IIb recommendation for pacing in patients with obstructive HCM who were poor candidates for septal reduction therapy.⁵ The choice of septal reduction strategy (myectomy or alcohol septal ablation) requires a comprehensive evaluation of clinical symptoms, comorbidities, and hemodynamic, echocardiographic, and angiographic features and should incorporate the wishes of a well-informed patient.¹⁰

ROLE OF SURGICAL MYECTOMY

The Morrow procedure, a transaortic approach to septal myectomy, was initially adopted as safe and effective after presentation of the outcomes of 83 patients in 1975.¹¹ Failure of this procedure in selected patients and a greater appreciation of the diversity of mitral valve structural abnormalities in HCM by Klues and colleagues¹²,¹³ led to alternative surgical techniques to include a more extensive myectomy,¹⁴ as well as approaches to abnormalities of the mitral valve and papillary muscles¹⁵,¹⁶ using intraoperative transesophageal echocardiography monitoring. In patients with other cardiac issues such as
atrial fibrillation or obstructive coronary disease, additional procedures may be carried out (maze procedure or coronary bypass). In the current era, the risk of surgery in HCM centers of excellence has decreased significantly, with reported mortality for isolated myectomy ranging from 0.0% to 1.5%,\(^{17-20}\) with some reports of the additional procedures increasing risk to 2% to 3.4%.\(^ {17,21}\) Although long-term outcomes after myectomy have not been evaluated in a randomized controlled trial, observational studies have almost uniformly reported significant improvements in heart failure symptoms, functional capacity, and survival similar to that of the general population.\(^ {2,3,7}\)

Surgical myectomy results in permanent reductions in LVOT obstruction, reduces or abolishes mitral regurgitation, and is associated with long-term survival exceeding that of a comparable group of unoperated patients with LVOT obstruction.\(^ {3}\) Surgical myectomy results in excellent long-term outcomes and has a Class IIa indication in the 2011 guideline statement.\(^ {5}\) However, it is an invasive procedure that requires well-honed surgical skills not widely dispersed, and this has resulted in underutilization, particularly in Europe where its demise was inaccurately reported.\(^ {20}\)

**ROLE OF ALCOHOL SEPTAL ABLATION**

Alcohol septal ablation (ASA) is a percutaneous catheter-based procedure that was first reported by Sigwart\(^ {22}\) in 1995. He had previously noted that balloon occlusion of the first septal perforator artery temporarily reduced the LVOT pressure gradient and correctly surmised that delivery of alcohol would produce infarction of the hypertrophied septum and permanent reduction in LVOT gradient. When performed by skilled operators,\(^ {23-27}\) ASA leads to reductions in peak resting or provoked LVOT gradient in >80% of patients. Treatment of the portion of the hypertrophied septum producing the obstruction, that is, the SAM-septal contact area, leads to immediate at least partial relief of obstruction with further decrease over time as thinning of the septum occurs. Reductions in mitral regurgitation parallel the reduction in LVOT obstruction such that patients with severe obstruction and significant SAM-related mitral regurgitation do well with ASA (see Fig. 49-3). Long-term benefits include reduction in LV end-diastolic pressure, regression of
LV hypertrophy, reduced size of the left atrium, less atrial fibrillation, and relief of pulmonary hypertension.\textsuperscript{23,26-30} ASA results in significant improvement of heart failure symptoms, peak oxygen consumption, and exercise capacity. Similar to the experience with surgical septal reduction, patients after successful ASA also appear to have long-term survival rates comparable to the non-HCM population.\textsuperscript{27} The less invasive nature of ASA with prompt return to active lifestyle with continued improvement over time has led to a dramatic increase in ASA worldwide, far exceeding the number of surgical myectomy procedures. ASA limitations include the following: (1) less precise targeting of the anterior basal septum, the SAM-septal contact area removed by the surgeon; (2) the need for permanent pacing in a significant minority of patients; and (3) a septal scar with, as yet, uncertain long-term consequences.

**Patient Selection for ASA**

Patients selected for ASA must qualify based on clinical, hemodynamic, and anatomic criteria. The 2011 ACC/AHA guideline statement and the European guidelines recommend that ASA be offered only to patients with severe symptoms despite optimal medical therapy (usually New York Heart Association (NYHA) functional class III or IV or other exertional symptoms that interfere with everyday activity or quality of life)\textsuperscript{5,9} (Table 49-2). The physician should be convinced that relief of obstruction and subsequent favorable changes in mitral regurgitation, diastolic compliance, and LV hypertrophy will result in significant improvement in symptoms. This assessment may be difficult in the patient with severe obstructive HCM and severe chronic pulmonary disease and/or other comorbidities. Hemodynamic criteria required include dynamic LVOT gradient at rest or with physiologic provocation $\geq 50$ mm Hg associated with SAM of the mitral valve. Dynamic outflow obstruction produces a characteristic “spike and dome” arterial waveform, post-extrasystolic potentiation, and the Brockenbrough sign (see Fig. 49-1). Anatomic features that must be present include basal septal hypertrophy $\geq 15$ mm. ASA is discouraged in patients with septal thickness $\geq 30$ mm due to uncertain effectiveness of ASA and in patients with septal thickness $<1.5$ mm due to the risk of creating a ventricular septal defect.\textsuperscript{5} Patients with midventricular obstruction, subvalvular membrane, intrinsic mitral valve or subvalvular abnormalities, and malpositioned papillary
muscles are not good candidates for ASA. Because ASA induces a right bundle branch block in a majority of patients, a preexisting left bundle branch block results in a high probability of complete heart block. The 2011 guideline statement gives a Class IIa indication for surgical myectomy and class IIa for ASA when surgery is contraindicated or high risk (see Table 49-2). ASA may be selected over myectomy by a well-informed patient, and this is a Class IIb indication. The most recent European guideline statement gave ASA and myectomy equal status as therapeutic options in drug-refractory obstructive HCM. The 2011 guideline statement indicates that ASA should not be done in patients less than 21 years of age and discouraged in those younger than 40. This recommendation to avoid ASA in younger patients is a result of the more complete relief of obstruction with myectomy, concern regarding the arrhythmic potential of the septal scar produced by ASA, and the paucity of a long-term data at the time the guideline statement was drafted. Since then, longer term follow-up has been completed, and although there remain some concerns, several studies have reported favorable outcomes in younger patients after ASA, with survival similar to the age-matched general population and to age-matched HCM patients without obstruction.

</tr>
<tr>
<td>1. Alcohol septal ablation may be considered as an alternative to surgical myectomy when a well-informed patient expresses a preference for septal ablation.</td>
</tr>
</tbody>
</table>
2. Septal ablation is discouraged in patients with marked septal hypertrophy (>30 mm).

Class III: Alcohol septal ablation should not be done in patients less than 21 years of age and discouraged in adults less than 40 years of age if myectomy is a viable option.

Performance of ASA

Although some have suggested omitting medications for 24 hours prior to ASA (to ensure a LVOT gradient that can be monitored during the procedure), it is the author’s practice to continue medication. A temporary pacemaker is inserted via the right internal jugular vein, which is left in place for 48 hours. Some have preferred screw-in temporary leads, but a balloon-tip pacing lead is adequate if carefully managed. Dual arterial access is obtained in order to monitor the LVOT gradient during the procedure. Unfractionated heparin is administered to achieve an activated clotting time >250 seconds. The degree of baseline LVOT obstruction is determined by measurement of resting and provoked pressure gradient using the Valsalva maneuver and/or nitroglycerin or post–premature ventricular contraction gradient. Patency of the right coronary artery is confirmed, and angiographic views of the left coronary artery are taken to highlight the arterial supply to the basal septum (30° right anterior oblique with cranial angulation and 30° left anterior oblique with caudal angulation are frequently the best angles to display the anatomy without overlap). The basal septum is most frequently supplied by septal perforating branches from the left anterior descending artery (LAD); however, there may be branches supplying the septum that arise from the diagonal, ramus intermedias, circumflex, left main, or right coronary arteries. Based on the location of the septal hypertrophy and SAM-septal contact, the most likely feeding septal artery is selected to be tested by myocardial contract echocardiography from a transthoracic approach. A short over-the-wire balloon catheter is chosen to approximate the septal artery diameter (frequently a 1.5 × 6 mm balloon) (see Fig. 49-3). A steerable coronary guide wire, preferably with hydrophilic coating, is introduced into the septal branch followed by the balloon catheter. If the septal artery is difficult to enter with the guide wire, reshaping of the guide wire may be necessary. The coronary arteries in HCM patients are frequently large, and it may be difficult to direct the guide wire tip, which is tracking along the roof of the artery, into the
small septal artery arising from the “floor” of the artery. The author avoids use of redirecting strategies such as the Venture catheter or “blocking balloon” and prefers to pass an extra-support “buddy wire” into the distal LAD, which straightens the artery slightly, permitting entry into the septal branch. In the presence of a very large septal perforating artery, it may be desirable to isolate a branch for treatment to limit the size of septal infraction and reduce the risk of complete heart block (Fig. 49-4). It is not essential that the septal artery meet any size requirements. Tiny, almost invisible, septal branches that supply the targeted septal region can often be entered with hydrophilic guide wires and small (1.25-mm) balloon catheters (Fig. 49-5). Once placed in the proximal portion of the septal artery, the balloon catheter is inflated to 4 to 5 atm. The coronary guide wire is removed, and contrast solution is injected through the balloon to ensure that it is occlusive and that no contrast enters the parent vessel. Oversizing of the balloon is avoided because it may lead to “melon seeding” of the inflated balloon back into the parent vessel with escape of alcohol, with potentially catastrophic consequences. After stability of the inflated balloon in the septal artery is assured, a 50/50 mixture of contrast and saline is agitated with air and injected. The myocardial segment receiving the “bubbles” appears bright on echocardiography (see Figs. 49-3 to 49-5; Figs. 49-6 and 49-7). If brightening of the SAM-septal contact zone occurs with no brightening elsewhere, 1 to 2.5 mL of alcohol is delivered over 8 to 10 minutes, after adequate analgesia is assured. If “brightening” of the right side of the septum occurs (see Fig. 49-6) or if brightening of papillary muscle (see Fig. 49-7) or other nonseptal areas is noted, another septal artery must be sought. In the author’s experience, septal arteries arising from a diagonal branch are more likely to supply the left side of the septum, as illustrated in Figure 49-6. The optimal amount of alcohol to administer is uncertain, but lower amounts of alcohol have been associated with lower rates of complete heart block. Careful monitoring of balloon stability, echocardiographic findings, and LVOT pressure gradient are carried out during alcohol injection. After administration of 1 to 2 mL of alcohol, reassessment of the LVOT pressure gradient is carried out (either resting or provoked gradient based on the initial assessment) with a goal of achieving a gradient <20 mm Hg if possible. Because adequate gradient reduction is highly correlated with long-term outcomes, residual gradient >20 mm Hg should lead to consideration of treating a second septal artery. If satisfactory LVOT gradient reduction is
achieved, the procedure is ended after testing the pacemaker and ensuring that it is well protected because there may be no escape rhythm if complete heart block occurs (see discussion of complications in the following section).
FIGURE 49-4 Subselecting a septal artery branch due to very large septal artery distribution: A. Coronary angiogram showing unusually large first septal perforating artery. B. Resting left ventricular outflow tract (LVOT) gradient of 100 mm Hg. C. Balloon inflation in the posterior branch of the septal artery and injection of 2 mL of alcohol after confirming appropriate basal septal brightening D. Postprocedure LVOT gradient was 11 mm Hg (E).

FIGURE 49-5 Use of a small, almost invisible, septal artery to deliver alcohol to the basal septum. A. Right anterior oblique coronary angiogram (arrow showing tiny septal artery). B. Balloon catheter inflated in the small septal artery. C. Septal brightening following contrast mixture injection. D. Resting left ventricular outflow
tract pressure gradient was reduced from 75 to 8 mm Hg with excellent subsequent clinical outcome.

**FIGURE 49-6** Seeking a septal artery supplying the left side of the basal septum. A. Left ventricular outflow tract (LVOT) gradient at rest of 100 mm Hg. B. Right anterior oblique cranial coronary angiogram showing septal branches arising from left anterior descending artery (LAD) and also from the first diagonal artery. C. Brightened right side of septum (arrow) when contrast bubbles were injected into balloon placed into the septal artery arising from the LAD. D. Balloon in septal artery arising from diagonal artery. E. Left side of septum brightened appropriately after contrast was injected into the septal artery from the diagonal artery. F. Resolution of LVOT gradient after alcohol injection in the septal artery arising from the diagonal artery.
FIGURE 49-7 Contrast myocardial imaging showing inappropriate myocardial brightening remote from basal septum. A. Left anterior oblique–caudal view showing septal artery arising from ramus intermedius artery. B. Arrow shows guide wire in this septal artery. C. Following injection of agitated contrast mixture, brightening occurred remote from the septum in what appears to be a papillary muscle. D. Right anterior oblique view of left coronary artery showing septal artery from left anterior descending artery (LAD). E. A balloon catheter is placed in a septal artery arising from the LAD. F. Brightening of the basal septum occurred after injection of contrast mixture. G. Left ventricular outflow tract gradient that was 100 mm Hg before ablation fell to zero and was 13 mm Hg during a Valsalva maneuver.

Complications of ASA

The most common complications of ASA involve the conduction system. Approximately 60% of patients develop right bundle branch block with left anterior hemiblock in 20%; 10% develop left bundle branch block, and transient complete atrioventricular (AV) block occurs in 25% to 55% of patients.\textsuperscript{24-27,38-40} Recently reported need for permanent pacemaker implantation ranged from 3%\textsuperscript{38} to 20%.\textsuperscript{26} Reinhard et al\textsuperscript{38} reported that 55% of patients experienced brief AV block during the procedure with persisting AV block in 23% at 14 hours, 18% after 3 days, 7% at 1 week, and only 3% at 13 days, leading the investigators to recommend waiting ≥7 days before permanent pacemaker implantation is performed. This length of time is unacceptable to many US physicians. Perhaps some form of temporary pacing that permits outpatient observation can be applied in the future. Also, a move to use lower alcohol dosing has reduced the rate of AV block, although less complete relief of LVOT obstruction has been associated with lower alcohol doses.\textsuperscript{41,42} Procedural complications reported among 874 ASAs performed in 9 US centers were LAD dissection in 8 patients, cardiac tamponade in 4, retroperitoneal bleed in 1, ventricular septal defect in 1, VT/VF in 14, high-grade AV block in 78, and death in 6.\textsuperscript{42} Among 459 ASA procedures reported from 9 European centers, there was only 1 in-hospital death; 18% of patients developed complete heart block and 9% had permanent pacemaker implantation.\textsuperscript{43} The volume of alcohol injected in the US cohort (2.9 ± 1.5 mL) was greater than in the European experience (median dose, 1.5 mL; 87% of patients received ≤2 mL). Although use of intraprocedural myocardial contrast echocardiography (MCE) is thought to reduce myocardial necrosis distant from the septal target area,\textsuperscript{44} inferior
myocardial infarction has been reported in 2 patients in whom MCE was used.45 The potential for collateral transport of alcohol suggests that ASA should not be attempted in patients with right or dominant circumflex coronary artery obstruction.

**Clinical Outcome After ASA**

Using a definition of procedural success as ≥50% reduction in peak resting or provoked LVOT gradient and final resting gradient ≤20 mm Hg without death or need for surgery, ASA was successful in 80% to 85% of patients.23-27 Procedural failure may occur due to absence of or inability to access an appropriate septal perforating artery or significant procedural complications. Failure to achieve a sustained LVOT gradient reduction after an apparently successful procedure may occur because of transient septal stunning due to balloon-induced septal ischemia or changing ventricular loading resulting in gradient reduction (intravascular volume increase due to angiographic contrast medium and/or saline infusion). A need for right ventricular pacing may also contribute to intraprocedural LVOT gradient reduction. Finally, administration of “extremely low-dose” alcohol (<1 mL) has been associated with higher LVOT gradients and persisting symptoms.43

In long-term follow-up, clinical efficacy of ASA has been demonstrated with improvements in NYHA classification from class III to I, improvements in exercise time and maximal oxygen consumption, and favorable LV remodeling. Fernandes et al46 showed progressive reductions in LVOT gradients and septal thickness out to 10 years. However, lack of precision inherent in ASA leaves a significant minority of patients (~15%) with disabling symptoms following the procedure due to residual LVOT obstruction and/or diastolic dysfunction. A repeat septal reduction procedure was needed in 10% of ASA-treated patients reported by Sorajja et al27 and in 18% by Fernandes et al46 (14% had repeat ASA; 4% had myectomy). In 94% of repeat ASA procedures, there was successful reduction in LVOT obstruction and long-term relief of symptoms.46 Among 874 ASA patients reported in a North American registry, 15.6% required at least 1 additional repeat septal reduction procedure (ASA in 12.8%; myectomy in 2.8%).42

**Survival After ASA**
Two small longitudinal studies raised concerns regarding a possible arrhythmogenic effect of septal ablation scar. Among 89 ASA-treated patients, there was no mortality attributed to sudden cardiac death during a 5-year follow-up period. However, among 42 patients with ICD or pacemaker, 9 had documented VT/VF, for an annual event rate of 4.9%. Among 91 ASA patients followed for 5.4 years, 19 (21%) experienced cardiac death or ICD-aborted cardiac death, with an estimated annual event rate of 4.4%. Whether the relatively large volume of alcohol administered (mean, 3.5 mL) contributed is uncertain. Several studies compared survival following ASA to that in the general population or to medically treated HCM patients. Sorajja et al found the 8-year survival of ASA-treated patients to be the same (79%) as the expected survival of a similar US population. Vriesendorp et al reported that 10-year survival was similar in medically treated obstructive HCM patients (84%), ASA-treated patients (82%), and nonobstructive HCM patients (85%). In a North American registry of 874 ASA patients, the 1-, 5-, and 9-year survival rates were 97%, 86%, and 74%, compared to 98%, 95%, and 88%, in a disease-free US population. In a Scandinavian 4-center study of 279 ASA-treated patients, the 10-year survival rate was comparable to the age- and sex-matched general population.

**COMPARISON OF ASA AND MYECTOMY**

Since the development of ASA more than 2 decades ago, there has been considerable debate as to the comparative efficacy and safety of the 2 septal reduction strategies of ASA and myectomy. Because there are no randomized comparisons and none are anticipated, consideration of observational studies of these very different therapies is necessary. MRI performed before and after ASA (n = 24) and myectomy (n = 24) showed that the site of septal reduction differed substantially with respect to location and extent. With myectomy, the surgeon consistently removed about 6 g of anterior basal septum, producing left bundle branch block in one-half of patients. ASA performed in patients 12 years older resulted in right bundle branch block in 60% and transmural septal infarction (involving 16 g of myocardium) in 75% of patients. Necrosis confined to the right side of the septum sparing the basal
septum occurred in 25%, accounting for failure to relieve obstruction in a substantial minority of patients. This observation highlights the importance of identifying septal arteries that supply the left side of the basal septum (see Fig. 49-6; Fig. 49-8). The comparative imprecision of ASA results in a need for repeat procedures, as has been noted, but yields long-term symptomatic benefit and survival similar to myectomy in published meta-analyses. Myectomy has a predictable track record, but the less invasive and repeatable ASA has considerable appeal to both patients and their physicians, and the favorable long-term (8-10 years) results currently being reported from multicenter and multinational registries are reassuring. The place of ASA in younger patients and in those with septal thickness ≥30 mm is less clear. Sorajja et al reported that younger patients (<65 years old) obtained better symptom relief with myectomy. However, among 110 younger patients (<45 years old; mean age, 35 years), Leonardi et al reported that, despite greater septal thickness in younger patients (2.2 vs 2.0 mm; \(P = .02\)), equally good relief of LVOT obstruction and symptoms was obtained with ASA with fewer procedural complications. Similarly, among 75 patients ≤50 years old (mean age, 42 years) treated with ASA in the Czech Republic and followed a median of 5.1 years, favorable relief of symptoms (NYHA class 2.8 to 1.6, \(P < .01\)), LVOT gradient reduction (73 to 16 mm Hg; \(P < .01\)), and reduced septal thickness (2.3 to 1.4 mm; \(P < .01\)) were reported with only 1 case of SD (annual risk, 0.2%). In a European multinational registry, 26 patients had basal septal thickness ≥30 mm (median, 32 mm; maximum, 54 mm) and underwent ASA, which was equally effective compared with patients without massive septal hypertrophy. These studies suggest that ASA results in similar hemodynamic and symptom improvements in adult patients independent of age and may be effective in selected patients with massive septal hypertrophy.
FIGURE 49-8 Pathologic specimen of the heart of an 84-year-old woman who died several days following an otherwise successful alcohol ablation procedure because of retroperitoneal bleeding while on intravenous heparin bridge to warfarin anticoagulation for stroke prevention. There was necrosis of the left side of the thickened basal septum, which had resulted in complete relief of left ventricular outflow tract obstruction and mitral regurgitation. Bleeding is one of the complications of alcohol septal ablation. Contrary to the report of Valeti et al in which magnetic resonance imaging studies following alcohol ablation showed either transmural necrosis or necrosis of the right side of the septum, this patient appears to have had necrosis primarily of the left side of the septum involving the systolic anterior motion (SAM)–septal contact point (note the presence of a septal callus as the result of repeated contact with the anterior mitral valve leaflet).

**MULTIPLE CHOICE QUESTIONS**

1. What are the prevalence of hypertrophic cardiomyopathy (HCM) in the general population and the number of Americans affected?
   A. 1 in 10,000; 35,000 Americans affected
2. Which statement most accurately characterizes the occurrence of left ventricular outflow tract (LVOT) obstruction (gradient >30 mm Hg) in patients with HCM?
   A. 9 in 10 have resting or provoked obstruction
   B. 6 in 10 have resting or provoked obstruction
   C. 3 in 10 have resting or provoked obstruction
   D. 1 in 10 have resting or provoked obstruction

3. What is the most useful method of confirming a diagnosis of HCM?
   A. History
   B. Physical examination
   C. Electrocardiogram
   D. Echocardiogram
   E. Magnetic resonance imaging

4. Which statement most accurately characterizes the comparison of surgical myectomy and alcohol septal ablation (ASA) in treatment of patients with drug-refractory symptoms and obstruction?
   A. Higher in-hospital mortality with myectomy; similar 1-year mortality
   B. Similar in-hospital and 1-year mortality
   C. Higher in-hospital and 1-year mortality with ASA
   D. Higher in-hospital and 1-year mortality with myectomy

5. Which of the following most accurately describes outcomes of ASA?
   A. Right bundle branch block in a majority
   B. Left bundle branch block in one-third of patients
   C. Transient complete heart block in 70%
   D. Transient complete heart block in 20%

BACKGROUND

Unintended loss of material during catheter-based cardiovascular procedures is uncommon but may have serious consequences. Occasionally, a lost or embolized item ends up in a small peripheral vessel, where it can be left in place safely. More often, retrieval of the lost material is desired to reduce risks of thrombosis, infection, and perforation.

The problem of lost foreign bodies in blood vessels is long-standing; early reports of percutaneous vascular foreign body removal first appeared 50 years ago.\textsuperscript{1,2} A review of the published literature in 1991 found nearly 200 reported cases with a percutaneous retrieval success rate of 90%.\textsuperscript{3} A more recent review concluded that percutaneous retrieval of peripheral intravascular foreign bodies has a high success rate and minimal morbidity and is preferable to open vascular surgical removal.\textsuperscript{4} All manner of gear has been liberated into blood vessels (filters, plugs, coils, torn balloon fragments, rotational atherectomy burrs, fractured catheters, percutaneous heart valves), but in the adult catheterization laboratory, losses most often involve retention of fractured coronary guide wire fragments or unexpanded coronary stents that have been stripped free of their delivery balloon catheters. Stent loss and attempts at their retrieval are associated with increased rates of complications, including need for coronary artery bypass grafting surgery, myocardial infarction, and death.\textsuperscript{5} Loss of foreign bodies in the coronary arteries has been reported to occur in slightly less than 1\% of cases,\textsuperscript{6} but
retention and embolization events are likely to be significantly underreported. As radial artery access gains in popularity, retrieval of lost foreign bodies may prove more difficult, although the techniques described herein have proven useful in this setting. Optimal management of lost interventional products requires (1) judgment about when to leave retained components in place and when to remove them; (2) knowledge of those techniques proven to be effective and efficient at foreign body removal; and (3) competency with a few specialty devices designed to assist in component removal.

AGGRESSIVE OR CONSERVATIVE MANAGEMENT

Significant harm can befall a patient with a retained component. Although late infection, perforation, and even material toxicity are concerns, the principal anxiety is thrombosis; occurring in a coronary artery or similar sensitive vessel, thrombosis around a foreign body can be fatal. However, extraction of foreign bodies from the vascular system carries risk. Thus, before attempting to retrieve a misplaced or embolized component, it is reasonable to ask, “Can I just leave the foreign body where it is?”

Several factors must be considered in the decision process:

1. **Is the retained component in a location that is highly sensitive to the impact of thrombosis?** A sudden thrombotic event in any blood vessel is unwanted but is more easily tolerated in noncritical locations. Fragments left in the left main coronary artery; the proximal portions of the left anterior descending arteries or dominant left circumflex or right coronary arteries; the profunda femoralis; or any cranial artery represent very high risk of harm in the event of thrombosis. Those in arterial or venous structures serving somatic tissue (not organs) are least sensitive to thrombosis.

2. **Is the retained component deformed in such a manner that it disturbs blood flow significantly?** A study of coronary stent design found that increasing stent thickness from approximately 81 to approximately 161 μm increased thrombus development by approximately 150% in animals and ex vivo flow chambers. Lost components typically intrude into the
vessel lumen to a much greater extent. Venous structures may be more prone to thrombosis related to flow perturbation than arteries even when antiplatelet therapies are used. The more adherent a component is to the vessel wall, the less blood flow is disturbed, and clot risk is reduced. In general, smaller fragments that lay close to the vessel surface are better candidates for conservative management.

3. **Can the component be compressed?** In view of the above, reducing the profile of an offending component may significantly reduce the risk it poses. This is especially attractive for coronary stents, which are meant to be compressed into the vessel wall, but compressing other materials into vessels (especially benign peripheral arterial locations) may be safer than attempting component retrieval. If conservative management is under consideration, an attempt to reduce the profile of the retained fragment through balloon angioplasty should be considered.

4. **Does the retained fragment extend from one vascular area to another?** A fractured guide wire may be unspooled over a distance of several feet, resulting in a trail of thin wire that may extend from a coronary artery to the descending aorta. This imbues risk to multiple vascular segments simultaneously and favors fragment retrieval. The thin filaments of wire, when adjacent to coronary stents or other vascular objects, appear to create an environment of high risk for thrombosis.

5. **Is the approach to the retained component with a retrieval device complicated?** The simpler the approach, the greater the likelihood that the component will be extracted safely. Excessive tortuosity, diffuse vascular disease, calcification, thrombosis, and (especially) small vessel caliber make component retrieval more difficult. Although these characteristics likely contribute to thrombosis risk also, the risk of causing additional harm during attempted retrieval may be prohibitive. Note that retained foreign bodies that are entrapped pose greater risk than those that are simply embolized.

### DEVICES

**Snares**
Snaring devices remain the most useful and ubiquitous commercial retrieval devices available. Before the widespread availability of commercial vascular snares, loop snares were fashioned by doubling over a long coronary guide wire, feeding both ends of the wire into the distal end of a vascular catheter, and pulling the wire ends simultaneously at the proximal end of the catheter to collapse the loop of wire formed at the distal catheter tip (Fig. 50-1). Creating a kink in the mid-portion of the guide wire before it is inserted can be helpful, since this facilitates formation of a rounder loop. Unfortunately, these crude loops lack maneuverability: the plane of the loop runs parallel to the catheter, limiting utility. Attempting to angle the loop before insertion can be somewhat helpful, but creating a loop that deviates from the axis of the delivery catheter by more than 20° to 30° is difficult.

**FIGURE 50-1** Forming a loop snare using a coronary guide wire and a simple hollow catheter. Advancing both ends of the wire into the distal catheter tip forms a loop. Pinching the wire to create a bend increases the circularity of the formed loop.
Commercial loop snares are now widely available in a variety of sizes and shapes, including loops with angles (relative to the delivery catheter) ranging from 0° to 90° and snare diameters ranging from 2 to 35 mm (Fig. 50-2). Snares with loops less than 10 mm in diameter are generally referred to as “micro-snares,” Commercial snares are made of complex alloys, like braided nitinol, that hold their shape much better than steel-based wires. The snare portion may be coated in gold or other radio-opaque material to enhance fluoroscopic visualization. Closure of the snare is affected by retracting a lever or a single wire, which can usually be locked into place with a turnscrew device, freeing hands for other purposes. The catheter portion ranges in length from 65 to 120 cm (micro-snares may be up to 175 cm) and are typically 4 to 6 Fr in diameter.
Variants on the single-loop snare theme include the EN snare (Merit Medical, Jordan, UT), which incorporates 3 interlaced nitinol loops angled 120° from one another that form a tulip-shaped device when opened (Fig. 50-3). Seven different snare configurations and sizes ranging from 2 to 45 mm provide broad applicability; the delivery catheter is 6 Fr. A 4-loop device that forms a clover-shaped snare is appropriately called a CloverSnare 4-Loop Retrieval System (Cook Medical, Bloomington, IN) (Fig. 50-4). Designed chiefly for use in the peripheral arterial system, this 6-Fr system uses a telescoping guide delivery system; the outer sheath is 80 cm, the inner sheath is 85 cm, and the snare catheter length is 90 cm.
FIGURE 50-3 EN snare. This unique snaring device assumes a tulip shape with 3 petal-like nitinol loops that expand outward when the inner wire is advanced and retract inward as the wire is retracted. (Merit Medical, reprinted by permission.)

FIGURE 50-4 CloverSnare 4-loop Retrieval System. This 4-wire device resembles a 4-leaf clover when fully expanded. Retracting the loops into the delivery catheter forms an effective trap. (Permission for use granted by Cook Medical, Bloomington, Indiana.)

An innovative snare device is the LoopMaster-Sochman snare (Andramed Medical Devices), available in Europe. This somewhat more complex device is designed to help when a closed loop snare cannot be advanced around the free end of a lost component (Fig. 50-5). Instead, a closed loop with a preformed “cobra head” shape is advanced along one side of a lost
component. A second straight wire is then advanced along the opposite side of the lost component and through the loop snare. When the loop snare is closed, it captures the second wire, forming a new snare around the lost component.

![LoopMaster-Sochman snare](image)

**FIGURE 50-5** LoopMaster-Sochman snare (Andramed Medical Devices, Reutlingen, Germany). When a loop snare cannot be passed around the end of a foreign body, the curved portion of this snare can be advanced alongside the retained item and manipulated around it. Then, the straight wire component is advanced, creating a loop around the item. (Used with permission from Andramed GmbH, Germany.)

The ExPro (Radius Medical, Maynard, MA) straddles the boundary between loop snares and basket retrievers. This device is essentially a loop snare with a twist—literally. The snare portion is twisted such that the snare makes a 180° turn as it exits its delivery catheter, which may facilitate entrapment of a foreign body.

**Baskets**

Basket retrievers are somewhat more complex variants of loop snare retrieval devices. Basket retrievers were developed to aid in management of ureteral or gastrointestinal stones, but many have been used successfully in the vasculature. Some have leading flexible wire tips, although most do not (Fig. 50-6). These are generally larger tools suitable for use in the aorta or larger
arteries and veins, but not in the coronary arteries or bypass grafts. Although elegant in design, their use in product retrieval is generally crude: the basket is brought close to the lost component; the system is manipulated to grab, snag, or entangle the component; and the system is withdrawn.

![Gemini Paired Wire Helical Basket Retrieval devices](image)

**FIGURE 50-6** Gemini Paired Wire Helical Basket Retrieval devices. Double wires increase flexibility and grip. Some versions have an incorporated flexible wire at the tip. (Image provided courtesy of Boston Scientific. Copyright © 2017 Boston Scientific Corporation or its affiliates. All rights reserved.)

The prototypical vascular basket retrieval system is the Dotter Intravascular Retrieval Set (Cook Medical). The system consists of a relatively stiff activation wire used to extend the basket out the distal tip of the delivery catheter. The system is advanced through a guide catheter until near the object of interest; the delivery catheter is gently advanced into the vascular space and the activation wire pushed forward to open the basket. Retraction on the activation wire closes the basket, hopefully entrapping the sought component. Baskets have many shapes, most of interest to physicians working outside the vasculature. Some have multiple strands of wire for each arm of the basket (improves entanglement), and some have complicated contours to create a wider opening on one side of the basket (facilitates grabbing stones and other large items).

*Forceps*
Open-mouthed grapping tools that replicate the grabbing function of forceps have been developed for intravascular use. Low-profile, high-tension cable systems are used to activate the forceps. These include the following:

1. **Side-biting vascular forceps.** These catheters are designed for use in the peripheral arterial tree (Fig. 50-7). A formable guide wire may be attached to the distal tip for use without a delivery catheter, producing a streamlined 3-Fr device.

![FIGURE 50-7 Vascular forceps. Designed for use in the peripheral vasculature, a flexible guide wire at the tip improves the safety of passage through vessels outside of a guide catheter. (Permission for use granted by Cook Medical, Bloomington, Indiana.)](image)

2. **Forward-biting forceps.** Most such devices are intended for nonvascular medical applications, such as urology or gastrointestinal procedures, but they may be of use in some vascular situations. Most are relatively small caliber (3-4 Fr) but are intended to be used through endoscopes; no guide wire can be placed at the catheter tip, so advancing the device through a vessel can be hazardous. The forward-facing “teeth” of the forceps can be used to grip lost gear. Some forward-biting forceps have 2 or more operational arms (double-jaw), whereas others have 1 operational arm set against a stationary base (single jaw). Such systems have limited or no
safeguards to prevent inadvertent seizure of vascular tissue, which is an obvious safety concern.

3. Neuro-interventional forceps. Percutaneous intervention in the cerebrovasculature has increased the risk of component loss or embolization into the neck and brain. This space is uniquely unforgiving and requires small-caliber, atraumatic, highly flexible systems. Engineers have responded with a 4-arm preshaped grasping forceps that is compressed and delivered inside any soft, flexible cerebrovascular catheter; retraction of the catheter expands the forceps arms, and advancing the catheter closes them (Fig. 50-8). Despite an aggressive-appearing grasping tip configuration, the hooked portions of this system are fairly soft and designed to open fully when the delivery catheter is retracted, allowing a “catch and release” approach when needed.

**FIGURE 50-8** Alligator Retrieval Device. Designed for use in the small, delicate intracranial vessels, the aggressive appearance of the forceps arms belies a relatively soft material. (Image courtesy of Medtronic. Copyright © Medtronic. All rights reserved.)
The simplest retrieval tools may be coronary guide wires. As described below, they may be used to entangle a component and extract it. Occasionally, standard catheterization laboratory tools may be used to effect retrieval of lost components. Simple aspiration through a diagnostic or guide catheter, or a dedicated aspiration thrombectomy catheter, may capture smaller fragments and debris. Fractured angioplasty balloons or other devices being advanced over a guide wire can be more easily recovered if approached while still attached to the guide wire; in such cases, recovery is usually successful if approached through guide wire entanglement or by advancing a loop snare coaxially over the original guide wire. Catheters, including over-bent designs such as pigtail and Grollman catheters, can be useful for dislodging stuck material, making a component easier to approach with a proper retrieval device. Angioplasty balloon catheters can also be very helpful. Balloons may be used to hold a fragment in place during snare or basket manipulations, or if a lost object is attached to a guide wire and an angioplasty balloon can be passed over the wire and beyond the object (eg, a partially expanded coronary stent), then inflating the balloon may permit retrieval. A balloon inflated alongside a foreign body might be used to drag it from a distal to a more proximal vascular location. Balloons are also helpful for fixing components in place while other equipment is brought into the field and can also be used to reduce blood loss when an arteriotomy or venotomy is needed to extract a foreign body.

**TECHNIQUES**

**Entanglement**

Entanglement is a crude but effective method that involves largely uncontrolled and unpredictable but relatively secure engagement between components. This technique can be used for large and small vascular foreign bodies.

Entanglement to retrieve fractured coronary guide wires has been very successful. This long-standing technique has proven to be quick and effective in recovery of fractured guide wire fragments. Coronary guide wires have historically been constructed with a shapeable, flattened steel alloy ribbon (optimizes for shaping and visualization) wound with a length of high-tensile
strength steel or other material; the ribbon is welded to a steel shaft. The weld is a weak point in the wire and will fracture if stressed excessively. The metal wire wound around the ribbon has a separate weld and will unravel when the wire body is retracted. Newer guide wires are constructed differently, some having a continuous length of nitinol or other modern alloy extend from the body of the wire to the distal tip, and may be less prone to fracture.

Simply advancing 1 or more other wires alongside a fractured wire fragment and twisting repeatedly can entangle the wires. Note that a few simple turns may not suffice; dozens of 360° turns may be needed. Entangling also distributes the tension of retraction along a long portion of a retained wire rather than at one point as occurs with snaring. Figure 50-9 displays a series of images illustrating use of wire entanglement to distribute the tension along a length of fractured guide wire to improve odds of successful retraction, even when a wire has been snared. Placing multiple additional wires and twisting in different directions is helpful.
FIGURE 50-9 Retrieving a fractured guide wire through wire entanglement. A. During a retrograde approach to a right coronary artery (RCA) chronic total occlusion, a guide wire was advanced (through a Corsair catheter; Asahi Kasei, Sakai, Osaka, Japan) successfully through a septal perforator, into the distal RCA, through the occlusion, and into the right coronary guide catheter. The wire was trapped with a loop snare (hollow arrow), but fractured when an attempt was made to exteriorize the
wire tip (solid arrow denotes the thin strand of wire connecting the radio-opaque wire tip with the body of the wire). B. The distal wire tip was released, and new coronary guide wires were advanced alongside the damaged tip. C. The wires were rotated vigorously to entangle the fractured wire component and distribute the retraction stress. D. The wire was retracted and exteriorized successfully.

Entanglement of larger components can be achieved in a similar fashion using a braiding technique, described below.

**Snaring**

Snares are most easily employed when a free edge of a retained foreign body is accessible. The prototypical example would be the proximal limit of a fractured guide wire; encircling the proximal end with a snare, cinching it tight, and retracting should effect successful retrieval. However, snares today are more likely used to retrieve lost stents.

A stent is likely to be lost by being stripped free of its delivery balloon. This is most easily managed when the stent is at the coronary ostium or, better yet, dangling on the guide wire within the aorta. In this case, removing the delivery balloon and passing a snare over the guide wire, then negotiating the stent loop beyond the stent, effectively traps it. Occasionally, catching the proximal end of a stent with a snare allows it to be removed without grossly deforming the stent, such that it can be withdrawn through a guide catheter (Fig. 50-10).
FIGURE 50-10 Loop snare gripping a damaged stent. This coronary stent would not pass through the target lesion, and the proximal edge of the stent caught on the tip of the guide catheter when an attempt was made to remove the stent. A loop snare was advanced coaxially over the guide wire to which the stent was still attached. The proximal edge of the stent was distorted, creating a convenient feature to grip with the snare. After successful removal and release of the snare tension, the stent was still entangled with the snare loop.

As mentioned, cleverly designed 2-component snares can facilitate snaring a foreign body even when a free end is not accessible (see Snares section).
When no commercially available snare is suitable, advancing a coronary guide wire around a foreign body and gripping the free end of the guide wire with a standard loop snare can facilitate component removal.

Snares are also invaluable for retrieving components from the venous system. Figure 50-11 illustrates recovery of the distal portion of an infusion catheter fractured as a consequence of a “pinch off” complication.\textsuperscript{15}
FIGURE 50-11 Retrieval of foreign body from venous system. A. Chest x-ray of patient with infusion port catheter indicates catheter is pinched at the junction of the clavicle and first rib (solid arrow). B. Subsequent chest x-ray indicates fracture of catheter, with distal portion embolized into the right atrium and ventricle. C. A loop snare advanced through a sheath in the right jugular vein captures the fragment, which was extracted successfully.

**Braiding**

Similar to wire entanglement, catheter braiding\(^1^6\) can be used to entrap a large foreign body. This involves advancing a catheter adjacent to the foreign body and rotating it until it “braids” with the foreign body. In Figure 50-12, a portion of catheter that has embolized to the pulmonary artery is braided with a Grollman catheter to entangle it. While the grip is not usually strong enough to allow full retrieval, this technique can be helpful in dislodging a trapped foreign body and moving it to a location from which it can be more easily gripped with a snare or forceps device.
FIGURE 50-12 Braiding technique. A portion of a Hickman infusion catheter had fractured and embolized to the pulmonary artery. The fragment could not be accessed with a snare or basket device. A Grollman pulmonary catheter was advanced alongside the fragment and twirled until the Hickman fragment and Grollman catheter were entangled. The materials were retracted out of the pulmonary artery and right heart, and the fragment removed successfully.

CONCLUSIONS

Lost components are inevitable in an interventional practice. Some sterile foreign bodies may be left in place without harm. Most are best removed, and familiarity with commercially available devices to aid in foreign body extraction is valuable. Wire entanglement, gripping forceps, and loop snares are of greatest value in extracting components lost in a vascular space.

Percutaneous Treatment of Coronary Artery Fistula

Sanford Zeigler
Michael D. Dake

INTRODUCTION

Coronary artery fistula is defined as any abnormal luminal connection between 1 or both coronary arteries and the cardiac chambers or great vessels. Coronary artery fistulae (CAFs) are a rare entity, found in 1 out of 50,000 live births and in 1 of 500 patients undergoing coronary angiography. They may be congenital or acquired and, clinically, can range from completely asymptomatic to florid congestive heart failure and ischemia with electrocardiogram (ECG) changes and other typical presenting complaints.

In the majority of cases, CAFs are isolated, but they can be associated with other anomalies in 20% to 45% of cases. Common associated anomalies include tetralogy of Fallot, atrial septal defect, patent ductus arteriosus, and ventricular septal defect. CAFs are an important component of pulmonary atresia with intact ventricular septum, as they can provide the only blood supply to areas of the left ventricle.

Acquired CAFs can be a consequence of surgical or percutaneous intervention, trauma, or infection. Most cases are congenital malformations, although an increased incidence of CAF to the right ventricle has been observed in the heart transplant population due to repeated endomyocardial biopsy. The presence of a CAF places the patient at increased risk of
Coronary artery fistulas are classified according to the Congenital Heart Surgery Nomenclature and Database Project completed in 2000, which incorporates the prior angiographic classification schema of Sakakibara et al.\(^6\) along with the etiology of the lesion (acquired vs congenital), vessel of origin, and site of drainage.\(^2\) In the era of percutaneous treatment, the morphology of the fistulous connection is also important to recognize. The condition was first treated in 1947 with surgical ligation, and in 1990, 2 separate groups first described transcatheter embolization of large coronary fistulas using both coils and detachable balloons.\(^7,8\) There is a paucity of clinical data supporting any particular treatment modality, although outcomes are favorable with both percutaneous and open surgical techniques.\(^9\)-\(^12\) Current management favors catheter-based closure of these anomalies unless open fistula closure is to be performed as an adjunct to surgical correction of associated anomalies.

**SELECTION**

There are no clear guidelines regarding patient selection for fistula closure. Most authors agree that all symptomatic patients should be treated. There is no clear consensus regarding the management of asymptomatic patients. Criteria for closure of asymptomatic fistulae include presence of a systolic murmur, presence of a continuous murmur, and Qp/Qs >2.0 as a cutoff for significance, whereas others propose a shunt fraction greater than 1.5. Some groups recommend closure of fistulas >1.5 mm.\(^13\) Other authors have endorsed closure of all large fistulas to prevent future endocarditis\(^14\) or atherosclerosis.\(^13\) Some small fistulas in young patients will spontaneously close, and in low-risk cases, follow-up angiography could be considered.

In any case, anatomic considerations must inform the decision to pursue percutaneous fistula closure. The fistula should be accessible and safe to embolize. No large branches that could be inadvertently embolized should be near the fistula, and the neck should be narrow enough to be closed by available devices. Major contraindications to catheter-based closure include

- bacterial endocarditis
- myocardial ischemia
- arrhythmias
- coronary aneurysm with or without rupture
- coronary atherosclerosis
- hypervolemic chamber overload.\(^5\)
very young age or coronary arteries too small to catheterize, a large and wide-based fistula, multiple fistulas, a distal fistula, adjacent myocardial branches, and the need for other surgical repairs. 

**DEVICES**

Devices include the following:

A. Coils (0.010-, 0.012-, 0.014-, 0.018-, 0.021-, and 0.035-inch diameters)
   1. Pushable
   2. Detachable
B. Vascular plugs
C. Septal occluders (atrial septal defect, ventricular septal defect)
D. Duct occluders (patent ductus arteriosus)

**TECHNIQUE**

Wang et al\textsuperscript{10} recently published a review of percutaneous treatment of CAF in 54 patients, including their technical approach. After selective coronary angiography, they selected a site within the fistula that was favorable to device occlusion. Optimal sites for occlusion include acute vessel curves or sites where the vessel narrows but that are far from normal coronary artery branches. Arterial side access to the fistula was attempted first in all cases, using a 2.5-Fr microcatheter in some cases to help navigate through difficult tortuositites.

In cases that had a more favorable occlusion site on the venous side or in which the device delivery catheter could not reach the occlusion site from the arterial side, an atrioventricular (AV) loop technique was used. After arterial catheterization, the guide wire was threaded through the fistula to the superior vena cava or pulmonary artery. The wire was then snared and exteriorized. The venous end of the wire then was used to place a 6- or 7-Fr delivery sheath into position. This technique was used in 21 of 32 patients, of whom 2 patients developed moderate or severe tricuspid regurgitation. When the AV loop technique was not used, no tricuspid regurgitation was reported. Other cases were approached from a more straightforward transvenous or
The Boston Children’s Hospital group used an AV loop method in all patients, and reported no resulting tricuspid regurgitation. Distal angiography should then be performed to identify any distal coronary side branches near the site of occlusion. If present, a detachable device should be used. In these cases, the authors deployed the device for 10 to 15 minutes under 12-lead ECG surveillance prior to releasing the device. Completion angiography was performed, followed by placement of additional devices if needed. Only 3 of 32 patients needed an additional device.

Acute myocardial infarction due to extension of thrombosis from the fistula has been reported following surgical and transcatheter coronary fistula closure. In cases with a large residual cul-de-sac or a giant coronary artery aneurysm that has not been excluded from the arterial circulation, Wang et al recommend attempting to close the inflow to fistula or aneurysm, followed by dual antiplatelet therapy or therapeutic anticoagulation to prevent subsequent myocardial infarction due to progression of fistula thrombosis, again paying close attention to nearby normal coronary branch vessels.

The choice of a specific transcatheter device for the endovascular management of a CAF is traditionally predicated on considerations of both anatomic and physiologic characteristics of the individual lesion.

Relevant anatomic features that are commonly factored into device selection include the length, diameter, and morphology of the aberrant fistulous tract between the afferent and efferent vessels and the size of the parent vessel supplying the lesion and the vessel draining the fistula. In terms of the physiologic variables that warrant evaluation when planning therapy, flow through the fistula, perfusion of tissue by the feeding artery and its branches distal to the shunt, and perfusion of the tissue subtended by the vessel draining the fistula are all important to assess.

**Coils**

A variety of transcatheter agents have been used successfully to occlude coronary fistulas. Embolization coils are clearly the most traditional and versatile type of device employed. Their transcatheter placement is the most common embolization technique reported in the medical literature. Coils are
available in multiple different configurations from simple cylindrical forms to a variety of preformed geometric shapes to amorphous strands ideal for packing. They are manufactured in multiple different coil diameters and lengths out of a wide variety of metallic (e.g., platinum, nitinol, stainless steel) and nonmetallic (polymeric) materials of different diameters (0.010, 0.012, 0.014, 0.018, 0.021, and 0.035 inches).

The method of transcatheter deployment is typically classified as either pushable or detachable. Pushable coils are loaded into the delivery catheter from a cartridge and then advanced by means of a guide wire, usually of the same gauge, or a dedicated coil pusher. Once the coil segment is introduced to the target position at the catheter tip, it is either deployed by further guide wire advancement or injected using a syringe. In either case, the coil is not able to be repositioned or retrieved once it is outside the delivery catheter. Of course, a dedicated coil retriever, snare, or forceps can be subsequently used to retrieve a malpositioned coil, but this requires skill and time.

Detachable coils are a more recent advancement and allow the coil to be test placed before it is finally deployed. The coil and pushing “wire” are essentially one until a detach mechanism is activated and the distal coil becomes disconnected from the proximal delivery segment. Until the coil is detached, it may be advanced and withdrawn from the catheter multiple times until the desired morphology is achieved. There are many proprietary methods to allow detachment when the interventionalist is satisfied with the coil’s appearance. These include mechanical (e.g., ball and claw, screw), electrical, radiofrequency, and other methods.

Irrespective of the particular type of delivery mechanism, coils are also selected based on a variety of anatomic factors, including the diameter and shape of the vessel tract and parking space or length available to deposit a coil pack.

The size of the coil is chosen to allow for an oversize of 15% to 30% depending on the target vessel diameter. This allows for some margin of tolerance in providing the necessary friction and interference fit between the coil and vessel wall. Ideally, this will prevent coil migration while providing a stable coil configuration to the coil matrix. A tight coil nest or pack promotes an accelerated tempo of vessel occlusion. If the coil is too oversized, it cannot reach its preformed shape and elongates into a sinusoidal strand that is not as effective.

The fundamental coil element may be supplemented with attached fibers
or other supplemental agents to promote thrombus formation. Recently, coils with hydrogel polymeric jackets have been introduced. Once deployed, the polymeric coating swells to effectively enlarge the coil diameter so it occupies more space, filling in gaps in the coil matrix to facilitate vessel occlusion. Predictably, technologic developments will continue to contribute to coil use by providing new adjunctive features that will increase the efficiency of vessel occlusion.

The coil length is another variable to consider before selecting a devise. The labeled nominal length on coil package is the length of the device measured in its unconstrained or reconfigured shape. Depending on the diameter of the target vessel or fistula tract and the degree of coil oversizing based on the flow and critical importance of downstream tissue at risk from coil migration, the length of the deployed coil can be reasonably estimated. This calculus, however, takes operator experience to anticipate any elongation beyond the nominal length secondary to variable degrees of oversizing. Suffice it to say, this is not an exact science, and one should factor in a generous margin of error when selecting a coil length to match the available parking space.

**Vascular Plugs**

Vascular plugs are typically self-expanding nitinol mesh devices with or without a fabric covering that are placed via a catheter to occlude a blood vessel. Similar to embolization coils, vascular plugs come in a variety of sizes and designs depending on the target anatomy and the manufacturer.

The Amplatzer Vascular Plug (St. Jude Medical Inc., Saint Paul, MN) is the modern day prototype of the vascular plug. It was specifically designed for occlusion of arteries or veins within the peripheral vasculature. More recently, the original design has been modified to address specific anatomic challenges, and currently, there are 2 other devices in addition to the initial Amplatzer Vascular Plug—the Amplatzer Vascular Plug II and Amplatzer Vascular Plug 4. The plugs should be distinguished from the Amplatzer occluders, which are a family of devices comprised of 2 nitinol disks with or without a polyester fabric cover that are used to permanently occlude septal defects within the heart.

The original Amplatzer Vascular Plug is a cylindrical nitinol mesh with proximal and distal radiopaque markers. The proximal marker has a
microscrew that attaches the plug to a 135-cm nitinol delivery wire. The plug comes in 7 sizes from 4 to 16 mm in diameter in 2-mm intervals.

The Amplatzer Vascular Plug is advanced through a catheter or sheath with an appropriately sized inner lumen to the target. The device selected should be 30% to 50% larger than the diameter of the vessel to ensure good apposition to the wall and optimal occlusion. Once in proper position, the plug is expanded by advancing the delivery wire and withdrawing the constraining catheter. After the device is deployed to the satisfaction of the operator, it is detached by unwinding the microscrew. Prior to final actuation of the microscrew and device detachment, the plug may be withdrawn back into the delivery catheter and repositioned to achieve a desired position.

Subsequent iterations of the device produced the Amplatzer Vascular Plug II and Amplatzer Vascular Plug 4. The Amplatzer Vascular Plug II incorporates a central cylindrical plug (like the original plug) with occlusion disks at each end. The central lobe and 2 disks provide 3 zones of apposition and 6 planes of occlusion. This is intended to enhance effectiveness of plug occlusion. It is available in 11 sizes from 3 to 22 mm in diameter. The delivery system varies from a 5- to 8-Fr sheath depending on the size of the plug, and the deployment steps are identical to the original device.

The most recent addition to the family of Amplatzer Vascular Plugs and the most procedurally relevant for the management of coronary artery fistulas is the Amplatzer Vascular Plug 4. This smaller device is composed of 2 fine-meshed tapered lobes. The advantage of this device is the size of the catheter system necessary for delivery. The Amplatzer Vascular Plug 4 can be deployed through any 4- or 5-Fr angiographic catheters with a minimum 0.038-inch inner lumen diameter.

The plug is attached to a 155-cm nitinol wire with a 20-cm floppy distal segment to aid in delivery through tortuous vascular anatomy and distal vessels. It is available in diameter sizes of 4 to 8 mm, and the device selected should be 30% to 50% larger than the vessel to be occluded. Given the size of most coronary artery fistulous tracts and the anatomic challenges facing catheterization of the channels, the Amplatzer Vascular Plug 4 represents the most logistically feasible option of the Amplatzer family of plugs.

Over the past few years, there has been a growing interest in microcatheter design and development of compatible microdevices to treat neurovascular lesions and superselective distal anatomic challenges within abdominal and peripheral vascular beds. As a result, microvascular plugs and occluders are
now emerging into the market place. These smaller devices are attractive additions to our catheter armamentarium for accessing and occluding CAFs and other lesions.

An example of this new technology is the MVP (Microvascular Plug System; Covidien, Dublin, Ireland). This device incorporates a 12-mm long nitinol basket with a partial polytetrafluoroethylene (PTFE) covering over its distal aspect. The device is available in 2 sizes to occlude vessels of 1.5 to 3.0 mm (MVP-3) and 3.0 to 5.0 mm (MVP-5). It is delivered on a 180-cm delivery wire, and the plug is detached electrolytically using a separate detachment system and cable set. The MVP-3 can be delivered through a microcatheter with a 0.021-inch inner diameter and the MVP-5 via a catheter with a 0.027-inch inner lumen. These new devices may prove particularly well suited to catheter occlusion of CAFs; however, experience with their use in this application is limited.

**Septal Occluders**

Intracardiac septal defect closure devices for occlusion of atrial or ventricular septal lesions have a proven track record, and in many situations involving atrial pathology (especially secundum atrial septal defects), they are currently the primary treatment option. Not all septal defects are the same; however, the designs of most septal occluders incorporate a double disk configuration with or without a fabric cover of polyester (St. Jude Inc.) or PTFE (W. L. Gore and Associates Inc., Flagstaff, AZ).

Without going into specific details, the main difference between atria and ventricular septal devices concerns the length of the waist between the 2 occluding disks. The more muscular ventricular septum requires a device with a longer interdisk waist to accommodate anchoring of the disks on either side of the thicker wall between the cardiac chambers. Other differences between atrial and ventricular devices exist in terms of symmetry of design and size of the 2 disks. Both atrial and ventricular septal defect occluding devices can be easily recaptured into the delivery catheter and redeployed to secure optimal placement.

A range of devices with a large variety of dimensions is available. In terms of an atrial septal occlude (St. Jude Inc.), the minimum disk diameter is 12 mm with an interdisk waist diameter of 4 mm and a waist length of 3 mm. These dimensions increase to disk diameters of 54 mm with a waist diameter
of 38 mm and a length of 4 mm. The smallest disk diameter of a ventricular septal occluder (St. Jude Inc.) is 9 mm with a waist diameter of 4 mm and a length of 7 mm.

The use of these devices to treat a CAF requires a specific anatomic configuration amenable to the unique design of these double-disk devices. In practical terms, they may be used if the communication to a cardiac chamber can be catheterized and an appropriately sized disk can be positioned at the intracardiac orifice of the fistula. In this regard, authors have advocated that when using a septal occluder to straddle the drainage site into a cardiac chamber, the device should be twice the size of the orifice.12

**Duct Occluders**

One additional specific structural heart closure device warrants description because it is relatively well suited to the endovascular management of coronary artery fistula. The Amplatzer Duct Occluder (St. Jude Inc.) is a mushroom-shaped nitinol mesh device with a polyester graft covering. The leading end of the occluder has a skirt to secure positioning and prevent embolization. The trailing end is a slightly tapered stalk that conforms to tapering anatomy.

The smallest device has a length of 5 mm and a 9-mm skirt, and the largest occluder is 8 mm long with an 18-mm skirt. There are 3 intervening sizes available. In the setting of coronary artery fistula, the plug would be placed with the skirt end inside the cardiac chamber immediately adjacent to the orifice of the fistula and the stem extending into the fistulous tract.

**Figures 51-1, 51-2, 51-3, and 51-4** are radiographic images showing the clinical findings in patients who presented with coronary artery fistulas.
FIGURE 51-1 A 15-year-old girl with fistula between left anterior descending (LAD) coronary artery and the pulmonary artery with 1 large and 1 tiny entrance just above the pulmonary valve. A. Axial computed tomography image displays a large left coronary artery measuring 4.2 mm. B. The LAD is also large (4.0 mm), and 2 circular enhancing densities are noted between the LAD and the main pulmonary artery just at the level of the pulmonic valve. C. A small serpentine vessel is evident entering the main pulmonary artery just above the valve (arrow). This is the largest of the fistulous tracts from the LAD. D. Approximately 2 cm proximal to the trifurcation of the LAD, the origin of a bizarre fistula is evident. The vessel has both dilated and narrowed segments as it courses toward the pulmonary artery.
FIGURE 51-2 Axial computed tomography images of a 49-year-old man with complex coronary artery fistula with multiple feeders emanating from a left coronary artery branch and a right conal branch and draining into the main pulmonary artery. 

A. Large left coronary artery and multiple adjacent circular densities representing tortuous fistulous channels. Also, similar findings are evident in the region just cephalad to right coronary artery. 

B. A complex network of small vessels courses anteriorly along both sides of the pulmonary artery. 

C. At the level of the pulmonary valve, a tangle of channels is adjacent to the left wall of the main pulmonary artery. 

D. The multiple fistulous vessels course anteriorly to communicate with the anterior aspect of the main pulmonary artery. 

E. A complicated array of vessels is noted just above the site of communications with the pulmonary artery.
FIGURE 51-3 Three-dimensional reconstructions of a computed tomography data set from a 49-year-old man with a complicated coronary artery fistula network first noted on echocardiography. A. Tangled mass of coronary artery branches originating predominantly from the left anterior descending artery, but also with contribution from a right coronary artery conal branch. B. The fistulous channels course anteriorly along the lateral aspect of the main pulmonary artery (not shown) and coalesce to drain into the anterior aspect of the pulmonary artery just above the valve.
FIGURE 51-4 Images from a computed tomography (CT) scan performed after coil embolization of the coronary artery fistula network. A and B. Axial views show metallic artifacts from coils placed in feeding branches of both the left and right coronary arteries. Most of the communications between the right coronary artery and left anterior descending (LAD) branches to the main pulmonary artery have been obliterated, and only a few small
abnormal channels persist. **C and D.** Multiplanar CT reformations through the course of the LAD display metallic embolization coils in branches of the vessel, as well as in a branch of the right coronary artery (C). The majority of fistulous vessels are occluded and only 1 or 2 small residual channels are identified.

**CONCLUSION**

The successful endovascular management of a symptomatic CAF requires experience and judgment on the part of the interventionalist. These lesions are rare, and a prudent evaluation or risks and benefits is important to ensure patient safety and procedural effectiveness.

The use of a spectrum of transcatheter endovascular devices has been described in the medical literature. Reports of experience with embolization coils, vascular plugs, and septal and duct occluders have all been detailed. Currently, the most commonly employed technique to promote occlusion of a fistula involves direct catheterization of the fistula and deployment of metallic coils through either a diagnostic angiographic catheter or a microcatheter. In the future, the role of a microvascular plug as a single device to occlude a fistulous tract may expand.

MULTIPLE CHOICE QUESTIONS

1. Which of the following statements regarding coronary artery fistulae (CAF) is true?
   A. A coronary-cameral fistula is a type of CAF between a coronary artery and a chamber of the heart.
   B. A CAF may close and resolve spontaneously.
   C. Most CAFs are small and do not cause any symptoms or complications.
   D. A and B.
   E. All of the above.

2. All of the following techniques are currently used to treat CAF except:
   A. Open surgical ligation with suture
   B. Transcatheter coil embolization
   C. Hyperbaric oxygen therapy
   D. Transcatheter placement of patent ductus arteriosus, atrial septal defect, or ventricular septal defect occluder devices

3. Which of the following statements is true regarding CAF and children?
   A. Children with CAF usually show no symptoms other than a heart murmur.
   B. The size and significance of a CAF cannot usually be determined by echocardiography.
   C. After diagnosis, closure of the CAF is often performed because of the danger of complications, such as rupture of the fistula, myocardial ischemia, or endocarditis.
   D. A and B.
   E. A and C.
   F. All of the above.

4. All of the following statements regarding CAF and concerns about exercise are true except:
   A. There are no exercise restrictions for patients with small CAF with
negligible symptoms.
B. Patients with CAF are at a slightly higher than normal risk for arrhythmias or sudden death during extreme exertion, such as athletic competition.
C. Stress testing is not recommended for patients with CAF before participating in sports requiring extreme exertion.
D. Patients with CAF should be monitored regularly by a cardiologist to guard against the late development of arrhythmias, ischemia, or heart failure that may limit safe levels of exercise.

5. Which of the following general statements regarding patients with CAF is true?
A. In the absence of significant associated symptoms such as arrhythmias, ischemia, or heart failure, a woman with CAF should experience no difficulty bearing children.
B. Infants who are born with CAF are more likely than normal infants to have other heart defects.
C. In nearly all series of patients with CAF, the vast majority (>90%) of the defects drain to the right side of the circulation.
D. Small, asymptomatic fistulae arise much more commonly (>85%) from the left coronary system.
E. A and C.
F. B and D.
G. All of the above.

ANSWERS

1. E
All of the statements are correct.

2. C
Hyperbaric oxygen therapy has no effect on CAF and is not recognized as a standard treatment. The other techniques are commonly performed in clinical practice for treatment of CAF.
3. E
Echocardiography is often used to determine the size and importance of CAF. Typical echocardiographic features that indicate a significant CAF include cardiac chamber dilation, narrowest color Doppler flow jet ≥4 mm, or reversal of flow in the descending aorta. Both answers A and C are correct.

4. C
It is recommended that adults with CAF undergo stress testing prior to participating in strenuous physical activities or athletic competition. The other statements are correct.

5. G
All of the statements are correct.
INTRODUCTION

Clinical benefit from any revascularization procedure will be the net gain due to reperfusion of the ischemic organ balanced against the risk of a procedural complication. The same is true for renal artery ischemia caused by atherosclerotic or, less commonly, fibromuscular dysplasia (FMD) lesions (Fig. 52-1). Recent clinical trials have attempted to determine the benefit of revascularization but have been seriously hampered by difficulty in defining a threshold for an ischemia producing renal artery stenosis (RAS).
Renal ischemia due to an obstruction of the renal artery causes 3 well-described clinical scenarios: (1) renovascular hypertension, (2) ischemic nephropathy, and (3) cardiac destabilization syndromes such as sudden-onset pulmonary edema, decompensated heart failure, and acute coronary syndromes. Helping to identify patients with these clinical manifestations of renal ischemia who also have anatomically suitable lesions for treatment is the purpose of this chapter. The primary method of revascularization for renal artery stenosis is endovascular, not open surgery. Open surgery is rarely performed today and usually accompanies another related open surgical procedure on the abdominal aorta, for example.

**PREVALENCE OF RENAL ARTERY STENOSIS**
The prevalence of renal artery stenosis (RAS) depends on the population examined. In a Medicare population (mean age, 77 years), screening renal ultrasound duplex studies demonstrated greater than 60% RAS in 6.8% of patients.\(^1\) There were almost twice as many males (9.1%) as females (5.5%; \(P = .053\)), and there were no racial differences (Caucasian, 6.9%; African American, 6.7%) in the prevalence of RAS. Among the general hypertensive population, RAS is the most common (2%-5%) secondary cause of hypertension. An autopsy series of patients older than 50 years found RAS (≥50%) in 27% of patients, and this rate increased to 53% if there was a history of diastolic hypertension >100 mm Hg. Among patients entering dialysis treatment, 10% to 15% have RAS as the cause of end-stage renal disease.\(^2\) Approximately 25% of elderly patients with renal insufficiency have unsuspected RAS.

RAS is predominantly due to atherosclerosis in the adult population, with FMD being more common in younger females.\(^3\) RAS is more common in patients who have atherosclerosis involving any other vascular bed. In patients undergoing cardiac catheterization for suspected coronary artery disease, the prevalence of RAS ranges from 25% to 30%, whereas peripheral arterial disease or abdominal aortic aneurysm is associated with RAS in 30% to 40% of cases.

**NATURAL HISTORY**

Atherosclerotic RAS generally progresses over time and is often associated with loss of renal mass and worsening renal function. Lesion progression in serial angiographic studies ranges from 39% to 49%. RAS lesion progression is directly related to the underlying severity of the stenosis. The more severe the narrowing (≥60%), the more likely it is to progress to occlusion.\(^4\) Worsening of “asymptomatic” RAS is associated with a progressive loss of renal function.\(^5\) Control of blood pressure with medical therapy does not prevent progression of RAS.\(^6,7\) Renal artery occlusion occurred in 16% of the medically treated arm over a 1-year period in a randomized trial.\(^8\)

Atherosclerotic RAS remains a major cause of end-stage renal disease. In a serial angiographic study of RAS patients compared to normal controls, renal function significantly declined and was related to the severity of the
RAS. RAS is estimated to be responsible for renal failure in 10% to 15% of patients entering dialysis programs. In patients starting dialysis secondary to atherosclerotic RAS, the mean survival was 25 months, and the 2-, 5-, and 10-year survival rates were 56%, 18%, and 5%, respectively.

RAS is an independent predictor of adverse cardiovascular events such as myocardial infarction, stroke, and cardiovascular death. Patients with significant RAS are more likely to have renal insufficiency, coronary artery disease, peripheral arterial disease, hypertension, and cerebrovascular disease. In patients identified as having greater than 75% RAS at the time of cardiac catheterization, the 4-year survival was 57% compared to 89% in patients without RAS ($P < .001$). Patients with greater severity of RAS have worse survival than those with milder or no RAS. Patients with bilateral RAS exhibit a lower 4-year survival (47%) when compared to patients with unilateral RAS (59%; $P < .001$), independent of prior myocardial revascularization procedures.9

**DIAGNOSIS**

**Screening for RAS**

Screening for RAS is appropriate in patients at increased risk for RAS (Table 52-1). Whenever possible, screening tests for RAS should be performed noninvasively using direct imaging tests (Doppler ultrasound, computed tomographic angiography [CTA], or magnetic resonance angiography [MRA]) (Fig. 52-2). Noninvasive imaging has become so sophisticated and accurate that it is seldom necessary to perform catheter-based angiography for the diagnosis of renal artery disease.

**Table 52-1 Increased Prevalence of Renal Artery Stenosis**

- Onset of hypertension ≤30 y or ≥55 y
- Malignant, accelerated, or resistant hypertension
- Unexplained renal dysfunction
- Development of azotemia with an ACE inhibitor or ARB medication
- Unexplained pole-to-pole diameter discrepancy of ≥1.5 cm between
Kidneys

- Cardiac disturbance syndrome (flash pulmonary edema)
- Peripheral arterial disease (abdominal aortic aneurysm or ankle-brachial index <0.9)
- Multivessel (≥2) coronary artery disease

Abbreviations: ACE, angiotensin-converting enzyme; ARB, angiotensin receptor blocker.

FIGURE 52-2 Magnetic resonance angiography showing a right accessory renal artery with a suspicious narrowing of the right main renal artery. RAS, renal artery stenosis.

It may be appropriate to perform screening angiography for RAS at the time of cardiac or peripheral vascular angiography of other vascular beds. For patients who are candidates for revascularization with risk factors as outlined in Table 52-1 or clinical syndromes suggestive of RAS, aortography is given a Class I indication for screening at the time of angiography performed for other clinical indications. There is good evidence that nonselective, diagnostic, screening renal angiography is safe and is not associated with incremental risk when performed at the time of cardiac catheterization.

**Duplex Ultrasonography**
Duplex ultrasonography (DUS) is an excellent noninvasive imaging test to detect RAS but is highly dependent on the skills of the technician performing the test. It is the least expensive of the imaging modalities and provides useful information about the degree of stenosis, the kidney size, and other associated disease processes such as obstruction. The location and degree of stenosis can accurately be determined by duplex ultrasound of the renal artery.

Overall, when compared to angiography, DUS has a sensitivity and specificity of 84% to 98% and 62% to 99%, respectively, when used to diagnose RAS. Renal artery duplex is an excellent test for the follow-up after renal stenting to confirm patency. Following endovascular therapy, a renal artery duplex should be obtained within the first few weeks to establish a baseline, and then at 6 months, 12 months, and yearly thereafter to ensure patency.

One drawback of DUS is that it may not identify RAS in accessory renal arteries (67%) compared to main renal arteries (98%). Therefore, if the patient has hypertension that cannot be adequately controlled with a good regimen, and the DUS fails to demonstrate RAS, another imaging modality may be considered to identify stenosis of an accessory renal artery.

**Resistance Index**

The intrarenal resistance index (RI) is the ratio of the peak systolic to end-diastolic velocity within the renal parenchyma at the level of the cortical blood vessels.\(^{13}\) The RI is a representation of small vessel glomerulosclerosis. There have been conflicting reports regarding the usefulness of RI to predict individual patient response to revascularization. One retrospective study demonstrated that an elevated RI greater than 0.80 predicted a lack of improvement in blood pressure and renal function after revascularization; however, it included balloon angioplasty without stent procedures, a strategy that is now recognized as less optimal compared to stenting (see below).\(^{14}\) A prospective study of renal stenting in 241 patients with an elevated RI (>0.70) showed improvement in blood pressure and renal function after intervention.\(^{15}\) Patients with a higher RI (>0.8) actually benefitted more from revascularization than did those with milder elevations.
Noninvasive Angiography

CTA uses ionizing radiation and iodinated contrast to produce excellent images of the abdominal vasculature (Fig. 52-3). CTA has a sensitivity and specificity for detecting RAS of 89% to 100% and 82% to 100%, respectively. Excellent 3-dimensional image quality with enhanced resolution can be obtained with multidetector-row CTA technology. The advantages of CTA over MRA include greater spatial resolution, an absence of flow-related phenomena that may overestimate the degree of stenosis, and the capability to visualize calcification and metallic implants such as endovascular stents and stent grafts. CTA is well tolerated with an open gantry, and thus, claustrophobia is not as limiting a factor as it is for MRA. The disadvantages of CTA compared to MRA are exposure to ionizing radiation and the need to administer potentially nephrotoxic iodinated contrast agents.

FIGURE 52-3 Computed tomography angiogram showing a patent left renal artery
MRA also provides excellent imaging of the abdominal vasculature and associated anatomic structures (see Fig. 52-2). When compared with angiography, MRA has demonstrated a sensitivity of 91% to 100% and a specificity of 71% to 100%. Contrast-enhanced MRA using gadolinium improves image quality when compared with noncontrast studies and shortens imaging time, thereby eliminating some of the artifact created by gross patient movement. However, MRA does not have the same sensitivity and specificity in patients with FMD and is generally not a good screening test if FMD is suspected.

MRA should not be used in patients with a glomerular filtration rate less than 30 mL/min/1.73 m\(^2\) because of the increased likelihood of developing nephrogenic systemic fibrosis. MRA may not be used in patients with metallic (ferromagnetic) implants such as some mechanical heart valves, cerebral aneurysm clips, and electrically activated implants (pacemakers, spinal cord stimulators). At present, MRA is not very helpful in following patients after stent implantation due to imaging artifact produced by the metallic stent.

**Invasive Angiography**

The traditional “gold” standard for determining the severity of RAS has been invasive angiography. The Achilles heel of renal stenting is the inaccuracy of the angiographic determination of the severity of the ostial renal stenoses. Even with quantitative measurement, angiography may be unable to discriminate between nonobstructive stenoses and clinically significant ones (Fig. 52-4).\(^\text{16}\) Most would agree that interventionalists are able to identify “critical” stenoses in renal arteries, but for mild to moderately severe lesions, physiologic confirmation is necessary.
Translesional Pressure Gradients

Hemodynamic measurement of the severity of RAS assures that there is a physiologic reason to expect benefit with revascularization. Confirmation of a hemodynamic gradient is evidence of physiologic RAS with renin release and has been documented by De Bruyne and colleagues.\textsuperscript{17} Hemodynamic parameters of significant RAS (peak systolic gradient $>21$ mm Hg,\textsuperscript{18} renal fractional flow reserve [FFR] of $\leq 0.8$,\textsuperscript{19} and a dopamine-induced mean translesional gradient $\geq 20$ mm Hg\textsuperscript{20}) are associated with clinical improvement after renal stenting in patients with mild to moderate renal artery stenoses.

Renal FFR is measured after induction of maximum hyperemia. This hemodynamic assessment of flow, which is widely used in the coronary
circulation, is based on the principle that flow across a conduit artery is proportional to pressure across the vascular bed and inversely proportional to the resistance of the vascular bed. Under conditions of maximum hyperemia, the flow through the conduit artery is maximal, while the resistance of the vascular bed is at a minimum and constant. Any reduction in flow under these conditions is caused by the stenosis and is proportional to the ratio of pressure distal to the stenosis (Pd) and the pressure proximal to the stenosis (Pa). Renal hyperemia can be achieved with papaverine, dopamine, or acetylcholine. Translesional pressure gradients are measured, and FFR (Pd/Pa) is calculated using a 0.014-inch pressure guide wire. Renal artery FFR correlates well with other hemodynamic parameters of lesion severity and, in some series, has been proven to be a better predictor of clinical response. In one study, renal FFR was measured after renal stent placement in 17 patients with refractory hypertension and moderate to severe (50%-90% stenosis) unilateral RAS. Ten patients had normal baseline renal FFR (defined as FFR ≥0.80), whereas an abnormal baseline renal FFR (<0.80) was recorded in 7 patients. At 3 months after intervention, 86% of patients with an abnormal renal FFR experienced improvement in their blood pressure, compared with only 30% of those with normal renal FFR (P = .04). In this small series, baseline systolic, mean, or hyperemic translesional pressure gradients were not different between patients whose blood pressure improved and those in whom it did not.

**Renal Frame Count**

Angiographic measurements of renal blood flow by using renal frame counts (RFC) and renal blush grades (RBG) for microvascular flow can differentiate normal patients from patients with FMD. RFC is the number of cine frames required for the contrast to reach the smallest visible distal branch in the renal parenchyma. As in Thrombolysis in Myocardial Infarction (TIMI) frame counting, the first frame used for the RFC is the frame in which the contrast first fills the main renal artery. The last frame is when contrast enters the smallest visible branch of the distal renal parenchyma along the axis of the main renal artery. The measurements are done with 30-frames-per-second angiography.

RFC was initially described in patients with FMD of the renal arteries (15 kidneys), who were compared to subjects with normal renal arteries (50
kidneys) and had a significantly higher (prolonged) mean RFC (26.9 vs 20.4; 
\( P = .0001 \)). Hypertensive patients with renal artery stenoses have also been 
shown to have decreased renal perfusion as measured by RFC. Clinical 
responders tended to have higher baseline RFCs than nonresponders and had 
greater improvement in their RFC values following renal stenting. Three-
quarters of the hypertensive patients who responded to renal stenting had a 
baseline RFC ≥25, and if the RFC improved by >4, then 79% were 
responders to renal stenting.

RENOVASCULAR HYPERTENSION

**Clinical Characteristics**

It has been shown that patients with the highest systolic blood pressures have 
the greatest decrease in systolic pressure, but there is no correlation 
between blood pressure improvement after renal stent placement and the 
variables of age, sex, race, severity of stenosis, number of vessels treated, 
baseline diastolic pressure, or baseline serum creatinine. Two variables, 
bilateral RAS (odds ratio [OR], 4.6; \( P = .009 \)) and mean arterial pressure 
>110 mm Hg (OR, 2.9; \( P = .003 \)), are associated with improved blood 
pressure response following renal artery stent placement. Studies comparing 
the results in elderly (≥75 years) versus younger (<75 years) patients or in 
females versus males have failed to show any difference in response to renal 
stent placement.

**Evidence-Based Treatment**

An analysis of 527 renal stent patients enrolled in 5 modern prospective, 
multicenter (117 centers) studies demonstrated that systolic blood pressure 
(SBP) and diastolic blood pressure (DBP) were significantly decreased at 9 
months. An SBP reduction >10 mm Hg occurred in 61% of patients. A 
baseline SBP >150 mm Hg was strongly associated with blood pressure 
response, but other clinical characteristics were not. In hypertensive patients 
in whom RAS is identified, the best predictor of RAS benefit was a baseline 
SBP >150 mm Hg.
The current American Heart Association (AHA)/American College of Cardiology (ACC) guideline indications for RAS in hypertensive patients with hemodynamically significant RAS and a viable kidney (linear length >7 cm) include: (1) accelerated hypertension, (2) refractory hypertension (failure of 3 appropriate drugs, 1 of which should be a diuretic\(^{29}\)), (3) hypertension with a small kidney, and (4) hypertension with intolerance to medications (Class IIa, Level of Evidence B).\(^{30}\) By convention, a hemodynamically significant lesion requires demonstration of a ≥70% RAS by visual estimation, ≥70% RAS by intravascular ultrasound measurement, or a 50% to 70% RAS with a systolic gradient of ≥20 mm Hg or a mean translesional gradient of ≥10 mm Hg.\(^{30}\)

The recently published Cardiovascular Outcomes in Renal Atherosclerotic Lesions (CORAL) trial compared the initial treatment strategy for renovascular hypertension patients; patients received either multifactorial medical therapy (eg, an angiotensin receptor blocking agent, a thiazide-type diuretic, amlodipine, atorvastatin, antiplatelet therapy, and diabetes managed according to clinical practice guidelines) or medical therapy plus renal stenting consistent with the guidelines.\(^{31}\) The CORAL study found that the primary composite end point (death from cardiovascular or renal causes, myocardial infarction, stroke, hospitalization for congestive failure, progressive renal insufficiency, or the need for renal replacement therapy) in patients with RAS (>60% diameter stenosis) and poorly controlled hypertension on at least 2 medications did not differ between groups. The number of blood pressure medications was not different between the groups (medical vs stent: 3.5 ± 1.4 vs 3.3 ± 1.5 medications) at the completion of the trial, and both groups had a similar decrease in SBP (15.6 ± 25.8 mm Hg in the medical therapy group vs 16.6 ± 21.2 mm Hg in the stent group). The CORAL recommendations for an initial trial of multifactorial medical therapy are consistent with the current AHA/ACC guidelines, which require that patients fail medical therapy for renovascular hypertension prior to revascularization.

**ISCHEMIC NEPHROPATHY**

Treatment of ischemic nephropathy continues to be a source of debate among experts. Opponents of revascularization of RAS patients with renal
insufficiency contend that the kidney is supplied with an excess of nutrient blood flow, and therefore, few kidneys will benefit from revascularization. This does not explain the 10% of patients beginning dialysis for end-stage renal disease due to renal artery occlusion.

Evidence-Based Treatment

The literature is replete with patient series in which RAS improves renal function, as well as counterbalancing reports of worsening of renal failure after successful RAS. However, there are no large randomized studies demonstrating benefit of revascularization over medical therapy alone for improving renal function.

Unfortunately, there are several poorly done studies, such as the recently completed STAR (Stent Placement and Blood Pressure and Lipid Lowering for the Prevention of Progression of Renal Dysfunction Caused by Atherosclerotic Ostial Stenosis of the Renal Artery) trial and the ASTRAL (Angioplasty and Stenting for Renal Artery Lesions) trial, comparing renal stenting plus medical therapy to medical therapy alone. Unfortunately, methodologic problems, such as enrolling study patients with mild (<50%) or nonobstructive RAS, invalidated these “intent-to-treat” trials. The clinical evidence does not support the sweeping negative statements regarding revascularization for ischemic RAS.

Dramatic benefit for RAS versus medical therapy in patients with the most severe renal disease was demonstrated in a large cohort study. One center offered patients (n = 182) medical therapy only, and the other center offered RAS plus medical therapy (n = 348). Patients were matched for the degree of renal dysfunction, and outcomes were compared over 5 years. Patients who underwent RAS had a marked reduction in mortality (relative risk, 0.55; 95% CI, 0.34-0.88; P = .013) by multivariate Cox regression analysis. When analyzed according to the degree of renal impairment, there were striking improvements in renal function after RAS for the patients with moderate to severe renal impairment. Patients with RAS and advanced chronic kidney disease (stages 4 and 5) benefited from renal stenting with improved renal function and also enjoyed a survival advantage.

Currently, there are several parameters that suggest that a patient is likely to experience improved renal function after revascularization. First, there
must be a hemodynamically obstructive RAS causing hypoperfusion of the kidney. The more renal tissue at risk, the more likely there will be a response or improvement in renal function with RAS. Patients with bilateral renal stenosis and solitary kidney stenosis are traditionally thought to be most likely to improve. Patients with small kidneys (<7 cm) and those with significant proteinuria are less likely to benefit.\textsuperscript{44}

Patients with rapidly declining renal function, as opposed to those with stable renal failure, have the most to gain from revascularization.\textsuperscript{36,45} The rate of decline in renal function, determined as the slope of the regression line of serum creatinine over time, is a very strong predictor of benefit with RAS.\textsuperscript{36} A multivariate analysis demonstrated that the only significant predictor of benefit following RAS was the rate of decline of renal function that preceded the procedure. Baseline creatinine, the presence of proteinuria, renal size, and diabetes were not significant predictors of improvement in this study.

The current AHA/ACC guideline recommendation\textsuperscript{11} for catheter-based therapy to preserve renal function concludes that RAS is reasonable for patients with RAS and progressive chronic kidney disease with bilateral or a solitary functioning kidney with stenosis (Class IIa, Level of Evidence B). RAS may also be considered on an individual basis for patients with hemodynamically significant stenosis and chronic renal insufficiency with unilateral RAS (Class IIb, Level of Evidence C).

**CARDIAC DESTABILIZATION SYNDROMES**

Cardiac destabilization syndromes attributable to RAS include exacerbations of coronary ischemia and congestive heart failure due to peripheral arterial vasoconstriction and/or volume overload.\textsuperscript{46} Renovascular disease may also complicate the management heart failure patients by preventing administration of an angiotensin-converting enzyme inhibitor (ACEI) or angiotensin II receptor blocker (ARB).

The importance of renal artery stent placement in the treatment of cardiac disturbance has been described in a series of patients presenting with either congestive heart failure or an acute coronary syndrome.\textsuperscript{47} Successful renal
stent placement resulted in a significant decrease in blood pressure and control of symptoms in 88% (42 of 48) of all patients. Assessments of the acute treatment effects and effects at 8 months using the Canadian Cardiovascular Society (CCS) angina classification and the New York Heart Association (NYHA) functional classification (see Fig. 52-4) were not different between the combined coronary and renal revascularization group and those who had only renal stent placement, suggesting that renal revascularization was the most significant intervention.47

Another case series of 39 patients treated with RAS for control of congestive heart failure demonstrated that blood pressure improved in 72% of patients and renal function improved in 51% and was stable in 26% of patients.48 The mean number of hospitalizations for congestive heart failure prior to stenting was 2.37 ± 1.42 (range, 1-6), and after renal stenting, the number of hospitalizations was 0.30 ± 0.065 (range, 0-3; P < .001). Seventy-seven percent of patients had no further hospitalizations after RAS over a mean follow-up period of 21.3 months. RAS can relieve the renal ischemia and result in marked improvement in both heart failure and angina symptoms.47 The ACC/AHA guidelines make percutaneous revascularization for hemodynamically significant RAS and recurrent unexplained congestive heart failure or sudden unexplained pulmonary edema a Class I, Level of Evidence B indication. RAS for renal artery stenosis and refractory unstable angina earned a Class IIa, Level of Evidence B indication.11

**ASYMPTOMATIC RAS**

There is no evidence to support beneficial outcomes for revascularization of an asymptomatic RAS, regardless of the severity of the stenosis. The current ACC/AHA guidelines make renal intervention for unilateral asymptomatic, bilateral asymptomatic, or solitary asymptomatic RAS a Class IIb, Level of Evidence C recommendation, which suggests there is an uncertain risk-to-benefit ratio for this treatment. Patients with compelling anatomic lesions threatening global renal function may be considered for treatment on a case-by-case basis.11

**RENAAL ARTERY INTERVENTION**
Balloon angioplasty is much less effective than stent placement for treating atherosclerotic aorto-ostial plaque (Fig. 52-5). Renal stents significantly lowered the translesional pressure gradient reduction when compared with balloon dilation alone. The superiority of renal stents compared to balloon angioplasty alone was confirmed in a randomized trial and in 2 meta-analyses. This evidence led to a Class I ACC/AHA guideline recommendation for primary stent placement in atherosclerotic RAS.

![FIGURE 52-5 A. Baseline significant ostial renal artery stenosis (arrow). B. Poststent deployment.](image)

**Patient Selection**

Optimal patient selection for renal revascularization is more complex than a visual estimation of stenosis or a measurement of a translesional pressure gradient. This is because patients with RAS have multifactorial reasons for hypertension and renal insufficiency that may or may not improve as renal blood flow improves. Perhaps the most common reason for failure to improve after renal revascularization is overestimation of the severity of the RAS by angiography. The ostial segment of the renal artery has a complex 3-dimensional geometry that can be very difficult to appreciate by 2-dimensional angiographic imaging. Performing angioplasty or stent placement in mildly narrowed renal arteries would not be expected to be of clinical benefit and may be the reason why no more than 70% of hypertensive patients fail to improve after renal revascularization. In addition, the presence of anatomic RAS does not necessarily establish that the
hypertension or renal failure is caused by the RAS. Many patients have had essential (primary) hypertension for years and then develop atherosclerotic RAS later in life. The mere presence of RAS does not imply that the RAS per se is causing the high blood pressure.

The pathophysiology of renovascular hypertension has been well understood since the experiments of Goldblatt and others. De Bruyne and colleagues\textsuperscript{17} demonstrated this cause-and-effect relationship by performing an in vivo experiment that showed a threshold gradient for the release of renin following graded renal artery obstruction.

Restenosis after renal artery stent placement is related to both acute gain and late loss, similar to coronary artery restenosis. In the largest single series of renal stent implantation, a larger reference vessel diameter (RVD) and larger acute gain (ie, poststent minimum luminal diameter [MLD]) after stent deployment were strongly associated with a lower incidence of restenosis. For example, restenosis in a vessel with an RVD of <4.5 mm was 36% compared to only 6.5% for an artery with a RVD of >6.0 mm in diameter.\textsuperscript{51} Renal stenting has been shown to be a durable treatment, with 1-year patency rates $\geq$85% (Table 52-2)\textsuperscript{49,52-55} and 5-year primary patency approaching 80%.\textsuperscript{52,54}

Percutaneous catheter-based therapy with primary stent placement has replaced open surgery as the treatment of choice for atherosclerotic RAS.\textsuperscript{11} However, despite a technical success rate exceeding 95% for renal artery stent placement, there remains wide variation in the reported success rates in improving hypertension. While at least some of the variability in outcomes is
attributable to a lack of standard reporting criteria, the dominant factor appears to be poor patient and nonobstructive lesion selection for treatment. Variability in the angiographic assessment of the hemodynamic severity of renal artery stenoses has undermined the predictability of a treatment response with successful stenting. Although the majority of hypertensive patients with atherosclerotic RAS and hypertension will experience improved blood pressure control and/or the need for fewer medications, few patients will be cured of hypertension.

**Procedural Complications**

Complications associated with catheter-based renal intervention are related to vascular access, catheter trauma, or systemic complications related to contrast reactions or renal toxicity. Vascular access complications are the most common complications in renal artery intervention. They include access site bleeding and hematoma (1.5%-5%), access site vessel injury (1%-2%), retroperitoneal hematoma (<1%), pseudoaneurysm (0.5%-1%), arteriovenous fistula (<1%), and nerve injury (<1%). Major complications of peripheral vascular angiography range from 1.9% to 2.9% (Table 52-3). One solution to reducing vascular access complications is to perform RAS from radial artery access (see Fig. 52-1A).

| Table 52-3 Complications of Renal Stent Placement |

| Dorros et al   | 163            | 0.6            | 0              | 1.8                        |
| Total/Mean     | 795            | <1             | <1             | 2                          |

Catheter-related renal artery complications include atheroembolism, vessel dissection, or arterial perforation; these are rare (<1%) but often devastating events. Anaphylactic contrast reactions occur in fewer than 3% of patients, and fewer than 1% of these patients require hospitalization. The risk of contrast-induced nephropathy (CIN) is increased in patients with baseline chronic renal insufficiency, diabetes mellitus, and multiple myeloma and
those who are receiving other nephrotoxic drugs such as aminoglycosides. Prevention of CIN requires vigorous hydration and the use of as little iso-osmolar contrast as possible.\textsuperscript{60}

**Radial Artery Access**

Vascular access complications account for the majority of clinical complications of renal stenting. One way to minimize access site bleeding is to use the radial artery (Fig. 52-6). The coronary interventional literature has demonstrated a marked reduction in vascular access complications with radial artery access compared to both brachial and femoral artery access. Low-profile radial sheaths and the ability to use a “sheathless” technique with 6-Fr guiding catheters make the radial artery approach a viable option. In addition to minimizing vascular access complications, the radial artery approach has other advantages, including increased patient acceptance and improved guiding catheter engagement due to the downward or caudal orientation of most renal arteries. The radial approach may require longer (125-cm) guide catheters and longer shaft length balloons and stents (140-150 cm). The undeniable benefit of the radial access approach, however, is a major reduction in the vascular access–related bleeding complications with same-day discharge and increased patient satisfaction.\textsuperscript{61}

**FIGURE 52-6** A. Baseline right renal artery stenosis via the radial approach. B. Poststent deployment.

*Embolic Protection Devices*
Atheroembolism has been associated with an increase in surgical morbidity and a dramatic reduction in 5-year survival compared with patients who had no evidence on biopsy of renal atheroembolization (54% vs 85%; \( P = .011 \)). Because atheroembolism is a potential complication of renal artery stenting, investigators have looked for a role of embolic protection devices (EPDs) in optimizing outcomes after renal intervention (Fig. 52-7). However, distal protection is technically difficult given the early bifurcation of renal arteries. In a small randomized trial, 100 patients undergoing renal artery stenting were randomly assigned to an open-label EPD or use of abciximab in a 2 × 2 factorial design. A positive interaction was observed between treatment with abciximab and embolic protection. Renal artery stenting alone, stenting with EPD, and stenting with abciximab were associated with similar and modest declines in estimated glomerular filtration rate (eGFR) at 1-month follow-up (–10, –12, and –10 mL/min/1.73 m\(^2\) eGFR change, respectively); however, the group treated with both EPD and abciximab was protected from a decline in eGFR and was superior to the other 3 groups (+9 mL/min/1.73 m\(^2\) eGFR change; \( P < .01 \)).
In an uncontrolled retrospective trial, RFC were measured in 66 patients undergoing renal artery intervention with and without EPD. EPD was associated with improved renal blood flow measured by RFC compared with the control group following RAS (mean reduction in RFC, 14.2 vs. 6.7; \( P = .03 \)).\(^{64}\) EPDs may be effective in preventing renal atheroembolic injury, and a controlled trial measuring the impact of EPDs on renal blood flow following RAS should be performed.

**In-Stent Restenosis**

The optimal treatment of renal artery in-stent restenosis (ISR) is uncertain. Primary renal artery stent placement compared to successful balloon angioplasty of ISR lesions demonstrated improved patency for the stent
group with a 58% reduction in recurrent ISR (29.4% vs 71.4%; \( P = .02 \)) and a 30% reduction in follow-up diameter stenosis (41% vs 58.2%; \( P = .03 \)). The repeat stent group also had better secondary patency (\( P = .05 \)) and a greater freedom from repeat ISR (\( P = .01 \)) when compared with balloon angioplasty alone. Other methodologies such as coronary drug-eluting stents, covered stents, cutting balloons, and brachytherapy have been reported, but no systemic studies or any comparative data are available to support any strategy other than optimal repeat bare metal stenting.\(^{65-68}\)

**CONCLUSION**

Patients with presumed atherosclerotic renovascular hypertension should initially be given a trial of multifactorial medical therapy to treat their blood pressure as suggested by the results of CORAL. For patients whose blood pressure is not controlled with medical therapy, the recommendation of the ACC/AHA guidelines document states that it is reasonable to offer renal artery stenting to patients with an atherosclerotic severe RAS (>70% angiographic diameter RAS or 50%-70% stenosis with hemodynamic confirmation of lesion severity) associated with resistant hypertension and failure of 3 drugs, 1 of which is a diuretic, or in patients with hypertension and intolerance to medication.\(^{11}\)

Catheter-based therapy for symptomatic (hypertension, ischemic nephropathy, or cardiac destabilization syndromes), hemodynamically significant, atherosclerotic RAS is the preferred method of revascularization. The discordance between the high (>95%) procedural success and the moderate (60%-70%) clinical response is most likely due to 3 major factors: poor patient selection, poor discrimination of lesion severity by angiography, and the presence of severe parenchymal renal disease. Encouraging data suggest that the use of physiologic lesion assessment can enhance selection for revascularization and improve clinical response rates.\(^{17-19}\) In addition to maximizing the clinical benefit by better patient and lesion selection for renal stenting, the broader use of radial artery access for renal stenting decreases vascular access complications, improves patient satisfaction, and enables same-day discharge in a subset of patients.

**MULTIPLE CHOICE QUESTIONS**

1. A 52-year-old woman undergoes magnetic resonance angiography (MRA) of the abdomen for abdominal pain, which identifies a unilateral
80% left renal artery stenosis. She is referred to you for an opinion regarding treatment. The patient has normal renal function and a diagnosis of hypertension, which is well controlled on 2 medications. Which of the following is appropriate?
A. Perform a renal ultrasound to obtain a baseline image and velocity.
B. Perform an angiogram to confirm the MRA stenosis.
C. Perform an angiogram with renal stenting.
D. There is no need for renal stenting unless her blood pressure becomes uncontrolled.

2. A 72-year-old man with a known unilateral 70% renal artery stenosis and normal renal function is referred for further evaluation by his primary care physician. His blood pressure has ranged from 150/92 mm Hg to 165/88 mm Hg on his home blood pressure cuff over the past several weeks. He is taking a diuretic and an angiotensin-converting enzyme (ACE) inhibitor for his hypertension. In the office today, you measure his blood pressure at 138/86 mm Hg in both arms after 5 minutes of resting. Which of the following is appropriate?
A. Add a β-blocker to his regimen.
B. Add a calcium antagonist to his regimen.
C. Repeat the ultrasound to look for progression of the lesion.
D. Ask him to bring his home cuff into the clinic so that it can be checked against the clinic blood pressure cuffs.

3. An 82-year-old woman presents to the emergency department in acute heart failure manifested by pulmonary edema. She is managed with diuretics. Her blood pressure is 142/90 mm Hg on diuretics and a β-blocker. During her hospital stay, an abdominal ultrasound reveals a 60% to 99% unilateral right renal artery stenosis. Her renal function is mildly impaired with an estimated creatinine clearance of 62 mL/min. Which of the following is most appropriate?
A. Perform an angiogram, and if an ischemic renal artery stenosis is confirmed, perform renal stenting.
B. Add an ACE inhibitor.
C. Add a calcium antagonist.
D. Discuss minimizing sodium in her diet.
4. You follow a 65-year-old man with well-controlled hypertension on 3 medicines and stable coronary disease in your clinic. You notice that his estimated glomerular filtration rate has fallen from 64 mL/min to 48 mL/min over the past year. An ultrasound shows a unilateral severe (>80%) renal artery stenosis with a small kidney (pole to pole is 6 cm). Which of the following is most appropriate?
   A. Perform renal stenting to improve his renal function.
   B. Perform a computed tomography angiogram or MRA to confirm the stenosis severity.
   C. Refer him to nephrology for a consultation regarding his declining renal function.
   D. Discontinue his diuretic and repeat his renal function tests.

5. A patient is admitted and stabilized following a non–ST-segment elevation myocardial infarction on Saturday night. His blood pressure is uncontrolled (~160/90 mm Hg) on 3 medications (diuretic, ACE inhibitor, and β-blocker), and his estimated creatinine clearance is 45 mL/min. You are scheduled to perform a coronary angiogram on Monday morning. Which of the following is most appropriate?
   A. Delay the coronary angiogram several hours until he can get a renal duplex ultrasound performed.
   B. Perform a nonselective aortogram to image the renal arteries during the cardiac catheterization.
   C. Perform selective renal angiography to rule out significant renal artery stenosis during the catheterization.
   D. Add a fourth antihypertensive drug (eg, a calcium channel blocker).

**ANSWERS**

1. D
   There is no indication for revascularization of asymptomatic renal artery stenosis.

2. D
   There is no indication for intervention. It is important to resolve any
systematic measurement differences on home equipment.

3. A
This is a level I indication for renal revascularization.

4. C
There is no benefit from revascularizing a shrunken kidney (<7 cm). He has nephrosclerosis and should be introduced to a nephrologist who can help preserve his renal health.

5. B
This patient is at high risk for renovascular disease and should have a nonselective aortogram performed in conjunction with his cardiac catheterization.
INTRODUCTION

Hypertension is a common, modifiable risk factor of cardiovascular mortality. At present, 30% to 40% of adults in developed countries suffer from hypertension.\(^1\) When hypertension was first recognized, control was difficult due to limited treatment options and often regarded as a fruitless endeavor. In 1931, Dr. Paul Dudley White wrote, “Hypertension may be an important compensatory mechanism which should not be tampered with, even were it certain that we could control it.”\(^2\) Starting in the 1930s, surgical sympathectomy to reduce sympathetic tone was observed to significantly lower blood pressure at the expense of significant procedural morbidity and long-term disability. It was not until the late 1960s that pharmacotherapy for hypertension became available and widespread. Pharmacologic treatment for hypertension has proven generally effective, spurred development of many classes of medications, and assisted in the reduction in mortality from cardiovascular disease. Despite this success, many patients have hypertension that remains uncontrolled. Many cases of uncontrolled hypertension may be attributed to inaction or lack of awareness on the part of patient or provider, but the prevalence of true treatment-resistant hypertension is increasing. In recent years, interest in modifying the sympathetic nervous system has
reemerged with the advent of novel minimally invasive methods such as catheter-based renal artery denervation that can potentially restore more balanced autonomic nervous system physiology and offer alternative treatment options for systemic conditions such as hypertension. In this chapter, we will review what is known about the efficacy of catheter-directed autonomic modulation as a novel treatment of hypertension, discuss best practices to achieve desired results, and outline what the future may hold for this controversial area of endovascular medicine.

BACKGROUND

Pathophysiology

Although the pathophysiology of hypertension is complex and incompletely characterized, the sympathetic nervous system is known to play an important role. In essential hypertension, prior studies have demonstrated increased systemic sympathetic nerve firing as well as excessive sympathetic drive to the kidneys. In the 1850s, French physiologist Claude Bernard discovered that disrupting innervation of the greater splanchnic nerve resulted in diuresis and that electrical stimulation resulted in antidiuresis. Early work on the pressor nerves built the foundation for describing the sympathetic nervous system’s effect on regulation of blood pressure. In animal studies, stimulation of chemosensitive renal afferent nerves has been shown to increase systemic efferent sympathetic nerve activity and increase blood pressure. Renal efferent nerves increase systemic blood pressure by stimulating renin production, tubular reabsorption of sodium, and renal arterial vasoconstriction. Furthermore, dense sympathetic innervation of the renal tubules helps regulate pressure natriuresis and sodium excretion in the setting of hypertension, although this process is impaired in long-standing hypertension.

Direct measurement of renal sympathetic activation by sampling renal norepinephrine spillover confirms increased sympathetic drive to the kidneys in the setting of long-standing hypertension. Norepinephrine spillover is defined as the amount of norepinephrine escaping neuronal uptake and local metabolism and “spilling over” into the venous outflow of an organ. By
infusing radiolabeled norepinephrine, the outward flow of norepinephrine can then be measured by renal vein sampling. Measurements of renal norepinephrine spillover suggest elevated spillover in hypertensives compared to the normotensive population. Resistant hypertensives have even higher norepinephrine spillover than the general hypertensive population likely due to excessive underlying sympathetic stimulation and concurrent medications (eg, vasodilators, diuretics) that stimulate sympathetic activation.

**Surgical Sympathectomy and Rise of Modern Pharmacotherapy**

Surgical sympathectomy was the first intervention investigated for treatment of uncontrolled hypertension. In the 1930s to 1940s, several surgeons described different methods of sympathectomy resulting in significant and sustained reductions in systolic and diastolic pressure.\(^8\),\(^9\) Splanchnicectomy and lumbar sympathectomy were 2 more common procedures for malignant hypertension. Studies of surgical sympathectomy demonstrated a high risk of morbidity such as prolonged hospitalization, orthostatic hypotension, impotence, and gait disturbances.\(^10\) Despite associated morbidities, these trials showed a mortality benefit in selected subjects with malignant hypertension.\(^11\),\(^12\) These results were not generalizable to all who suffered from hypertension, and many clinicians remained skeptical of surgical therapeutics to reduce blood pressure.\(^2\) The first effective pharmacologic antihypertensives were ganglionic blockers (eg, tetraethylammonium) modeled after the initial surgical experience, although these too carried a high risk of side effects similar to surgical therapy.\(^13\)

The next stage of antihypertensive development produced centrally acting sympathetic inhibitors as well as \(\alpha\)- and \(\beta\)-adrenergic antagonists. Shortly afterward, diuretics and directly acting vasodilators like hydralazine became available. It was not until the Veterans Administration Cooperative Studies in the 1970s that pharmacologic therapy for hypertension became widely accepted.\(^14\),\(^15\) Angiotensin-converting enzyme inhibitors and angiotensin receptor blockers as well as dihydropyridine calcium channel blocking agents became commonly used in the 1990s as these medications were more tolerable and provided longer lasting blood pressure reduction. Current
guidelines from the Eighth Joint National Committee (JNC-8) recommend combination therapy with the following specific blood pressure targets: <150/90 mm Hg for patients >60 years old and <140/90 mm Hg for patients <60 years old or with chronic kidney disease or diabetes. Recently, new evidence suggests more aggressive antihypertensive control may provide further benefit in selected patients. The Systolic Blood Pressure Intervention Trial (SPRINT) showed a reduction in major adverse cardiovascular events compared to usual practice at 1 year with more aggressive antihypertensive therapy targeting systolic blood pressure <120 mm Hg in patients >50 years old with high-risk features for cardiovascular events. Existing guidelines and recent studies highlight the importance of antihypertensive therapy and the need for additional therapies.

**Resistant and Uncontrolled Hypertension**

Despite advances in our understanding of resistant hypertension and in pharmacologic treatment, the prevalence of true treatment-resistant hypertension is as high as 15% to 30% of treated hypertensive patients. Patients with resistant hypertension, according to an American Heart Association consensus document, are defined as patients whose blood pressure remains above goal despite adequate treatment with 3 or more different classes of antihypertensive agents, ideally including a diuretic. Physician inertia, medication noncompliance, and nonadherence to lifelong pharmacologic therapy are all attributed to hypertensive pharmacologic pseudoresistance, but a sizable proportion of remaining patients can be classified as true treatment-resistant hypertensives. Resistant hypertensives are at higher risk for cardiovascular events. In patients with hypertension and coronary artery disease, the prevalence of resistant hypertension is greater than 30% and is associated with a higher risk of all-cause death and a higher risk of cardiovascular mortality. An analysis of the Reduction of Atherothrombosis for Chronic Health (REACH) registry, a multinational database of patients with 3 or more atherosclerotic risk factors or with known coronary, cerebrovascular, or peripheral vascular disease, identified a resistant hypertension prevalence of 12.7%. These patients suffered an 11% higher hazard of a combined primary end point of cardiovascular death, myocardial infarction, and stroke at 4 years. A dose-response relationship was noted, with patients on more antihypertensive medications experiencing
a significantly higher incidence of cardiovascular outcomes.\textsuperscript{21}

The resistant hypertensive population can be difficult to separate from uncontrolled hypertensives as a whole. The spectrum of uncontrolled hypertension ranges from patients with high blood pressure due to inadequate medical regimens or nonadherence to true treatment resistance.\textsuperscript{19} In the Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT) cohort, nearly half the patients required 1 to 2 medications, whereas the rest needed 3 or more antihypertensives. At 5 years, approximately one-third of patients remained uncontrolled despite 2 medications.\textsuperscript{22} The ALLHAT study demonstrates that resistant hypertension remains prevalent despite close monitoring and protocol-directed medication titration. Due to the limitations of current pharmacotherapy and the long-term morbidity associated with resistant hypertension, novel catheter-directed and device-based therapies for hypertension are of great interest in their potential to achieve guideline-defined blood pressure targets in patients struggling to respond.

**RETURN OF INTEREST IN THE SYMPATHETIC NERVOUS SYSTEM AS A THERAPEUTIC TARGET**

Given the prevalence of resistant hypertension, there is intense academic and commercial interest in developing therapies that can predictably modulate autonomic tone for promotion of health. Ablating renal sympathetic innervation was originally thought to provide an antihypertensive effect by reducing tubular reabsorption of sodium and downregulating the renin-angiotensin-aldosterone system (RAAS) via interruption of signaling from the central nervous system (CNS) to the kidneys via renal efferent nerves. More recently, it has been recognized that disruption of renal afferent nerves also alters the feedback loop of sympathetic signaling from the kidneys back to the CNS, which may reduce central systemic sympathetic outflow as well. Studying the effects of total nephrectomy and sympathetic tone in patients with end-stage renal disease, Converse et al\textsuperscript{23} demonstrated increased postganglionic sympathetic nerve discharge in those who had not undergone
nephrectomy. Thus, excess sympathetic nervous activity in the setting of chronic renal insufficiency is associated with renal afferent innervation. The concept of a feedback loop of efferent and afferent signaling between the kidneys and brain may have far-reaching influence on other disease and metabolic activity.

From the initial surgical experience in the 1930s to 1940s, sympathetic denervation was established as a means to reduce blood pressure and mortality. However, how to selectively target renal sympathetic nerves for blood pressure reduction while avoiding the morbidity of disrupting neighboring abdominal, pelvic, and lower extremity innervation remained a challenge. The anatomy of postganglionic renal sympathetic nerves is favorable for catheter-directed therapy as neuronal fibers extending from the sympathetic chain reside in the adventitia along the length of the renal arteries in route to the kidneys. The first patented minimally invasive method to disrupt renal innervation emerged in the early 2000s with development of a single-lead endovascular radiofrequency ablation catheter that could be navigated along the length of the renal artery (Fig. 53-1). With electrode wall contact on the intimal side, externally directed radiofrequency energy could thermally ablate neighboring sympathetic nerves residing in the adventitia.

Initial studies applied radiofrequency energy every 5 mm along the length of bilateral main renal artery trunks. Early swine catheter studies demonstrated a reduction in norepinephrine content in renal outflow greater than 85%, which was comparable to direct surgical renal denervation. A subsequent first-in-human report described successful renal denervation in a 59-year-old man with a history of 2 transient ischemic attacks, obstructive sleep apnea, and long-standing hypertension despite 7 antihypertensive agents. His mean blood pressure prior to invasive treatment was 161/107 mm Hg. At 30 days, his blood pressure was reduced to 141/90 mm Hg and then to 127/81 mm Hg at 1 year. Total-body norepinephrine spillover was reduced by 42% along with reductions in other measures of sympathetic excess.
The initial open-label, proof-of-concept pilot study, SYMPPLICITY HTN-1,24 enrolled 153 patients at 19 investigational sites in Australia, Europe, and the United States (Table 53-1). Patients with systolic office blood pressure (OBP) ≥160 mm Hg despite taking at least 3 antihypertensive drugs, including a diuretic, were eligible. Investigators performed catheter-directed radiofrequency ablation of the renal sympathetic nerves with the Symplicity Flex catheter (Medtronic, Santa Rosa, CA). The study achieved systolic and diastolic OBP reductions of 20 and 10 mm Hg at 1 month, respectively. The study investigators have reported data on 88 subjects out to 3 years with sustained OBP reduction (–32/–14 mm Hg).26,27 A follow-up phase II study, SYMPPLICITY HTN-2, enrolled 106 patients at 24 centers in Australia, New Zealand, and Europe in a multicenter, prospective, randomized controlled trial (see Table 53-1).28 Patients with baseline systolic OBP ≥160 mm Hg (or ≥150 mm Hg in patients with type 2 diabetes mellitus) despite at least 3 antihypertensive drugs (diuretic was not mandated) were eligible for 1:1 randomization between catheter-based renal denervation (RDN) and control. The control arm of the trial was not blinded as patients continued preexisting antihypertensive therapy. The mean change in systolic and diastolic OBP at 6 months was –32/–12 mm Hg in the RDN group compared to an insignificant
change from baseline (mean, 1/0 mm Hg) in the control group. Further follow-up data of 70 of the 89 patients in SYMPPLICITY HTN-2 who received RDN demonstrated a mean 36-month (treatment) and 30-month (crossover) systolic and diastolic OBP reduction of –34 and –14 mm Hg, respectively.29

Abbreviations: ABP: ambulatory blood pressure; SSAHT, standardised stepped-care antihypertensive treatment; T2DM, type 2 diabetes mellitus.

Importantly, neither SYMPPLICITY HTN-1 nor HTN-2 reported any significant differences in adverse events or measures of safety between denervation treatment and control groups. At long-term follow-up, renal function was preserved in each study, and initial imaging substudy analysis showed no incidence of renal artery stenosis at the site of ablation. Postural hypotension was not observed, suggesting that venoconstriction remains intact after RDN. Finally, given persistent blood pressure reduction data and signs of an increasing responder rate over time, the Symplicity Flex catheter received CE (Conformité Européenne) market approval as a treatment for resistant hypertension in Europe and subsequent similar approval in several areas around the globe.
SYMPLICITY HTN-3

The success of SYMPLICITY HTN-1 and HTN-2 generated great enthusiasm for RDN as a novel treatment for resistant hypertension. In order to pursue US Food and Drug Administration (FDA) approval, SYMPLICITY HTN-3, a prospective, single-blind, randomized, sham-controlled phase III trial, was conceived with hopes to definitively demonstrate clinical efficacy and safety of RDN (see Table 53-1).\(^3\) A total of 535 patients with resistant hypertension taking maximally tolerated doses of at least 3 antihypertensive medications, including a diuretic, were randomized in 2:1 fashion, with 364 patients in the RDN group and 171 in the control group. The defined end points were as follows: a primary efficacy end point of change in OBP at 6 months, a secondary efficacy end point of change in 24-hour ambulatory blood pressure monitoring (ABPM) at 6 months, and a primary composite safety end point. All patients underwent baseline renal angiography, but after randomization, those in the control group remained on the table as a sham procedure with all randomized patients blinded to their treatment assignment. The intention was to identify patients with severe manifestations of resistant hypertension and to eliminate the bias of study subjects’ awareness of treatment assignment.

At baseline, patients in HTN-3 were taking an average of 5 antihypertensive medications, 4 of which were at maximal dosing. All patients enrolled were on diuretics, primarily of the thiazide class. Despite this aggressive medication regimen, the average baseline systolic OBP was 180 mm Hg. All patients enrolled in HTN-3 also underwent 24-hour ABPM with a mean baseline of 160 mm Hg. At 6 months, the adverse event rate was low and no different from control, demonstrating that RDN, as implemented in HTN-3, can be performed safely. Although OBP and 24-hour ABPM decreased by 14.13 mm Hg and 6.89 mm Hg, respectively, after RDN, similar declines were also seen in the control group. The mean difference in office-based systolic blood pressure was –2.4 mm Hg, and mean difference in 24-hour ABPM was –1.96 mm Hg. Both of these differences failed to meet predefined superiority margins and were statistically insignificant. After completing 6 months of follow-up, control group patients who qualified to crossover to RDN were treated and followed but failed to demonstrate any significant superiority in blood pressure lowering 6 months after RDN. Given
prior data suggesting a long-term responder effect, 12-month OBP and 24-hour ABPM measures of patients initially randomized to denervation were examined but also failed to demonstrate any significant long-term difference from those in the control arm on medications alone.\textsuperscript{31}

The results of SYMPLICITY HTN-3 greatly tempered prior enthusiasm that had developed around the concept of RDN. HTN-3 also launched a debate regarding the validity of all prior studies of RDN that had demonstrated such a stark difference in efficacy of blood pressure lowering while excluding sham procedure in a blinded control group. Questions surfaced as to whether previous demonstrations of blood pressure reduction after RDN were merely a manifestation of placebo effect. Given the many physiologic components driving elevated blood pressure in hypertensive patients, many also question whether denervation trial participants manifested the Hawthorne effect of behavior modification by virtue of being observed in a trial, thereby leading to blood pressure declines in both treatment and control groups. Another concern raised in the design of these RDN trials is the likelihood of regression to the mean given that qualifying patients were included primarily based on isolated OBP measurements above 160 mm Hg, and not 24-hour ABPM.\textsuperscript{32} Proponents of RDN have challenged that the design of HTN-3 underestimated the potential benefits of RDN. The following section will explore these questions.

\textbf{Technologic Limitations of the Symplicity Flex Catheter: Was Denervation Underdosed?}

The catheter tested in the SYMPLICITY trials was a first-generation device with a single-lead electrode. Precise electrode positioning within the renal artery, proper wall apposition, and successful circumferential denervation are extremely operator dependent with this device. Further refinements and engineering advances have created “second-generation” catheter platforms that may better ensure adequate denervation and optimization of results. These catheters can deliver multidirectional circumferential nerve ablation, which is more efficient and reproducible in achieving complete denervation by maximizing “4-quadrant” renal arterial denervation. Ideally, the procedure should achieve a full 360° ablation by applying energy at the superior, inferior, anterior, and posterior arterial walls. A substudy analysis of HTN-3
suggested the number of successful renal arterial quadrants ablated is an independent predictor of blood pressure reduction after RDN. Of note, less than 25% of patients received circumferential 4-quadrant denervation in both right and left renal arteries. A dose effect trend was also documented between the number of full 4-quadrant ablations achieved during RDN and blood pressure lowering. Although HTN-1 tested regional norepinephrine spillover after denervation to confirm the sympathetic modulation, HTN-3 did not include norepinephrine spillover measurements, rendering it difficult to compare the concept of dose effect between trials. The concept of a denervation dose effect requires further study for validation. Leaders in the field now debate that HTN-3’s failure to achieve its prespecified end points was attributable to inadequate denervation due to protocol limitations and overall operator inexperience. A wide range of operator volume was seen. Most operators had not previously performed RDN.7

**How Generalizable and Homogeneous Was the SYMPLICITY HTN-3 Patient Population?**

The severity of hypertension required to qualify for randomization was so extreme that it is difficult to generalize the HTN-3 study population to uncontrolled hypertensive patients typically seeking assistance in lowering their blood pressure. In one single-center study, only 0.8% of the entire hypertensive population of an academic cardiology patient practice would have met the general inclusion criteria of HTN-3. Some have speculated that the underlying pathophysiology of resistant hypertension in many patients enrolled in HTN-3 may have been beyond alteration, even if adequate circumferential denervation had been achieved.

Ideally, in testing the efficacy of blood pressure lowering of a novel therapy, a trial would include patients with similar acuity of illness and minimize any confounding factors that would cloud the true treatment effect of the tested intervention. Although only patients thought to have severe true treatment-resistant hypertension were enrolled, there was large variance between patients in the number and type of medications taken. After enrollment, a substudy analysis of HTN-3 revealed that 38.2% and 42.1% of patients in the RDN and sham control groups, respectively, changed either the number of medications or dosing during the 6-month study period.33 Such
common medication changes confound the testing of a treatment effect. It is impossible to retrospectively determine the underlying nature of resistant hypertension in patients who qualified for randomization. Compliance with pharmaceutical regimens was confirmed only by patient interview and without an objective measure of drug ingestion.

The measurement of blood pressure in these and other antihypertensive efficacy trials has come under criticism in that almost all have historically used OBP for qualification and as a primary outcome measurement. Increasingly, however, the use of OBP limits assessment of blood pressure to a small window of time that is prone to confounders in the office setting such as white coat hypertension. Twenty-four–hour ABPM, with interventions such as witnessed medication ingestion prior to recording, has been suggested as a potentially more valid method to measure blood pressure in such trials.

Differences in treatment efficacy between African Americans and non–African Americans were also noted. Assessing outcomes by ethnicity, systolic OBP response in the control (sham) arm showed a significant and larger reduction in African Americans than in non–African Americans. Assessing prescribed medications, African Americans were prescribed aldosterone antagonists and vasodilators more often than non–African American participants. Furthermore, African Americans had significantly higher baseline diastolic blood pressure and more complex antihypertensive regimens (eg, at least 1 medication prescribed 3 times daily). Through interaction analysis, some experts hypothesize that improved medication adherence after randomization contributed to greater blood pressure reduction in the control (sham) arm, especially in the African American cohort. In subgroup analysis, blood pressure response to RDN in non–African Americans was similar to that which has been described in prior RDN trials and global registries. These differences will need to be studied further to better understand what distinguishes RDN responders from nonresponders.

**DENER-HTN**

SYMPLICITY HTN-3 was praised for its sham design but criticized due to possible inadequate denervation and subgroup differences. DENER-HTN (Renal Denervation in Patients With Resistant Hypertension) was a randomized controlled trial designed to examine efficacy and cost-
effectiveness of RDN added to standardized antihypertensive therapy (see Table 53-1).\textsuperscript{36} Fifteen French centers recruited 106 patients with 24-hour ABPM systolic blood pressure ≥140 mm Hg or diastolic blood pressure ≥90 mm Hg despite 3 or more antihypertensives at maximally tolerated doses, including a diuretic. To confirm resistant hypertension, each patient was switched to a standardized 3-drug regimen for 4 weeks including maximally tolerated doses of indapamide, amlodipine, and ramipril or irbesartan. Patients were then randomized 1:1 to RDN with the Medtronic Symplicity Flex catheter or standardized oral antihypertensive therapy. Preselected antihypertensives from other classes could be added during follow-up (spironolactone, bisoprolol, prazosin, or rilmenidine, sequentially in this order) if 24-hour ABPM remained above the goal of 135/85 mm Hg. At 6 months, the average reduction in 24-hour ABPM systolic blood pressure was significantly greater in the RDN group than the control group in all 3 monitoring settings: daytime ambulatory monitoring (–15.8 mm Hg vs –9.9 mm Hg; \(P = .03\)), nighttime ambulatory monitoring (–13.9 mm Hg vs –7.6 mm Hg; \(P = .03\)), and 24-hour ABPM (–15.4 mm Hg vs –9.5 mm Hg; \(P = .02\)). A similar proportion of patients in each group received add-on treatment from other medication classes, reaching a median of 5 drugs in each group. Medication adherence was strictly followed using the Morisky Medication Adherence Scale questionnaire.\textsuperscript{36}

DENER-HTN was a smaller trial but possibly implemented a more relevant protocol and design than SYMPLICITY HTN-3. Patient selection was more homogenous by design with a 4-week period of medication standardization. DENER-HTN used 24-hour ABPM as the desired end point, providing a more complete understanding of hypertensive burden at baseline and overall change in blood pressure over time. Further, patients in both groups required additional therapy after randomization (mean, 5 medications). The continued addition of medical therapy in a stepwise fashion, with sympatholytic drugs after other classes, has led some to hypothesize that antiadrenergic agents may enhance the effects of RDN. From the DENER-HTN trial, patients with evidence of sympathetic dysregulation and hypertension may be more suited targets for RDN. Some investigators have even suggested that detecting excess sympathetic activity when diagnosing hypertension may be useful for selecting previously untreated patients who may benefit from RDN.\textsuperscript{37} The DENER-HTN study has reinvigorated interest in RDN’s therapeutic potential based on a stricter
trial design than HTN-3 and its thought-provoking results.

RENAL DENERVATION PROCEDURAL CONSIDERATIONS TO OPTIMIZE RESULTS

The renal afferent and efferent sympathetic nerves, as described earlier, reside along the adventitia of the renal arteries. Coursing from the sympathetic trunk, the nerves travel from the aorta to the main renal arteries. The limited histologic studies available at the time suggested that the distribution of nerves were most concentrated around the proximal segments of the renal arteries. For this reason, initial radiofrequency ablation techniques emphasized targeting RDN in the mid-to-proximal segments of the renal arteries.25

The Symplicity Flex catheter system, as used in the SYMPPLICITY HTN studies, is a single-electrode system designed to apply focal radiofrequency ablation to the renal nerves through precise operator manipulation. The catheter shaft allows the operator to rotate the tip and to partially flex the distal end to allow maneuverability. The catheter is connected to a generator console, which provides real-time data regarding treatment time, impedance changes, energy delivery in watts, and temperature. A renal angiogram is initially performed to assess for exclusions such as significant renal artery stenosis, vessel diameter <4 mm or target length <20 mm, and the presence of large accessory renal arteries. Using a 6-Fr guiding system via transfemoral access, the Symplicity Flex system is advanced directly from a selective guiding catheter into the renal arteries without the need for a guide wire. The HTN-1 and HTN-2 trials aimed for at least 4 radiofrequency ablations lasting 120 seconds at 8 watts or less applied to the lumen of the renal artery. As practiced in these studies, the initial ablation is performed 5 mm proximal to the distal bifurcation. The catheter is then retracted 5 mm and rotated to the next radiofrequency ablation site. Retracting the catheter toward the proximal renal artery, the goal is to provide 360° of circumferential ablation in superior, inferior, anterior, and posterior quadrants. During ablation, temperature and impedance are monitored and energy delivery is altered according to the generator’s proprietary algorithm. Patients generally require
dense conscious sedation and careful monitoring for associated visceral pain during catheter activation. Angiographically, operators may see denervation “notches,” or areas of focal spasm marking sites of applied thermal injury. These are typically self-limited, with severe cases resolving with intra-arterial nitroglycerin. Postprocedural monitoring is typically straightforward including standard of care for vascular hemostasis, supportive care for any residual visceral pain, and routine postprocedural monitoring per usual conscious sedation guidelines. Report has been made of platelet activation and possible luminal microthrombi where denervation was applied. For this reason, antiplatelet therapy may be considered periprocedurally, although this practice has not been formally studied.\textsuperscript{10,24,38}

A recent histologic analysis at autopsy demonstrates that the maximal number of nerves are present in the proximal and ventral segments of the renal arteries.\textsuperscript{39} As the paravertebral aorticorenal ganglia receives many branches from the greater, lesser, and least splanchnic nerves, which then form the renal plexus, the absolute number of sympathetic nerves near the ostia of the renal arteries is likely to be greatest. However, nerves are spatially closer to the luminal surface moving more distally along the length of the renal artery and at the bifurcation (mean, 2.84 mm in proximal segments vs 1.81 mm in the distal segments).\textsuperscript{39} A swine study of radiofrequency denervation in the main renal trunk versus main trunk plus vessels distal to the bifurcation suggests that more consistent denervation is produced by including suitable vessels distal to the bifurcation.\textsuperscript{40} Our enhanced understanding of variations in sympathetic fiber proximity to the renal artery luminal surface has influenced much of the newer technology for RDN, which we discuss later in the chapter.

STATE OF THE ART RENAL DENERVATION CATHETERS

\textit{Symplicity Spyral}

Given the lessons learned from the SYMPPLICITY trials outlined earlier, technical improvements in catheter design have been implemented with the newer Symplicity Spyral catheter (Medtronic). As opposed to a manually
directed single-lead electrode system, Spyral is a self-expanding helical 4-electrode design delivered over an 0.014-inch wire that conforms to various vessel diameters ranging from 3 to 8 mm (Figs. 53-2 and 53-3). The electrodes are positioned circumferentially to deliver a 4-quadrant pattern of radiofrequency-induced denervation with 1 simultaneous treatment cycle that lasts only 60 seconds. A newer generator console system allows simultaneous monitoring of performance of each electrode and the option to selectively power each on or off individually. Spyral is undergoing phase II testing through the SPYRAL HTN global clinical trial program.

FIGURE 53-2 Symplicity Spyral Catheter (Medtronic, Santa Rosa, CA). Spyral is a self-expanding helical 4-electrode design delivered over an 0.014-inch wire that conforms to vessel diameter. (Copyright © Medtronic 2016.)
**Vessix**

The Vessix catheter (Boston Scientific, Maple Grove, MN) is a balloon catheter that inflates to only 3 atm pressure placing 4 helical offset electrodes in contact with the renal artery to deliver treatment (Fig. 53-4). These electrodes are bipolar and can deliver radiofrequency energy with lower wattage than comparable unipolar systems and for shorter treatment time in as little as 30 seconds. Given the lack of a grounding pad, visceral discomfort may not be as severe as unipolar systems. Each electrode can be individually monitored and activated via a generator console. The catheter profile is 7 Fr, and different balloon sizes are available from 4 to 7 mm in diameter. Initial clinical studies have been promising but have yet to include published randomized data with a sham control group. Vessix is currently undergoing phase II testing in the REDUCE HTN: REINFORCE study.
The Vessix catheter (Boston Scientific, Maple Grove, MN) is a balloon catheter that inflates to only 3 atm pressure placing 4 helical offset electrodes in contact with the renal artery to deliver treatment. EnligHTN

The EnligHTN catheter (St. Jude Medical, Saint Paul, MN) delivers circumferential radiofrequency denervation through an 8-Fr multielectrode basket design expanded by the operator (Fig. 53-5). When fully expanded, the 4 electrodes of the basket are spaced circumferentially to target all 4 quadrants. Each electrode is individually monitored and activated through a generator console. The electrode systems are unipolar, and treatment time is 90 seconds for simultaneous electrode firing. Initial clinical trials have been encouraging but also lack randomized data compared to a sham procedure.

PARADISE

The PARADISE catheter (ReCor Medical, Palo Alto, CA) is a 6-Fr low-pressure balloon system that delivers rotational therapeutic ultrasound energy instead of radiofrequency energy (Fig. 53-6). Via a fluid-cooled balloon, the self-centered rotational ultrasonic source delivers energy that theoretically allows full circumferential denervation in a 360° donut pattern. Energy intensity can be adjusted by the operator via a generator console that can change the depth of desired thermal injury. Phase II trial enrollment has begun via the RADIANCE-HTN global clinical trial.

FIGURE 53-6 The PARADISE catheter (ReCor Medical, Palo Alto, CA) is a 6-Fr
low-pressure balloon system that delivers rotational therapeutic ultrasound energy instead of radiofrequency energy.

**Peregrine**

Since thermal denervation achieves its effect via tissue injury, alcohol has been explored as an alternative neurolytic therapeutic option. Alcohol has been safely used as a therapeutic tool in diseases such as hypertrophic cardiomyopathy septal ablation. The Peregrine catheter (Ablative Solutions, Kalamazoo, MI) delivers dehydrated alcohol to the periadventitial space of the renal arteries (Fig. 53-7). The Peregrine catheter is navigated into the renal arteries with deployment of 3 guide tubes from the catheter tip. These engage the intimal surface with subsequent penetration of the vessel with 220-μm needles. The guide tubes are spaced 120° apart and allow for 360° circumferential spread of the injected alcohol, which extravasates throughout the periadventitial space. First-in-man experience has been promising but will require further clinical investigation to confirm safety and efficacy.41
**FIGURE 53-7** The Peregrine catheter (Ablative Solutions, Kalamazoo, MI) delivers dehydrated alcohol to the periadventitial space of the renal arteries by deploying 3 guide tubes from the catheter tip that penetrate the intimal surface with 220-μm needles. **FUTURE TRIAL DESIGN TO EVALUATE RENAL DENERVATION**

As described earlier, the available evidence base of clinical trials that have tested the efficacy of RDN has been met with skepticism due to methodologic limitations. SYMPPLICITY HTN-1 and HTN-2 lacked adequate control arms to test for placebo effect and lacked sufficient 24-hour ABPM measurements to demonstrate true treatment-resistant hypertension in their population. SYMPPLICITY HTN-3, as discussed earlier, has raised more
questions than answers as uncertainty remains as to whether the RDN hypothesis for lowering blood pressure in a relevant population was adequately tested. The best way to study whether or not a specific population benefits from this therapeutic concept is still unclear. Many ideas have been proposed in how to design future trials of RDN.

Separating the treatment effect of RDN in patients on vastly different medication regimens with varying degrees of compliance who also manifest differing levels of disease severity or underlying pathophysiology remains a challenge. Ideally, an operator would be able to measure a marker of sympathetic tone or of renal nerve signaling before and after RDN to determine treatment success. Unfortunately, no such tool has yet been devised. In order to eliminate confounding, randomizing hypertensive patients off medications or hypertensive patients receiving an identical standardized drug regimen to RDN versus a sham procedure has been suggested as an alternative pathway in trial design. Such studies would be more sensitive to the treatment effect of RDN itself. Identifying patients who are more generalizable for potential treatment response then those enrolled in SYMPLICITY HTN-3 has also been suggested, given that patients enrolled in SYMPLICITY HTN-3 were supposedly uncontrolled on an average of 5 medications. Limiting the importance of OBP readings and relying, instead, on 24-hour ABPM and home blood pressure readings for study end points may ensure enrollment of patients with true treatment-resistant hypertension. Improved methods to screen for patient medication compliance (eg, monitoring of medication refills or pill counts, or testing for metabolites of medication) have also been suggested. In regard to catheter technology, currently available radiofrequency RDN systems, as described earlier, have improved from that which was tested in the SYMPLICITY trials. New-generation catheter designs offer improvements such as multiple electrodes, balloon-inflatable or expansive catheter designs to better ensure wall apposition, and circumferential treatment delivery to optimize adequate radial denervation. Hopefully, ongoing and future studies of novel denervation technology with modified trial designs can definitively answer the question of whether denervation alters pathophysiology for the potential benefit of patients.

Currently, the Symplicity Spyral, Vessix, and Paradise catheters are being evaluated via FDA-approved phase II trials in the United States through the SPYRAL HTN-ON MED and HTN-OFF MED studies, REDUCE HTN:
REINFORCE study, and the RADIANCE study, respectively. Proponents of RDN await the results of these trials to determine if RDN will prove to be a valuable addition to the armamentarium of antihypertensive therapies.

RENAL DENERVATION AS TREATMENT FOR OTHER DISEASE STATES

**Obstructive Sleep Apnea**

Patients suffering from obstructive sleep apnea (OSA) have an increased risk for cardiovascular morbidity and an increased prevalence of resistant hypertension. During airway obstruction and cumulative nocturnal hypoxia, OSA patients experience excessive upregulation of sympathetic tone, which is thought to increase susceptibility to cardiovascular morbidity. Whether sympathetic nerve activity drives the pathogenesis of OSA or whether persistent hypoxia from apnea and hypopnea drives an increase in sympathetic tone is incompletely understood. A few small observational studies have described physiologic effects of RDN in patients with OSA. A limited meta-analysis suggests that RDN may improve both blood pressure as well as the apnea-hypopnea index.\(^{42}\) The potential role of RDN in ameliorating the pathophysiology and consequences of OSA will need to be explored further in randomized trials.

**Cardiac Arrhythmia**

Multiple pathophysiologic perturbations influence the pathogenesis of atrial and ventricular arrhythmia including sympathetic nervous overactivity. Pharmacologic \(\beta\)-receptor blockade is a mainstay of treatment but with limited efficacy. For hypertensive patients with atrial fibrillation, limited trial data have demonstrated a reduction in recurrent atrial fibrillation after pulmonary vein isolation (PVI) treatment combined with RDN compared to PVI alone.\(^{43}\) This suggests a role of autonomic imbalance in the initiation or propagation of atrial arrhythmogenicity. Larger randomized trials are under
way to further validate this hypothesis.

Ventricular arrhythmogenesis is another similar target for modulation of autonomic activity with hope that RDN may reduce ventricular tachycardia in at-risk patients. Randomized trials are lacking, but ongoing trial results will determine whether there is merit in this approach.

**Insulin Resistance**

Alterations in glucose metabolism in patients with insulin resistance are driven by a complex interplay between different physiologic mechanisms, of which the sympathetic nervous system plays a role. RDN, primarily through disruption of afferent sympathetic nervous signaling, has generated interest as a therapeutic tool to potentiate sensitivity to insulin. When RDN was performed in a study of hypertensive patients, 40% of whom had type 2 diabetes, improved glucose metabolism was seen as measured by changes in fasting glucose, insulin, and C-peptide levels as well as by insulin sensitivity index and oral glucose tolerance test measurements. This study and subsequent reports have spurred interest in larger randomized controlled trials to further test the benefit of restoring autonomic balance to improve glucose metabolism.

**Chronic Congestive Heart Failure**

Heart failure is a complex pathophysiologic state in which multiple neurohormonal systems including the renin-angiotensin-aldosterone, arginine vasopressin, and sympathetic nervous systems are activated to maintain cardiac output. Increased sympathetic activity leads to enhanced vasoconstriction and increased systemic and pulmonary vascular resistance, which maintains left ventricular preload. Increased tubular sodium reabsorption from renal sympathetic stimulation and overall excess renal and cardiac sympathetic stimulation have been demonstrated in patients with chronic heart failure. Suppression of sympathetic input with β-blockade is now a mainstay of therapy by virtue of its clear mortality benefit. As an alternate means to reestablish autonomic balance, there is interest in therapeutic RDN in the setting of chronic heart failure with reduced ejection fraction (HFrEF) and preserved ejection fraction (HFpEF). The pilot study for REACH (Renal Artery Denervation in Chronic Heart failure)
demonstrated that RDN via the Symplicity system may be safe in 7 patients with chronic HFrEF (New York Heart Association [NYHA] class III-IV) on maximally tolerated medical therapy including β-blockers. Six months after RDN, renal function remained stable and there were no reported episodes of syncope, hypotension, or other hemodynamic disturbances. Additionally, the pilot study suggested an improvement in exercise capacity with significantly increased 6-minute walk distances at 6 months.

REACH (NCT01639378) is now ongoing with plans to randomize 100 patients to RDN plus maximal medical therapy versus a sham procedure plus maximal medical therapy with change in symptoms as the primary outcome. SYMPPLICITY-HF (NCT01392196) has completed enrollment of 40 patients with chronic HFrEF (NYHA class II-VI) in a phase II clinical trial evaluating physiologic response and safety of RDN in this population. Targeting the HFrEF population, the DIASTOLE (Denervation of the Renal Sympathetic Nerves in Heart Failure With Normal Left Ventricular Ejection Fraction; NCT01583881) study has enrolled 60 patients with HFpEF to RDN with the Symplicity system plus medical therapy versus medical therapy alone. The primary outcome is change in diastolic function as measured by the E/E’ ratio at 12 months. In coming years, a greater understanding of RDN effects in the setting of HFrEF and HFpEF will guide decisions to pursue more ambitious clinical trial evaluation.

**Chronic Kidney Disease**

Hypertension is a major risk factor for chronic kidney disease (CKD), and control of hypertension is known to reduce progression to end-stage renal disease. Excessive sympathetic activity in renal failure has been well described and is elevated in patients with end-stage renal disease compared to patients with end-stage renal disease who have undergone nephrectomy. In patients with CKD, resistant hypertension is common, and sympathetic overactivity has been shown to contribute to progression. In the SYMPPLICITY-HTN studies, patients with estimated glomerular filtration rates (GFR) ≤45 mL/min/1.73 m² were excluded. RDN trials have demonstrated no renal injury in patients randomized to denervation.

Given difficulties achieving control of blood pressure and in slowing the progression of nephropathy, alternative therapies in the CKD population that
can reduce cardiovascular risk and progression of CKD would be very valuable. Fifteen Australian patients with stage 3 to 4 CKD and resistant hypertension underwent RDN with minimal contrast exposure including 6 patients by carbon dioxide angiography. Estimated GFR was not adversely affected, but OBP significantly improved from an average 174/91 mm Hg at enrollment to 144/73 mm Hg after 1 year. With this suggestion of safety in the CKD population, a German group investigated rates of GFR change before and after RDN. Twenty-seven patients with stage 3 or 4 CKD and resistant hypertension confirmed by 24-hour ABPM underwent RDN. Renal function was analyzed for 3 years retrospectively and then for 1 year prospectively after RDN. The rate of estimated GFR decline prior to RDN was 4.8 mL/min/1.73 m² per year. After RDN, estimated GFR improved on average 1.5 mL/min/1.73 m² per year. Additionally, mean 24-hour ambulatory blood pressure improved from 151/80 mm Hg to 143/76 mm Hg at 1 year. If future studies are favorable, patients with CKD may prove to be a high-risk population that would benefit from the physiologic modification of RDN.

ALTERNATIVE CATHETER SOLUTIONS FOR BLOOD PRESSURE REDUCTION

Carotid Baroreceptor Modulation

Baroreceptor reflex function has long been appreciated as a potent mediator of homeostatic balance in blood pressure regulation. Baroreceptors in the carotid bodies, located in the wall of the carotid artery bilaterally, are easily accessible for therapeutic manipulation as has long been described during carotid artery massage. Pulsatile signaling from the baroreceptors delivers continuous feedback through the carotid sinus nerve to the CNS modulating sympathetic and parasympathetic feedback. Blood pressure lowering after carotid artery stenting is well recognized but typically short lived due to baroreceptor reset from the CNS. The MobiusHD device (Vascular Dynamics, Mountain View, CA) is a self-expanding stent-like device
deployed similar to comparable carotid stent technology that increases carotid artery wall strain to increase carotid sinus nerve feedback (Figs. 53-8A and B). Unlike carotid stents, however, the MobiusHD maintains pulsatility to theoretically prevent baroreceptor reset and to maintain blood pressure lowering. First-in-man trial results are promising thus far but await study completion and further investigation.51

FIGURE 53-8 The MobiusHD device (Vascular Dynamics, Mountain View, CA) is a self-expanding stent-like device (A) that increases carotid artery wall strain to increase carotid sinus nerve feedback (B).

Arteriovenous Shunting

The ROX Coupler (ROX Medical, San Clemente, CA) approaches catheter-based intervention for blood pressure lowering in a completely different way without any need to modulate the autonomic nervous system. Through a catheter-based sidewall puncture from the central iliac artery to the vein, the ROX arteriovenous coupler device is implanted, creating a fixed shunt to offload arterial pressure (Fig. 53-9). The procedure is technically reversible by placement of a covered endovascular prosthesis over the device to disable the shunt. The initial ROX CONTROL HTN study was an open label randomized study that demonstrated promising reduction in 24-hour ABPM (−13.5 mm Hg vs −0.5 mm Hg; P < .0001). Substudy analysis suggests that
patients with isolated systolic hypertension, whose hypertension may be due to excessive vascular stiffness as opposed to sympathetic overactivity, may derive benefit from this approach. Further studies will need to determine which patients may benefit the most and whether there are any long-term adverse physiologic sequelae from the coupler.52

FIGURE 53-9 The ROX Coupler (ROX Medical, San Clemente, CA) creates a fixed shunt to offload arterial pressure via a sidewall puncture from the central iliac artery to the vein.

POTENTIAL LIMITATIONS OF CATHETER-INDUCED AUTONOMIC MODULATION

Although there is great promise to the techniques described earlier, it must be noted that there is also great uncertainty. In addition to the debate regarding actual therapeutic benefit, it is unknown whether alteration of this physiologic system could provoke long-term risk for untoward effects such as postural hypotension or altered vagal responses. Long-term effects on renal physiology after RDN are also unknown, although the benefits of a sustained reduction in hypertensive severity are thought to outweigh any theoretical disadvantage. Whether sympathetic imbalance can relapse either through physiologic escape mechanisms, reinnervation, or altered CNS or postganglionic signaling is also unknown. All of these possibilities will need to be kept in mind as this exciting area of medical science continues to unfold.

**MULTIPLE CHOICE QUESTIONS**

1. According the US Preventive Services Task Force (USPSTF), 15% to 30% of the population may have lower blood pressure outside of the office setting. The USPSTF recommends which of the following as the most evidence-based method of diagnosing hypertension?
   
   A. Ambulatory blood pressure monitoring (AMBP)
   
   B. Mean of 3 office-based blood pressure (OPB) measurements on different days
   
   C. Home blood pressure monitoring (HBPM)
   
   D. The mean of 2 OPB measurements taken while the patient was seated with at least 5 minutes between entry into the office and blood pressure measurement

2. Patients with resistant hypertension are defined as which of the
following?
A. Patients with systolic blood pressure ≥160 mm Hg for >1 year despite antihypertensive therapy
B. Patients whose blood pressure remains above goal despite adequate treatment with ≥3 different classes of antihypertensive agents, ideally including a diuretic
C. Patients with systolic and diastolic blood pressure ≥180/100 mm Hg for 1 year after secondary causes have been excluded
D. Patients with systolic and diastolic blood pressure ≥160/100 mm Hg for 1 year despite treatment with ≥2 different classes of antihypertensive agents

3. Among hypertensives, what is the estimated prevalence of resistant hypertension?
   A. 5% or less
   B. 5%-15%
   C. 15%-30%
   D. 30%-40%

4. Renal sympathetic denervation is thought to provide an antihypertensive effect by which of the following mechanisms?
   A. Reducing tubular reabsorption of sodium and downregulating the renin-angiotensin-aldosterone system (RAAS) via interruption of signaling from the central nervous system (CNS) to the kidneys via renal efferent nerves
   B. Disrupting the feedback loop of sympathetic signaling from the kidneys back to the CNS, which may reduce central systemic sympathetic outflow
   C. Both

5. In SYMPLICITY HTN-3, the Simplicity catheter system delivered radiofrequency energy circumferentially to thermally ablate the sympathetic renal nerve fibers. The device was intended to provide full 360° ablation by applying energy at different points in the renal arteries along the superior, inferior, anterior, and posterior arterial walls. In a substudy analysis, which percentage of patients enrolled in HTN-3 received circumferential 4-quadrant ablation of both the left and right
renal arteries?
A. 10%
B. 25%
C. 50%
D. 75%

ANSWERS

1. A
The USPSTF recommends OBP as an initial screening. However, further evaluation with ABPM or HBPM is recommended to diagnose hypertension. According to the USPSTF, there is convincing evidence that AMBP is the best method for diagnosing hypertension and considers it the gold standard. Comparisons between OBP and HBPM have been less well studied.

2. B
Patients with resistant hypertension, according to an American Heart Association consensus document, are defined as patients whose blood pressure remains above goal despite adequate treatment with 3 or more different classes of antihypertensive agents, ideally including a diuretic.

3. C
Despite advances in our understanding of resistant hypertension and in pharmacologic treatment, the prevalence of true treatment-resistant hypertension is as high as 15% to 30% of treated hypertensive patients. In patients with hypertension and coronary artery disease, however, the prevalence of resistant hypertension is more than 30% and is associated with a higher risk of all-cause death and a higher risk of cardiovascular mortality.

4. C
Ablating renal sympathetic innervation was originally thought to provide an antihypertensive effect by reducing tubular reabsorption of sodium and downregulating the RAAS via interruption of signaling from the CNS to the kidneys via renal efferent nerves. More recently, it has been recognized that
disruption of renal afferent nerves also alters the feedback loop of sympathetic signaling from the kidneys back to the CNS, which may reduce central systemic sympathetic outflow as well.

5. B

Ideally, the renal denervation procedure should achieve full 360° ablation of the renal arteries. A substudy analysis of HTN-3 suggested only up to 25% of patients received circumferential 4-quadrant denervation in both right and left renal arteries. A dose effect trend was also documented between the number of full 4-quadrant ablations achieved during renal denervation and blood pressure lowering. Although HTN-3 has been widely cited as a neutral study, many consider that HTN-3’s results were attributable to inadequate denervation due to protocol limitations and overall operator inexperience. This criticism has led to further research, development of multiple new technologies, and new randomized trials.
Peripheral Arterial Disease

Enrique A. Flores
Khusrow Niazi

INTRODUCTION

Since the time of the first edition of this book by Yeung and King in 2006, the practice of peripheral vascular medicine has evolved into a more effective and well-organized discipline. Most would agree that practice guidelines for the management of patients with peripheral arterial disease (PAD) first published in 2006, with updates in 2011 and 2013, and 2016, coupled with the rapid innovation in technology (Table 54-1), clinical research, and continuing educational programs, have provided the backbone for the remarkable progress in this field.

Table 54-1 Advances in Technology for Management of Peripheral Arterial Disease

- Drug-coated ballons and stents
- Crossing devices for occluded vessels
- Reentry devices
- Scoring balloon catheter
- Retrograde recanalization using collaterals
- CTO crossing using external ultrasound guidance
- Peripheral orbital atherectomy
- Directional atherectomy
• Phoenix atherectomy device
• Laser atherectomy
• Jetstream atherectomy

Abbreviation: CTO, chronic total occlusion.

Vascular physicians representing a variety of medical, surgical, and imaging societies continue to work tirelessly to improve the quality of care, such as by writing guidelines for the management of patients with PAD and defining medical competence in the diagnosis and treatment of PAD. Since 2005, several thousands of physicians, mostly cardiologists and vascular surgeons, have become credentialed in vascular imaging interpretation after passing the Registered Physician in Vascular Interpretation examination. The American Board of Vascular Medicine also offers certification that recognizes expertise in both general vascular medicine and endovascular specialty.

In addition, hospitals have implemented plans to protect patients and health care personnel from the frequently prolonged radiation exposure in the catheterization laboratory at the time of treatment. The PVI Registry of the American College of Cardiology further demonstrates ongoing efforts to improve care by voluntarily tracking the outcomes of peripheral vascular procedures. The ultimate common goal is to deliver a safe, effective, sustained, and valuable service to the increasing number of PAD patients.

This chapter provides interventional cardiology specialists with practical information and general guidance for the evaluation and treatment of patients with PAD of the lower extremities. In part, this chapter replicates what the Emory interventional cardiology trainees are expected to learn during their years of training and represents a compilation of knowledge extracted from practice guidelines, relevant publications, and our personal experience.

As in other areas of medicine, treatment recommendations can be controversial and open to revision informed by research. Most controversy lies in the choice of treatment and the effectiveness of a variety of stents, balloons, and medical devices currently used in patients with symptomatic PAD.

For example, perhaps the most exemplary case of practice variation among vascular specialists is the treatment of a totally occluded, 15-cm-long, moderately calcified superficial femoral artery (SFA). The SFA is one the
most commonly affected vessels in patients with PAD, and surgery is the
gold standard therapy for these long calcified lesions when symptoms persist
despite risk factor modification, supervised exercise, and drug therapy with
cilostazol. Complex SFA lesions are increasingly treated with endovascular
techniques that, although less invasive, nonetheless carry the risk of
reintervention due to restenosis of the index vessel (Fig. 54-1).

**FIGURE 54-1** A. Angiogram of a patient with critical limb ischemia and an open
wound in the right foot from a long total occlusion of the right superficial femoral
artery (SFA). B. Complex endovascular revascularization of the right SFA using a Pioneer reentry device, atherectomy, balloons, and distal filter protection. C. Suboptimal angiographic results of the right SFA from unexpected thrombotic complication. Thrombus extending into the profunda artery, treated with Angiojet and systemic anticoagulation. D. Good blood flow to the right popliteal and trifurcation vessels, with subsequent healing of the ulcer in the right foot, despite suboptimal angiographic results shown in C. E. Restenosis of the right SFA 4 months later, diagnosed by surveillance arterial duplex ultrasound and confirmed by angiogram. F and G. Right SFA restenosis treated with repeat atherectomy. H. Patent popliteal artery and trifurcation vessels (not shown). The patient remains asymptomatic with a healed ulcer in the right foot 15 months after the initial procedure. The patient undergoes periodic surveillance arterial duplex ultrasound examinations to monitor for patency and to monitor the mild SFA vessel wall dilatation after atherectomy.

If an endovascular approach is preferred over surgery, several questions remain: Should the vascular obstruction undergo debulking with atherectomy first after using a reentry device, or be treated with a drug-coated balloon or stent instead, assuming no procedure-related complications? If the decision is made to place a stent, should it be a self-expanding nitinol stent, drug-eluting stent, or a flexible stent graft?

While the AHA/ACC guidelines from 2013 indicate that endovascular intervention is recommended as the preferred revascularization option for focal femoropopliteal arterial lesions (Transatlantic Intersociety Consensus [TASC] type A),4 the 2016 guidelines do not restrict lesion characteristics.

Future editions of this chapter and the management of PAD will benefit from innovation in endovascular procedures and medical devices and the availability of new drugs and outcome data from comparative effectiveness research, but until then, we must do what we believe is best, safest, and most effective for each patient.

**INITIAL PATIENT EVALUATION**

Patients seen in a cardiology practice should be asked about symptoms of PAD and examined for the consequences of this prevalent disease, especially those who are age 50 years and older and have risk factors for atherosclerosis, such as tobacco use, diabetes, hypertension, chronic kidney disease, and hyperlipidemia. Elevated plasma homocysteine and C-reactive
protein levels are also considered risk factors for developing PAD. In addition, all adults 70 years of age and older should be evaluated for PAD (Class I recommendation from American College of Cardiology [ACC]/American Heart Association [AHA] guidelines). Since the vast majority of patients with PAD have atypical symptoms, clinicians and health care personnel caring for these patients must have a high level of suspicion for vascular disease. Lower extremity claudication with typical effort-related limb pain occurs in only 11% of patients. Observing the patient’s gait and asking family members about the patient’s walking limitations may help diagnose PAD.

The physical examination should include a detailed assessment of the femoral, popliteal, dorsalis pedis, and posterior tibial pulses as absent (0), diminished (1), normal (2), or bounding (3), keeping in mind that about 10% of the population has congenital absence of the dorsalis pedis or posterior tibial pulses. If unable to palpate pulses, find them using a handheld Doppler device. However, the presence of pulses does not exclude PAD. Document the presence or absence of bruits in the carotids, subclavian, abdominal, and femoral artery territories. Be sure to obtain blood pressure in both arms to exclude subclavian artery stenosis; a >10 mm Hg systolic pressure difference between arms should be considered abnormal and suspicious for arterial stenosis in the upper extremities.

Examine the feet for tissue loss and previous amputations, which could indicate critical limb ischemia. Patients with critical limb ischemia often have rest pain and ischemic ulcers in the toes and forefoot. On physical exam, they may also have calf atrophy, thickening of the toenails, scaly/shiny skin from loss of subcutaneous tissue, loss of hair, pallor of the affected limb, diminished or loss of pulse, and skin that is cold to the touch.

If an ischemic ulcer is present, document the location, size in centimeters, presence of infection, and severity of tissue loss. The Wagner grade of the wound/gangrene provides an in-depth description of the affected limb with critical ischemia:

- Grade 0: pre- or postulcerative lesion
- Grade 1: partial-/full-thickness ulcer
- Grade 2: probing to tendon or joint capsule or fascia
- Grade 3: deep ulcer with abscess or osteomyelitis
- Grade 4: partial foot gangrene
• Grade 5: whole foot gangrene

Serial pictures of the wound are often helpful to monitor treatment progress.

Once the clinical diagnosis of limb ischemia is established, findings in the physical examination, such as the presence or absence of sensory loss and muscle weakness, and results of the Doppler signal in the arterial and venous systems will help determine if the limb is viable, threatened, or irreversibly damaged. Reviewing all operative notes from any previous surgical or endovascular revascularization procedures will also guide management decisions.

Critical limb ischemia with chronic rest pain, nonhealing ulcer, and gangrene requires a catheter angiogram and often revascularization procedures to minimize the risk of short-term amputation. These patients can be easily identified by physical examination, and the diagnosis can be confirmed with simple physiologic studies. The ankle pressure is likely to be <50 mm Hg, and the toe pressure is likely to be <30 mm Hg.

Acute limb ischemia with sudden-onset pain in the lower extremity accompanied by paresthesia and loss of motor function constitutes a vascular emergency. Patients require intravenous heparin and immediate evaluation and treatment to determine the level of vessel obstruction and restore the blood flow to the affected limb. Endovascular treatment using catheter-based thrombolysis and thrombectomy is preferred over open surgery (Fig. 54-2).
Acute simultaneous thrombosis of the right superficial femoral artery (A) and the left popliteal artery (B) with ischemic pain in both legs after a brief interruption of warfarin given for atrial fibrillation. Blood flow was restored in both legs (C and D) after urgent endovascular treatment using distal filter protection, Angiojet, atherectomy, balloons, and systemic anticoagulation.

**BASIC TESTING**

**Ankle-Brachial Index**

Ankle-brachial index (ABI) is a simple, cost-effective, noninvasive method for diagnosing PAD in the office setting. There is no formal contraindication for this test, but some patients may have intolerable pain in their legs and arms during cuff inflation. A detailed description of equipment preparation, procedure, calculation, and interpretation has been published. Although it is standard to calculate the ABI by dividing the highest systolic tibial artery pressure by the highest systolic brachial pressure, we find it clinically helpful to calculate and report the ABI for both the dorsalis pedis and the posterior tibial arteries. The normal ABI range is 1.0 to 1.4, borderline range is 0.91 to 0.99, and abnormal range is 0.90 or less. ABI <0.50 at rest suggests multilevel PAD, whereas ABI <0.30 defines critical limb ischemia.

Current ACC/AHA guidelines recommend ABI testing in patients with
exertional leg symptoms, nonhealing wounds, age 65 years and older, or age 50 years and older with a history of smoking or diabetes. Individuals with suspected lower extremity PAD who have effort-related symptoms, diminished pulses, femoral bruit, nonhealing wounds, gangrene, or sudden-onset ischemic leg symptoms or signs of acute limb ischemia should also undergo a resting ABI measurement. According to the Appropriate Use Criteria for lower extremity testing published by the ACC/AHA in 2012, repeat ABIs in patients with known PAD is justified for new or worsening symptoms of claudication, but surveillance ABIs every 12 months or greater were deemed to have uncertain benefit.

**Postexercise Ankle Pressure and/or ABI**

Postexercise ABI using a treadmill should be considered in patients with typical or atypical claudication to diagnose PAD when the resting ABI is normal (0.91-1.4). Abnormal treadmill response is defined as a drop of the postexercise ankle pressure >20 mm Hg compared with the resting pressure. Toe-tip exercise testing with pre- and postexercise ABI could be offered as an alternative to a motorized treadmill test if the patient cannot walk or if a treadmill is not available. Unfortunately, toe-tip exercise may not provoke symptoms in patients with significant PAD, and this alternative mode of exercise test is not accepted as a Current Procedural Terminology substitute code to the standard motorized treadmill by the Centers for Medicare and Medicaid Services.

**Toe Pressure**

Toe pressure measures digital perfusion and is the numerator of the toe-brachial index (TBI) calculation, which is the ratio of toe systolic pressure to brachial systolic pressure. The normal TBI range is 0.80 to 0.90; TBI <0.7 is abnormal, and TBI <0.2 is generally associated with ischemic rest pain or ischemic ulceration. TBI measurement is most helpful in patients with ABIs greater than 1.4 due to arterial wall calcification. Toe pressures provide valuable information in patients with small vessel arterial disease and give an estimate of the wound healing potential of the feet. Toe pressure <40 mm Hg suggests low perfusion pressure insufficient for wound healing, while toe pressure >60 mm Hg makes wound healing more likely. An absolute
variation of greater than 0.15 in the ABI and/or TBI is considered significant when done serially.

**Pulse Volume Recording and Arterial Duplex Ultrasound**

Analysis of the segmental pressures and pulse volume recording (PVR) establish both the physiologic significance of PAD obstruction and the segment of disease. PVR is often used to monitor primary and secondary vessel patency after revascularization, whereas PVR and TBI are used to diagnose and assess the severity of PAD in patients with noncompressible pedal pulses. Noncompressible vessels due to calcification generally have ABIs greater than 1.4 and are frequently encountered in patients with diabetes and chronic renal disease and the elderly. If ankle pressure is elevated due to vessel calcification, the amplitude of the resting waveform PVR should be compared with the PVR after exercise; the severity of the amplitude reduction provides valuable information regarding the significance of the PAD. However, in our opinion, analysis of the pulsed wave Doppler waveforms is more reliable than the PVR.

In addition to ABI, toe pressures, and TBI, interventional cardiologists who perform endovascular peripheral procedures should become proficient in the indication for and interpretation of duplex ultrasound technology. This portable, noninvasive imaging technology provides both anatomic and physiologic information about the arterial and venous vasculature. Duplex ultrasound is used in the initial diagnosis of PAD and is the preferred surveillance imaging modality for patency after revascularization procedures. Advantages of duplex ultrasound compared with magnetic resonance angiography (MRA) and computed tomographic angiography (CTA) for initial diagnosis and postrevascularization follow-up include the convenience and lower cost for the patient and the ease of the examination with no need for contrast. However, the quality of the duplex ultrasound examination is highly operator dependent.

**Postrevascularization Surveillance**

Patients undergoing lower extremity revascularization with endovascular techniques require a baseline ABI and a duplex ultrasound examination of the treated vascular segment within 1 month of the procedure. In addition to the
baseline study, we routinely repeat the ABIs and duplex ultrasound examinations at 3 and 6 months after the endovascular intervention to monitor for patency of the target vessel site. Patients are at highest risk for restenosis during the first 6 months following the procedure, and symptoms of recurrent disabling claudication may occur too late, after (re)occlusion of the index lesion. Repeat revascularization of a totally occluded artery from restenosis is expected to be difficult and time consuming, while also exposing both the patient and the operators to excessive direct radiation. Early detection of physiologic (ABI/PVR) or anatomic (duplex ultrasound) signs of significant restenosis will permit planning for reintervention, before progression to a total occlusion.

Patients previously treated for critical limb ischemia are especially vulnerable for restenosis and atherosclerosis progression. Therefore, this high-risk cohort requires periodic, at least semiannual, clinical and physiologic/imaging evaluation by an integrated team of vascular care professionals, including podiatrists, with the ultimate goal of preventing recurrent ischemic pain, skin ulceration, and amputation.

**ADVANCED TESTING**

**CTA and MRA**

New multidetector technology has made CTA a reasonable alternative to catheter angiography in detecting the location and severity of stenosis in PAD patients. However, MRA with gadolinium, which provides pristine angiographic-like images without radiation and without the need for iodine contrast, received a stronger recommendation as a diagnostic method in the 2013 ACC/AHA guidelines (Class I vs Class IIb). The 2016 guidelines give Duplex ultrasound, CTA, and MRA the same Class I recommendation for the detection of the location and severity of PAD stenosis. Table 54-2 lists the advantages and disadvantages of both imaging tests.

Table 54-2 **Advantages and Disadvantages of Magnetic Resonance Angiography (MRA) and Computed Tomography Angiography (CTA) in the Diagnosis of Peripheral Arterial Disease**

An underrecognized benefit of both is the ease with which these images can be shown and explained to the patient as well as the practicality of discussing angiographic findings and treatment options at the time of the outpatient follow-up office visit. With the development of these 2 technologies, the need for conventional diagnostic lower extremity angiograms has decreased, thus lessening the risk associated with invasive procedures. In our practice, we prefer MRA over a diagnostic catheter angiogram as the initial diagnostic procedure (Fig. 54-3).
Symptomatic patients with poor arterial perfusion who experience lifestyle-limiting or disabling claudication, ischemic pain at rest, or ischemic tissue loss benefit from a digital subtraction catheter angiogram, with an aim of correcting the vascular obstruction. Not all symptomatic patients with PAD need a complete aortogram with bilateral lower extremity runoff, and some require a more selective angiogram to limit the amount of contrast administered.

The choice of arteries imaged (abdominal aorta, right/left iliac, femoral,
popliteal, tibioperoneal trunk, anterior tibial, posterior tibial, and peroneal arteries) and the vascular access site (femoral, brachial, and radial) depend not only on findings from the history and physical examination but also on the patient’s comorbidities and previous revascularization procedures. Variables such as renal function, the intended treatment (endovascular vs open surgical revascularization), and heart failure are a few of the many factors that influence planning the catheter angiogram in patients with symptomatic PAD. A diagnostic abdominal aortogram with a bilateral lower extremity runoff generally requires the use of approximately 100 to 150 mL of contrast—20 mL administered for the abdominal angiogram, 30 mL for the iliac angiograms in 2 views, and 70 to 100 mL for the lower extremity runoff. A selective single lower extremity angiogram can be done with less than 50 mL of diluted contrast.

**Catheter Angiogram and Renal Disease**

Renal function must be assessed with a serum creatinine in all patients undergoing contrast exposure before scheduling an angiogram. Renal insufficiency should alert the interventionalist to carefully reevaluate the need for a test using contrast and to review and adjust the patient’s medications before the catheter angiogram. Administer intravenous fluids before contrast exposure to minimize risk of renal injury, and monitor renal function after the endovascular procedure. A duplex ultrasound of the abdominal aorta, iliac arteries, and arteries of the lower extremities before the angiogram could help better plan the diagnostic and endovascular revascularization procedures, such as limiting diluted contrast exclusively to the symptomatic vascular segment. A reliable, high-quality, noninvasive vascular laboratory with both imaging and physiologic testing is of utmost importance for the optimal management of patients with PAD and especially those affected with renal disease (Figs. 54-4 and 54-5).
The arterial duplex ultrasound of this patient with disabling claudication and severe chronic kidney disease predicted the angiographic findings and facilitated the revascularization procedure. The arterial duplex ultrasound shows a totally occluded proximal superficial femoral artery (SFA) with a “nubbin” at the ostium and a low echogenicity plaque in the most proximal SFA segment (A and B). The low echogenicity suggests a soft plaque with a high lipid content at the proximal end of the SFA occlusion. Poor Doppler signal in the proximal right SFA confirms absence of flow (B). The mid SFA is reconstituted by a collateral vessel (C). The distal end of the occluded SFA at the site of the collateral vessel has strong echogenicity, likely from a calcified and dense “hard” fibrous plaque (C and D). The result of the arterial duplex ultrasound facilitated the planning and performance of the right SFA revascularization procedure, as seen in Figure 54-5. CFA, common femoral artery.
FIGURE 54-5 The occluded right superficial femoral artery (SFA) by duplex ultrasound, with a “nubbin” and a proximal soft and hard distal plaque of the patient in Figure 54-4 was confirmed by angiogram (A). The soft plaque in the proximal end of the occluded right SFA was easily crossed with a Viance catheter without dissection (B), and the “hard” fibrous plaque at the distal end of the SFA occlusion was crossed with a 0.035-inch stiff Terumo straight glide wire, advanced through an angled KMP catheter (C), with excellent angiographic results and no complications (D). The crossing wire used with the Viance catheter first entered the collateral vessel in the mid SFA. This reference point in the mid SFA, also seen in the arterial duplex ultrasound (Fig. 54-4, C and D), facilitated the reentry into the distal SFA through the dense fibrous cap by simply pointing the KMP catheter and wire away from the collateral vessel and into the true SFA lumen.

Catheter Angiogram and Heart Disease

The presence of heart failure could also influence the angiographic technique, because left ventricular dysfunction limits hydration with intravenous fluids before and after contrast exposure and also because the patient may not be able to lay flat during and after the procedure. If feasible, a radial or brachial artery access approach may be preferable in patients with heart failure.

Heart disease is prevalent in patients with PAD and should not be
overlooked. It is good practice to exclude ischemic heart disease and heart failure before performing a diagnostic angiogram and treatment of the lower extremities. There is high coexistence of coronary artery disease and cerebrovascular disease with PAD. Knowing the left ventricular function and anticipating the tolerance to intravenous fluids can prevent heart failure decompensation. Knowledge of left ventricular function is also needed before prescribing cilostazol for symptomatic arterial disease, because heart failure with reduced ventricular systolic function is a contraindication for cilostazol use.

Catheter Angiogram and Chronic Anticoagulation

Patients with PAD who are on anticoagulation medications for chronic atrial fibrillation or for mechanical heart valves with a vitamin K antagonist are specially challenging candidates for catheter angiogram, mainly due to the potential risk of hemorrhage and arterial thromboembolism, even during heparin bridging. A careful discussion with the patient during the consent process, weighing the risks and benefits of the procedure, is needed, and an effort must be made to do the angiogram and the endovascular treatment during the same session. Noninvasive imaging studies, preferably with MRA, are of great value for planning the vascular treatment in patients with preserved renal function and no metal devices other than the mechanical valve, although new metal cardiac devices such as implantable cardioverter-defibrillators and pacemakers are now felt to be safe for magnetic resonance imaging (MRI).\textsuperscript{15} Duplex arterial ultrasound performed before the angiogram is a very good alternative to other imaging modalities, since it has the advantages of no contrast, no radiation, no contraindication with metal hardware, and lower cost.

Staged Catheter Angiogram

A limited catheter angiogram and endovascular revascularization are likely to be scheduled on the same day for symptomatic patients with focal disease localized to 1 extremity as indicated by the clinical and noninvasive vascular examination. This same combined approach, but on different days, is common in staged procedures, with the angiogram and endovascular revascularization performed first to correct the inflow disease (ie, iliac
stenosis), followed by treatment of the outflow (femoropopliteal artery stenosis) on a separate day. Treatment of the outflow segment may not be needed if the patient has complete or near-complete resolution of the symptoms of vascular insufficiency after treatment of the inflow vascular segment.

Staged interventions have the advantage of limiting the amount of contrast and radiation exposure to the patient. New hand-held injection devices, such as the AVERT system (Osprey Medical, Minnetonka, MN), reduce the amount of contrast injected during angiographic procedures without sacrificing the quality of the image and may help protect patients from contrast-induced nephropathy. At Emory University, we routinely use an 8-mL syringe with a manifold and use diluted (50:50) contrast to minimize the risk of kidney injury.

**Catheter Angiogram and Choice of Arterial Access**

The angiographic technique is also determined by the presence or absence of femoral arterial access and by prior vascular interventions with stents and surgical grafts. The radial or brachial artery approach is often used in patients with severely stenosed or occluded common femoral or iliac arteries (Fig. 54-6), severe disease, or total occlusion of the distal abdominal aorta as well as in patients who have undergone prior vascular bypasses. Radial artery access is also convenient when patients are unable to lay flat or use the urinal during strict postprocedure bed rest, since this access allows patients to get up sooner than the femoral access approach and with lower risk of bleeding complications. However, arm access should be avoided in patients with arteriovenous shunts for hemodialysis.
Successful endovascular intervention of a 100% ostial left common iliac artery (CIA) using the left radial artery access approach for treatment of rest foot pain and abnormal physiologic studies with ankle-brachial index (ABI) in the critical limb ischemia range at 0.17 and ankle pressure of 32 mm Hg (A-D). Aortoiliac angiogram from the right common femoral artery (CFA) shows stents in both CIAs with occluded left iliac artery at the ostium (B). Crossing of the 100% left iliac artery with a 4-Fr vertebral catheter along with an exchanged length 0.035-inch straight stiff Terumo glide wire, advanced from the left radial artery (C). The occluded left CIA stents were treated with balloon angioplasty and a new self-expanding stent in the left external iliac artery (not shown). Repeat physiologic studies 2 weeks after treatment.
of the inflow segment revealed significant improvement of the ABI from 0.17 to 0.55; however, the patient continued to have disabling pain in the left foot and the decision was made to treat the outflow stenosis in the left superficial femoral artery (SFA) using the right CFA and the contralateral access approach (F and G). Staged endovascular revascularization of the left SFA with directional atherectomy and adjunctive balloon angioplasty resulted in resolution of the pain in the left leg and further improvement of the physiologic studies (H). Notice the improvement of the pulse volume recording (PVR) waveforms and photoplethysmography (PPG) of the left toe as well (H).

The left radial artery side is a better option than the right side due to the closer proximity to the distal abdominal aorta. A 4 Fr × 135 cm long pigtail catheter is available for a diagnostic lower extremity catheter angiogram from the left radial artery. The radial access allows not only a complete diagnostic angiogram, from the abdominal aorta down into the distal vessels, but also allows moving ahead with the endovascular treatment on the same day, as long as the equipment used is compatible with a 6-Fr sheath system and the needed equipment reaches the arterial site to be treated. If a 7-Fr sheath is needed, brachial or femoral artery access is preferable.

VESEL CHARACTERISTICS AND LESION DEFINITIONS

The descriptions and classifications of lesion and vessel characteristics that we will use for the remainder of the chapter are as follows.

**Stenosis Severity**

<table>
<thead>
<tr>
<th>None</th>
<th>Mild</th>
<th>Moderate</th>
<th>Severe</th>
<th>Occluded</th>
</tr>
</thead>
<tbody>
<tr>
<td>&lt;50%</td>
<td>50%-69%</td>
<td>70%-99%</td>
<td>100%</td>
<td></td>
</tr>
</tbody>
</table>

**Translesional Gradient** (pullback gradient performed with a ≤4-Fr small lumen catheter for ambiguous 50%-70% range artery stenosis)
Significant $>$15 mm Hg
Nonsignificant $\leq$15 mm Hg

**Degree of Lesion Calcification** (criteria used at Emory University based on fluoroscopy at the lesion site)

Focal $\leq$1 cm in length, on 1 side of vessel wall
Mild 1-3 cm in length present on 1 or both sides of the vessel wall and not continuous
Moderate 3-5 cm on 1 or both sides and not continuous
Severe Continuous on both sides of vessel wall and/or $>$5 cm in length

**Lesion Length**

Focal $\leq$1 cm
Short $>$1 to $\leq$5 cm
Intermediate $>$5 to $\leq$10 cm
Long $>$10 cm

**Angiographic Outcome After Endovascular Intervention**

Primary patency: patent target lesion with no restenosis after intervention
Primary assisted patency: patent target lesion following reintervention for restenosis
Secondary patency: patent target lesion following reintervention of reocclusion

(In our opinion, this division is confusing, and lesions that restenose or occlude should be considered as restenosis.)
DECISION FOR REVASCULARIZATION

Endovascular or open surgical revascularization is justified for patients who experience lifestyle-limiting or disabling claudication despite adequate medical treatment with supervised exercise program and medications, as long as there is a reasonable likelihood of symptomatic improvement with a favorable risk-benefit ratio. Intervention is mandatory in patients with acute limb ischemia and critical limb ischemia for limb salvage.

An exemption to the symptom-driven rule should be considered in patients with severe but asymptomatic (or minimally symptomatic) iliac artery stenosis, because revascularization with a stent has a favorable risk-benefit ratio and progression to total occlusion could complicate treatment. Revascularization for asymptomatic but severe PAD below the inguinal ligament is currently debatable and should be individualized for each patient.

Patients with symptomatic PAD in the critical limb ischemia group (Rutherford categories 4, 5, and 6) should undergo prompt revascularization to avoid amputation or to convert a possible major amputation to a limited amputation. In acute limb ischemia, revascularization treatment should be immediate.

We believe that the majority of patients with symptomatic occlusive disease of the arteries of the lower extremities can be successfully treated with endovascular techniques. Table 54-3 denotes a few exceptions for which open surgical revascularization could be considered as the first line of treatment. However, none of these situations constitute an absolute contraindication to endovascular therapy, and the final decision is based on operator expertise and patient preference. It is always a good practice for the interventional cardiologist to review the patient’s clinical history and angiographic findings with a vascular surgeon, especially in difficult cases, with the aim of achieving consensus on the best revascularization treatment approach.

Table 54-3 Possible Indications for Open Surgical Revascularization as the First Line of Treatment

- 100% bilateral common iliac artery occlusion with severe calcification, nonfocal, and acceptable surgical risk
• Severe unilateral or bilateral common iliac artery stenosis with infrarenal AAA
• 100% occlusion of the CFA with at least moderate to severe calcification
• 100% occlusion of the SFA more than 15 cm long and severe calcification
• 100% occlusion of the popliteal artery greater than 5 cm in length with severe calcification

Abbreviations: AAA, abdominal aortic aneurysm; CFA, common femoral artery; SFA, superficial femoral artery.

GENERAL PROTOCOL

The protocol used to treat any vascular territory should always start with detailed advance planning, including a thorough review of the clinical history and physical examination, results of previous imaging studies, and laboratory data. Next, the equipment likely to be needed must be procured before initiating the case. There is no excuse for discovering during the diagnostic or endovascular procedure that the equipment needed is not available. The interventionalist should also be familiar with the different sheath sizes and lengths and the compatibility with the various balloons and stents. Sheath length depends on the location of the lesion: a longer sheath (25-30 cm) is needed for common iliac artery intervention from the groin, and a shorter sheath (6 cm) for proximal external iliac artery intervention also from the groin. Sheath size is chosen according to the balloon or stent diameter being used. For example, a 7 mm diameter × 22 mm long iCast-covered stent (Atrium Medical, Hudson, NH) requires a 7-Fr sheath, whereas a 5 mm diameter × 22 mm long iCast-covered stent requires a 6-Fr sheath. The 5-mm stent advanced through a 6-Fr sheath could be postdilated to any size up to 12 mm, but with some foreshortening, so understanding the compatibility of different balloons, stents, and devices with the different sheath sizes is of utmost importance.

At the conclusion of any procedure, dictate a complete report including the date of procedure, referring physician, operator(s), indications, description of procedure, complexity, complications, findings, recommendations, and type and amount of contrast used and radiation exposure. One format that we follow is shown in Figure 54-7.
COMMON AND EXTERNAL ILIAC ARTERY STENOSIS: INFLOW DISEASE

Clinical Presentation

Obstructive disease in the vascular segment between the distal abdominal aorta and the common femoral artery (CFA) results in buttock, hip, thigh, calf, and/or foot pain. This anatomic segment of obstruction is also called inflow disease. Inflow PAD is confirmed by diminished or absent pulses in the femoral arteries and suspected by the presence of bruits. Buttock and thigh claudication often progress to calf claudication upon ambulation in patients with inflow disease. PAD with inflow stenosis could be misdiagnosed as osteoarthritis of the spine or hip. Vasculogenic erectile dysfunction may occur in cases of inflow stenosis, especially when the disease is bilateral and proximal to the origins of the internal iliac arteries.

Vascular Testing

- Abnormal resting or postexercise ABIs.
- Abnormal PVR with amplitude reduction and monophasic waveform
morphology in the entire side of the affected leg.

- Duplex ultrasound with occlusive plaque in the iliac artery and color aliasing, monophasic waveform with spectral broadening, and increased peak systolic velocity >100% relative to the adjacent proximal segment. Increased acceleration time of the spectral Doppler flow velocity waveform in the CFA.

### 2013 ACC/AHA Practice Guidelines (Class I)

- Endovascular procedures are indicated for individuals with a vocational or lifestyle-limiting disability due to intermittent claudication when clinical features suggest a reasonable likelihood of symptomatic improvement with endovascular intervention and (1) there has been an inadequate response to exercise or pharmacologic therapy and/or (2) there is a very favorable risk-benefit ratio (eg, focal aortoiliac occlusive disease). (Class I, Level of Evidence: A)
- Endovascular intervention is preferred for TASC type A iliac single stenosis ≤3 cm. (Class I, Level of Evidence: B)
- Provisional stent placement in the iliac arteries can be used as salvage therapy for suboptimal or failed result from balloon dilatation (eg, persistent translesional gradient, residual diameter stenosis >50%, or flow-limiting dissection). (Class I, Level of Evidence: B)
- Stenting is effective as primary therapy for common iliac artery stenosis and occlusions (Class I, Level of Evidence B) and also for external iliac artery stenosis or occlusions (Class I, Level of Evidence: C).

### Emory Protocols for Endovascular Treatment

Most patients with symptomatic common and external iliac artery stenosis are treated using endovascular techniques unless: (1) there is an infrarenal abdominal aortic aneurysm requiring repair; (2) there is a 100% flush occlusion with no “beak” or “nubbin” at the ostium of the common iliac artery and with severe calcification and intermediate-length (>5 cm) occlusion; or (3) there is a long occlusion (>10 cm) with severe calcification.

The decision to use endovascular techniques versus open surgery should be made according to operator expertise and patient characteristics and preference after a detailed discussion of the indications, benefits and
limitations, alternative treatment, and potential complications related to each procedure. **Figure 54-8** shows a long, moderately calcified, left common iliac artery flush occlusion at the ostium treated successfully with contemporary endovascular techniques, including a reentry device. This complex lesion would have normally required open surgery with a right-to-left, femoral-to-femoral bypass graft and a stent to the ostium of the right common iliac artery.

**FIGURE 54-8** Angiogram of a long, symptomatic, moderately calcified left common iliac artery occlusion with a flush occlusion at the ostium (A), successfully treated with contemporary endovascular technique, including a Pioneer reentry device (B and C).

**Protocol for Iliac Arteries**

Once the equipment is chosen and readily available to the catheterization laboratory team, the protocol continues by accessing the CFA ipsilateral to the lesion, using a micropuncture 21G needle with a 30-cm-long micropuncture sheath from Vascular Solutions (Minneapolis, MN). The micropuncture wire is used to cross the stenosis in the ipsilateral common iliac artery and/or proximal external iliac artery. After the micropuncture sheath is passed over the wire, the micropuncture wire and dilator are removed, and a 0.035-inch preferably stiff wire (eg, Supracore, Abbott Vascular, Temecula, CA) is passed through the sheath into the abdominal
aorta. The micropuncture sheath is then replaced by a 6- or 7-Fr, 25- to 30-cm-long sheath that crosses the lesion. The 0.035-inch wire is then removed and replaced with a 0.018 inch × 300 cm long Steelcore wire (Abbott). The sheath is retrieved back into the distal ipsilateral iliac artery below the lesion. The treatment of a mid to distal external iliac artery requires a different approach, which is discussed in the protocol variation section below. Intervention in the ipsilateral mid to distal external iliac artery is not advisable, because the sheath, once repositioned at the distal external iliac artery, cannot be too close to the lesion. The indication for using alternative sheath sizes is also discussed in the protocol variations section.

Use of sheath with radiopaque markers allows the tip to be visualized with fluoroscopy, although the metal marker is a few millimeters proximal to the true tip of the sheath. This is of utmost relevance when positioning the balloon or stent at the stenosis site and reinforces the need to leave the metal marker at least 2 cm proximal to the device edge to prevent deploying part of the balloon/stent inside the sheath.

The standard anticoagulation regimen used in peripheral intervention is heparin. The activated clotting time (ACT) should be monitored at regular intervals to keep it within the 200- to 250-second range. A digital subtraction angiogram of the iliac artery stenosis in 2 views must be obtained before the intervention, after which the digital roadmap, bony landmarks, or measuring tape can be used for precise balloon and stent placement.

After sheath placement and wire positioning, proceed with balloon predilation of the common or external iliac artery stenosis to a near-nominal pressure with a balloon size 1 mm in diameter smaller than the reference vessel diameter. Next, exchange the predilation balloon for a balloon-expanded stent with a 1:1 stent-to-vessel size ratio if the stenosis is at the ostium of the common iliac artery, while monitoring for lower abdominal pain. Stop the balloon inflation if abdominal or flank pain occurs to minimize the risk of vessel dissection or rupture. Precise placement of the balloon-expandable stent at the ostium of the common iliac artery, without any prolapse of the stent into the aorta, may allow the future use of the contralateral access approach. During treatment of the ostium of a unilateral common iliac artery, it is good practice to have readily available access on the contralateral femoral side in case there is need for simultaneous “kissing” balloon inflations to prevent plaque shift to the opposite common iliac artery.

A self-expanding nitinol stent is recommended after a balloon predilation
if the iliac stenosis is 2 cm away from the aortoiliac ostium or if it involves the external iliac artery, since these vascular segments require greater flexibility; the size of the self-expanding stent should be 1 mm in diameter larger than the reference iliac vessel diameter. Always do a poststent balloon dilatation with a 1:1 balloon-to-vessel size, at a nominal or slightly above nominal pressure as tolerated, monitoring for lower abdominal pain. For poststent dilatation, always position the balloon inside the self-expanding stent to avoid edge dissections.

After the destination therapy with balloons, stents, or both has been completed, repeat the angiogram of the iliac arteries using the digital subtraction angiography technique with diluted contrast and low magnification. Before moving the patient out of the catheterization laboratory, obtain a final ACT and record the amount of contrast used and the radiation exposure to the patient.

**Protocol Variations**

**Vascular Access Site**

- Use left brachial access if needed for a 7-Fr sheath, or left radial artery access if a 6-Fr sheath can be used, to treat severe obstructive disease of the CFA ipsilateral to the common iliac artery stenosis or if the “nubbin” of the occluded side of the common iliac artery is in the cephalic (proximal) end.
- Use left brachial or left radial access if simultaneous balloon inflation is needed in a nonsignificant contralateral ostial common iliac artery to avoid plaque shift at the time of the stent placement, especially if there is significant stenosis of the contralateral external iliac artery severe enough to require stenting. If no significant disease exists in the contralateral external iliac, use a bilateral femoral access approach to do simultaneous balloon inflation in the nonsignificant ostial common iliac artery.
- Use left brachial or, preferably, radial access if there is a need to intervene in the common or external iliac artery of a patient with a patent femoral-to-femoral bypass.
- Use left brachial or radial access when intervening in the proximal external iliac or common iliac arteries, and when extreme tortuosity distal
to the iliac artery stenosis is present.

- Right brachial artery access is rarely used for lower extremity vascular interventions and only if the left side brachial access is not possible. The right arm is a longer distance to the aortoiliac bifurcation and has a more tortuous trajectory. Access from the right arm could also increase the risk of transient ischemic attack and CVA due to excessive manipulation in the innominate artery segment with the equipment required for lower extremity intervention. In our opinion, right arm access should be avoided.

- Radial or brachial artery access may be needed when distal external iliac artery stenosis coexists with severe stenosis in the path to the contralateral approach, unless the decision is to perform bilateral iliac artery revascularization.

- For brachial or radial approach, give the radial “cocktail” (see below) after inserting a 4 Fr × 10 cm long sheath, and then advance a 4 Fr × 100 cm long JR4 diagnostic catheter (or internal mammary artery) over a stiff 0.035 inch × 300 cm long wire (Supracore) into the descending abdominal aorta and leave the tip of the diagnostic catheter just above the aortic bifurcation. Next, exchange the 4-Fr diagnostic catheter for a 6 Fr × 90 cm long sheath over a 0.035 inch × 300 cm long stiff (Supracore) wire. The tip of the flexor sheath can be manually shaped 1 to 3 cm away from the end to a 45° bend, with the purpose of aiming to the affected iliac artery. Cross the common or external iliac artery stenosis with the same Supracore (or 0.035-inch standard angled glide wire) and a 4 Fr × 100 cm or 125 cm multipurpose (MP) catheter, advanced through the flexor sheath. Then, remove the wire and inject contrast through the MP past the stenosis to confirm the intraluminal placement of the catheter. Balloon angioplasty and stenting with self-expanding stent can proceed once intraluminal placement of the wire has been confirmed.

- Administer the radial “cocktail” consisting of 3000 U of intravenous heparin mixed with 200 μg of nitroglycerin and 2.5 mg of verapamil intra-arterially, immediately after placing the 4-Fr sheath in the brachial or radial artery, to minimize the risk of arterial spasm and thrombosis.

- Use the contralateral femoral approach when the common iliac artery stenosis is in the distal segment and/or extends into the external iliac. The common iliac artery stenosis must be at least 5 cm away from the aortoiliac bifurcation to avoid prolapse of the sheath and wire back into the aorta during the intervention. The radiopaque marker of the sheath
should be more than 3 cm away from the aortoiliac bifurcation to minimize the risk of sheath prolapse. Remember to keep the marker of the sheath several millimeters proximal to the stenotic segment, as the tip of the sheath is a few millimeters distal to the marker. If there is any doubt about sheath stability, use the radial or ipsilateral access.

**Vascular Access Side: Bilateral Versus Unilateral Femoral Access**

- Use bilateral femoral access with a 6 or 7 Fr × 25 to 30 cm long sheath with radiopaque markers at the tip when placing kissing balloon-expandable stents in both ostial common iliac arteries. Place one 0.018 inch × 300 cm long Steelcore wire (or 0.035-inch wire) across each iliac artery, and leave the tip of the wires in the thoracic aorta when doing intervention from the common femoral approach. Balloon-expandable stents must protrude approximately 1 to 2 mm into the aorta when using the kissing technique in patients with severe bilateral aortoiliac disease. Unfortunately, kissing common iliac stents will likely preclude the use of the contralateral approach if needed in the future.
- Use bilateral femoral arterial access for treatment of an ostial/proximal common iliac artery stenosis with a stent when anticipating the need for simultaneous contralateral balloon inflation to prevent plaque shift to the nondiseased opposite iliac side. Combination of ipsilateral femoral and left radial access would be another option.

**Larger Sheath/Wires Sizes**

- Use a 7 Fr × 25 to 30 cm sheath with a radiopaque marker tip and preferably 0.035-inch wires if iCast stents will be used in a calcified tortuous vessel, if Viabahn (Gore Medical, Flagstaff, AZ) stents will be used to treat iliac artery aneurysms, or if there is an increased risk of vessel perforation. Avoid covering the take-off of the internal iliac artery, unless performing bailout for vessel perforation.
- Use a 7-Fr sheath from the brachial artery if balloon-expandable stents ≥7 mm in diameter are needed and the left brachial artery is at least 3 mm in diameter by ultrasound. All self-expandable stents up to 10 mm in
diameter go through a 6-Fr sheath. Some manufacturers even make self expanding stents (up to) size 12 (mm) and 14 mm diameter for 6-Fr sheath. As of 2017, several medical device companies have self-expanding stents up to 10 mm that go through 5-Fr sheath (Zilver, Cook Medical, among others).

• If unable to deliver a stent due to heavy calcification and/or tortuosity, use a 0.035 inch × 300 cm long stiff Supracore wire instead of the 0.018-inch Steelcore wire to straighten the iliac artery.

Covered Stents

• Use balloon-expandable iCast-covered stents in the ostial, proximal, and mid common iliac artery locations when there is an increased risk for vessel perforation, such as calcification and increased tortuosity of the diseased segment. iCast-covered stents can also be used as a bailout in the case of vessel perforation.

• Use a Viabahn self-expanding covered stent in the common iliac artery location as long as the lesion is not ostial and the take-off of the internal iliac artery is not covered by the Viabahn stent. This covered stent can also be used in the external iliac artery above the inguinal ligament.

Balloon Angioplasty Alone (No Stenting)

• Use balloon angioplasty as a destination therapy if good angiographic results are shown at the aortoiliac segment after simultaneous bilateral balloon inflations using the kissing technique or after unilateral iliac balloon dilatation. Measure the pressure gradient across the balloon-treated area; a good angiographic result with ≤15 mm Hg translesional pressure gradient after balloon dilatation could eliminate the need for stents.

• Consider using a Chocolate balloon (QT Vascular, Singapore) if the intention is to treat with balloon-only therapy and if the vessel diameter is 5 mm or smaller, since the largest balloon diameter available as of 2017 is 6 mm, and our own experience indicates that these balloons should be sized 1 mm larger than the reference vessel diameter. Chocolate balloons may have the advantage of decreasing the risk of vessel dissection compared with regular balloons.
**Total Occlusion of the Common or External Iliac**

- Use the ipsilateral CFA approach using a 6 or 7 Fr × 25 cm sheath with a radiopaque marker if there is a favorable “beak” at the distal iliac artery occlusion site.
- Use the left brachial access with the antegrade approach and a 6 or 7 Fr × 90 cm sheath if the beak of the iliac occlusion is at the proximal occlusion site and if there are no signs of significant left subclavian artery stenosis. Puncture the brachial artery under ultrasound visualization. Alternatively, use the left radial access with the 6 Fr × 90 cm long sheath in patients less than 5 feet, 8 inches tall.
- Advance the Viance catheter (Medtronic, Dublin, Ireland) through the 6- or 7-Fr sheath with a 0.014-inch Grand Slam wire (Abbott) that has been given a 45° bend 1 cm away from the tip; advance the wire to engage the “beak.”
- Carefully advance the Viance catheter over the wire until it engages the iliac artery occlusion. Pull the Grand Slam wire back 1 cm into the Viance and rapidly spin the Viance catheter in different directions with simultaneous gentle forward pressure. When the Viance crosses the occlusion, stop spinning to see if the 0.014-inch Grand Slam wire comes out without any resistance and its tip moves freely. The free motion of the wire tip suggests an intraluminal position. Keep advancing the wire into the distal aorta or into the femoral artery if access is from the arm, twisting the wire and confirming free motion of the tip. Advance the Viance over the wire, and then remove the wire. Inject diluted 50% contrast using a 3-mL syringe through the Viance catheter to confirm the intraluminal position. Once confirmed, pass the Grand Slam wire back in again and position it distal to the lesion. Remove the Viance and dilate the occlusion with an undersized balloon. If the tip of the Viance catheter does not enter the true lumen, pull the Viance back approximately 1 to 2 cm into the occlusion; then take a 0.014-inch Confianza Pro (Abbott) 300-cm wire, make a 30° bend 2 to 3 mm away from the tip, and use this wire to probe the occlusion to see if it can reenter the true lumen.
- Use the Viance Crossing catheter inside a 0.035 inch × 135 cm angled Quick Cross catheter (Spectranetics, Colorado Springs, CO) when more support is needed to cross the iliac artery. Usually, the Viance Crossing catheter is used without extra support from the Quick Cross catheter.
Always confirm the intravascular location of the wire by injecting contrast before dilating or passing larger devices. Then, proceed with predilation of the stenosis with a balloon, followed by stenting. Remember to avoid kissing stents if possible and to deploy the balloon-expandable stent precisely at the site of the stenosis. The extra effort at achieving a precise stent deployment may allow future use of the contralateral access if needed.

As an alternative approach to the Viance catheter at crossing total occlusions, a 0.035 inch × 135 cm Quick Cross, Navicross (Terumo, Somerset, NJ), CX1 (Cook Medical), or Slip (Cook Medical) catheter along with a 0.035-inch angled or straight glide wire can be used.

**Use of Reentry Devices in the Common Iliac Artery**

Consider using a Pioneer catheter (Volcano, San Diego, CA) with direct intravascular ultrasound visualization if, during the attempt to cross the occluded common iliac artery from the femoral approach, the wire and crossing catheter remain in the subintimal vascular space.

Before using the Pioneer catheter, a 0.014 inch × 180 cm Thunder wire (Medtronic) must be located in the subintimal space and the wire tip positioned a few millimeters beyond the occlusion.

The entire subintimal track of the wire should first be predilated using a 3-mm balloon to allow the passage of the 6-Fr Pioneer catheter (see Fig. 54-8). The monorail segment of the Pioneer catheter will then be loaded onto the Thunder wire. A 0.014-inch Cougar wire (Medtronic) will be loaded in the needle port of the Pioneer catheter after giving a 45° bend to its tip. After entry of the needle into the true lumen, the 0.014-inch Cougar wire is passed through the needle into the distal vessel while visualizing the free movement of the tip.

Following reentry of the 0.014-inch Cougar wire with the Pioneer catheter, the intraluminal position of the wire must be confirmed with contrast (mandatory). Then, predilate with a 0.014-inch wire compatible with 3.0 × 20 mm coronary balloon at the Pioneer needle reentry site. Do a second balloon dilatation at the same distal reentry site using a 0.018- or 0.035-inch balloon, but with a diameter 1 mm smaller than the reference vessel size, and cover the entire lesion length. The second balloon dilatation across the lesion in the subintimal space is always needed to facilitate the
passage and deployment of the stent(s). Exchange the 0.014-inch wire for a 0.018 inch × 300 cm long Steelcore wire before stenting the diseased iliac artery segment.

**Surveillance After Endovascular Revascularization of the Iliac Arteries (Including Aortoiliac Segment)**

All patients who have undergone revascularization of the iliac arteries with balloon angioplasty, stent, or both should undergo periodic outpatient visits to monitor for symptoms of PAD, presence of femoral pulses, ABIs, and surveillance duplex ultrasound as follows:

- Duplex ultrasound of the treated vascular segment and ABI within 1 month of the initial procedure (baseline surveillance study) and with any subsequent new or worsening lower extremity symptoms.\(^\text{12}\)
- Duplex ultrasound and ABI annually thereafter. During the first year, a 6-month study is also advisable.

**COMMON FEMORAL ARTERY STENOSIS: OUTFLOW DISEASE**

**Clinical Presentation**

Since claudication is generally manifested in the segment distal to the site of the vascular stenosis or occlusion, it is expected that hemodynamically significant CFA disease will result in symptoms felt in the thigh and calf. Claudication is often accompanied with femoral bruits and diminished or absent pulses in the femoral, popliteal, and infrapopliteal arteries (trifurcation vessels). Severe CFA disease may present with critical limb ischemia due to compromised flow in the SFA and the profunda arteries.

Outflow disease is PAD in the vascular territory beginning at the CFA below the inguinal ligament and extending down into the popliteal arteries. Occasionally, revascularization of the inflow segment is sufficient to ameliorate claudication and critical limb ischemia (CLI). Patients with CLI often need additional revascularization procedures more distally, in the
arteries of the outflow segment, to improve blood flow to the foot and correct the low-perfusion state.\textsuperscript{17}

**Vascular Testing**

- Abnormal resting or postexercise ABIs.
- Abnormal PVR with amplitude reduction and monophasic waveform morphology in the affected leg.
- Duplex ultrasound with findings similar to those for the iliac/CFA stenosis.

**2013 ACC/AHA Practice Guidelines (Class II)**

- Stents (and other adjunctive techniques, such as lasers, cutting balloons, atherectomy devices, and thermal devices) can be useful in the femoral, popliteal, and tibial arteries as salvage therapy for suboptimal or failed results from balloon dilatation (eg, persistent translesional gradient, residual diameter stenosis >50%, or flow-limiting dissection). (Class IIa, Level of Evidence: C)
- The effectiveness of stents, atherectomy, cutting balloons, thermal devices, and lasers for the treatment of femoropopliteal arterial lesions (except to salvage a suboptimal result from balloon dilatation) is not well established. (Class IIb, Level of Evidence: A)

**Emory Protocols for Endovascular Treatment**

Surgical endarterectomy with patch angioplasty of the CFA is reserved for totally occluded, severely calcified, bulky plaques, especially if they extend into the deep profunda and ostial SFA. Surgery is also recommended when there is more extensive disease in the SFA/popliteal segments that requires a bypass graft, or when an endovascular revascularization attempt fails. Figure 54-9 shows the angiographic result of a nontotal but severely calcified CFA stenosis treated with orbital atherectomy and adjunctive balloon angioplasty, with excellent clinical and hemodynamic results. There was no translesional pressure gradient after the procedure, and the patient had complete resolution of the leg claudication.
Endovascular treatment of the CFA almost always involves the use of debulking devices, such as directional atherectomy and/or orbital atherectomy, to increase the lumen diameter and to minimize the risk of vessel dissection from balloon angioplasty. Stenting of the CFA should be avoided and used only as a bailout procedure.

The access for patients with symptomatic stenosis of the CFA is preferentially the contralateral approach, using a 7 Fr × 45 cm long Pinnacle destination sheath (Terumo) advanced into the distal external iliac artery and left approximately 5 cm proximal to the CFA lesion. This distance is important to avoid performing the atherectomy inside the sheath and also to allow more effective cuts by permitting good apposition of the debulking device.

The CFA stenosis is generally crossed with a 0.014 inch × 180 cm long wire, but a Progreat (Terumo) catheter with the included 0.018-inch wire is sometimes needed as an alternative to cross the most difficult CFA lesions. Distal filter protection is frequently used to minimize the risk of distal
atheromatous plaque embolization. Use the Spider filter (Medtronic) for directional atherectomy, and the Emboshield filter (Abbott) mounted on a 0.014-inch Viper wire (Cardiovascular Systems, St. Paul, MN) for orbital atherectomy; choose a filter size 1 mm in diameter larger than the reference vessel diameter when the Spider filter is used. Place the filter in the mid SFA when intervening in the CFA. Use a Hawk 1 LS (Medtronic) atherectomy if the CFA is >5 mm when no calcium or mild to moderate plaque calcification is present, and do four 90° segmental cuts to reduce plaque to <30% angiographic stenosis. If needed, do additional cuts to reduce to <30%. If the CFA is <5 mm in diameter, do more frequent angiographic evaluations after each cut to reduce the risk of device-related perforation. After debulking the CFA lesion, use Chocolate or VascuTrak (Bard Peripheral Vascular, Tempe, AZ) balloons for residual stenosis >30%.

Use drug-coated balloons when the residual stenosis is <30% and when it is a restenotic lesion. For critical stenosis and if the intention is to intervene with atherectomy, first predilate with a 3-mm balloon. For severe calcified plaque affecting both sides of the wall, cross the CFA with a 0.014-inch Viper wire and perform orbital atherectomy. If the Viper wire does not cross the CFA stenosis, use a Progreat catheter with its wire, and once crossed, change to the Viper wire. Alternatively, use a 0.014-inch coronary wire with or without a supportive 0.014-inch catheter. Once the 0.014-inch non-Viper wire has crossed the CFA lesion, exchange for the Viper wire using the same supportive catheter.

Perform orbital atherectomy with a 2-mm solid crown for 4- to 7-mm diameter CFA vessels; a 1.5-mm solid crown may be needed in the case of critical calcific stenosis. If >30% residual stenosis exists after debulking and without flow-limiting dissection, use Chocolate or VascuTrak balloons to achieve a larger final lumen diameter. Size the Chocolate balloon 1 mm larger than the vessel diameter, with expansion to 3 to 5 atm, increasing 1 atm every 30 seconds until the balloon is uniformly expanded for a total of 5 to 8 minutes. Perform gradual balloon inflation under direct fluoroscopic visualization. If >50% residual stenosis remains after orbital atherectomy, use a Hawk 1 LS atherectomy device, keeping in mind the increased procedure-related cost.

Alternatively, >30% residual stenosis can be treated with a VascuTrak balloon using 2- to 4-atm pressure inflations, increasing 1 atm every 30 seconds, for at least 5 to 8 minutes; size the VascuTrak balloon diameter 1:1
to the vessel diameter. We have found consistent good angiographic results when doing prolonged low-pressure inflations for 5 to 8 minutes.

**Protocol Variations**

**Vascular Access Site**

- Use the left brachial artery when the contralateral approach is not possible. Lesions in the CFA can generally be reached with directional atherectomy and orbital atherectomy from the left brachial artery in patients shorter than 5 feet, 8 inches tall. Use a 6 Fr or 7Fr × 90 cm long flexor sheath for directional atherectomy and a 6 Fr × 90 cm length sheath for orbital atherectomy. The orbital atherectomy device will go through a 6-Fr sheath, but if balloon inflation is needed with a 7-mm diameter VascuTrak balloon, a 7-Fr sheath will be required. The distance of the CFA from left brachial puncture site can be estimated using a peripheral balloon with a known 150-cm shaft if needed.

**Total Occlusion**

- Use the standard Viance catheter procedure protocol to cross total ostial CFA occlusions as a first option, as described in the earlier total iliac artery section.
- As a second option, especially if the angiographic “nubbin” at the proximal side of the occlusion is present, cross the occluded CFA using the contralateral approach with a 4-Fr 0.035 inch × 135 cm Navicross, CX1, or Quick Cross catheter with a straight Terumo regular glide wire through a 7-Fr sheath; use the angiogram roadmap for better visualization. Switch to a stiff glide wire if the total occlusion cannot be crossed with a regular 0.035-inch glide wire. Avoid buckling the wire so as not to go subintimal into the ostial SFA and clip off the profunda artery.
- A straight catheter (Navicross, CX1, or Quick Cross catheter) can be used if there is a funnel shape angiographic “nubbin.”
- If there is no angiographic “nubbin” with flush occlusion, probe a straight 0.035-inch regular or stiff 180-cm-long glide wire against the CFA by pointing straight or medially away from the profunda artery.
If the occluded CFA tract cannot be located by angiogram, consider using duplex ultrasound of the groin. Pedal access can also be considered if the occlusion cannot be crossed using the antegrade approach.

SUPERFICIAL FEMORAL-POPLITEAL ARTERY STENOSIS: OUTFLOW DISEASE

Clinical Presentation

The superficial femoropopliteal artery is the most common vascular segment affected in PAD, and the stenosis is often diffuse with a variable degree of calcification. Typical calf claudication with ambulation relieved by rest occurs in less than 15% of patients. More commonly, patients present with atypical or no symptoms, but they may alter their lifestyle and become more sedentary. Since the deep femoral artery ipsilateral to the SFA/popliteal lesion often provides collateral circulation for the reconstitution of the distal flow, preservation of this vessel should be maintained.

Vascular Testing

- Abnormal resting or postexercise ABIs.
- Abnormal PVR with reduced amplitude and monophasic waveform morphology in the affected leg.
- Duplex ultrasound with diffuse, often calcified atherosclerotic plaque with monophasic waveform, spectral broadening, and peak systolic velocity >100% relative to the adjacent proximal segment at the site of the stenosis with distal tardus parvus flow.
- Velocity ratio >2.0 between the stenotic and the proximal adjacent segment.

2013 ACC/AHA Practice Guidelines (Class I-II)

- Endovascular intervention is recommended for disabling claudication
despite maximal medical treatment, including supervised exercise program, and as long as the invasive option has a very favorable risk-benefit ratio. (Class I, Level of Evidence: A)

- Endovascular intervention is preferred for TASC type A. (Class I, Level of Evidence: B)
- Stents (and other adjunctive techniques, such as lasers, cutting balloons, atherectomy devices, and thermal devices) can be useful in the femoral, popliteal, and tibial arteries as salvage therapy for suboptimal or failed results from balloon dilatation (eg, persistent translesional gradient, residual diameter stenosis >50%, or flow-limiting dissection). (Class IIa, Level of Evidence: C)
- The effectiveness of stents, atherectomy, cutting balloons, thermal devices, and lasers for the treatment of femoropopliteal arterial lesions (except to salvage a suboptimal result from balloon dilatation) is not well established. (Class IIb, Level of Evidence: A)
- For individuals with combined inflow and outflow disease in whom symptoms of critical limb ischemia or infection persist after endovascular inflow revascularization, an outflow revascularization procedure should be performed. (Class I, Level of Evidence: B)

**Emory Protocol for Endovascular Treatment**

The contralateral access approach is used in virtually every case of intervention in the SFA, with the exception of a technically impossible crossover, such as kissing aortoiliac stents, previous aortoiliac bypass, and other anatomic difficulties discussed in the protocol variations below. Debubking with atherectomy and adjunctive balloon angioplasty is our favored mode of SFA and popliteal artery revascularization.

Once the selected equipment, based on review of clinical history, imaging studies, and laboratory data, is available in the catheterization laboratory, the procedural protocol begins by accessing the CFA opposite the side of the SFA/popliteal stenosis. Needle entry, using a 21-guage needle and 30-cm-long micropuncture kit from Vascular Solutions, should be in the midline head of the femur, below the inferior epigastric artery and above the distal CFA bifurcation.

We recommend doing the crossover either with a 4 Fr × 65 cm Rim or 4 Fr VCF catheter (Cook Medical) and using a 0.035 inch × 180 cm Bentson
(Cook Medical) or an angled glide wire advanced through a 4 Fr × 10 cm long sheath. If the VCF does not allow engagement of the contralateral common iliac artery, a 4 Fr × 65 cm Rim or, rarely, a Sim 1 (Terumo) catheter may facilitate the contralateral common iliac artery engagement. After performing the digital subtraction angiogram of the contralateral limb, the Rim or VCF catheter is exchanged for a 7 Fr × 45 cm long Pinnacle Destination sheath using a 0.035 inch × 180 cm Supracore wire. Intravenous heparin should be administered after completing the crossover, and the ACT should be kept in the 200- to 250-second range throughout the endovascular intervention.

Distal filter protection is strongly recommended when planning atherectomy in the SFA/popliteal arteries with: (1) single-vessel runoff, (2) more than mild calcification of the vessel being treated, (3) intermediate to long lesion length, or (4) total occlusion. A Spider filter is favored when doing directional atherectomy, and the Emboshield filter is favored in severe calcified lesions treated with orbital atherectomy. Choose a filter 1 mm in size above the reference vessel diameter to where the filter is being deployed, and place the filter not less than 10 cm distal to the lesion to avoid disturbing the filter with the endovascular device (ie, nose cone of the atherectomy catheter). The Spider filter can also be deployed through a 0.035-inch (5-Fr) Quick Cross or Trailblazer (Medtronic) catheter. This alternative mode of deployment is most useful when crossing a total occlusion with a catheter, which allows the filter to be deployed immediately after injection of contrast distal to the total occlusion to confirm the intraluminal position of the catheter. The most common location used to deploy the filter in the SFA/popliteal intervention is in the popliteal artery, but it can also be deployed in the distal SFA, in the largest caliber size trifurcation vessel, or in the single runoff vessel present. If the lesion is <10 cm from the take-off of the anterior tibial artery and distal protection is needed, the filter can be deployed in the dominant tibial vessel or in the vessel in the distribution of the ischemic ulcer.

**Treatment of Ostial <100% SFA Stenosis**

When treating severe but less than totally occluded ostial SFA/popliteal artery stenosis, the tip of the 7 Fr × 45 cm sheath should be left in the proximal CFA, approximately 5 cm or more proximal to the lesion, to avoid
doing atherectomy cuts inside the sheath and to allow proper apposition of the atherectomy device. The SFA/popliteal artery is then crossed with a 0.014 inch Spartacore wire (Abbott Vascular), advanced inside a 0.035-inch Quick Cross catheter. If filter protection is used, as noted earlier, deploy the Spider filter in the distal segment of the artery and keep it not less than 10 cm away from the distal edge of the lesion to prevent contact with the nose cone of the atherectomy device.

The cutter is chosen according to vessel size. We prefer to use directional atherectomy to reduce the obstructive plaque to <50% residual stenosis. The Silver Hawk MS cutter is recommended for SFA/popliteal arteries sizes up to 5 mm in diameter, while the SX-C cutter is recommended for vessel diameter <4 mm. The LX cutter with a long-nose cone stores the largest amount of plaque and requires less cleaning. Drug-coated balloons are recommended after debulking with atherectomy in restenotic lesions. Chocolate or VascuTrak balloons are preferred in de novo SFA/popliteal artery lesions. VascuTrak balloons are used in 6- to 7-mm diameter vessels and selected with a 1:1 balloon-to-vessel ratio. For vessel sizes less than 6 mm, we recommend using Chocolate balloons at 1-mm size greater than the reference vessel diameter. For critical stenosis, predilate with a 3-mm balloon before performing directional atherectomy to facilitate passage of the device. The use of drug-coated balloons is evolving and, in the future, may be the norm for even de novo lesions.

**Treatment of 100% Ostial SFA Stenosis**

For treatment of a total ostial SFA occlusion, leave the tip of the sheath in the proximal CFA. If there is a “nubbin” at the site of the occlusion, use the Viance catheter to cross the total ostial SFA as described under the iliac artery occlusion. Alternatively, use a 4-Fr 0.035 inch × 135 cm angled stiff catheter, such as the Navicross, CX1, or angled Quick Cross catheter with a straight Terumo regular glide wire under angiographic roadmap visualization. Abandon the Viance procedure and switch to a 0.035-inch stiff glide wire if there is no success in crossing the total occlusion. Consider using a straight catheter (Terumo Navicross or Cook CX1 catheter) if there is a funnel shape “nubbin.” If there is no “nubbin” with flush occlusion, probe a straight 0.035-inch regular or stiff 300-cm-long glide wire on an angled 4-Fr catheter against the distal CFA by pointing medially, away from the profunda artery.
If unable to find the occluded SFA tract by angiogram, consider using duplex ultrasound of the groin, which may aid in finding the occluded path. Consider pedal access if unable to cross using the antegrade approach.

**Treatment of Severe <100% SFA/Popliteal Stenosis 1 cm Away from the Ostium**

In the presence of severe stenosis 1 cm away from the ostium of the SFA, leave the tip of the sheath in the distal CFA or proximal SFA at a distance not less than 5 cm proximal to the lesion. This distance will avoid doing atherectomy inside the sheath and also will allow more effective cuts by obtaining good apposition of the debulking device. We prefer doing directional atherectomy to remove noncalcified, mild, or moderately calcified plaque, although balloons, lasers, and stents may also be considered as a destination therapy.

Use a Turbo LX (Medtronic) long nosecone atherectomy catheter for SFA lesions longer than 10 cm of length (long lesions) and 10 cm above the take-off of the anterior tibial artery. We use the Hawk 1 short nose cone for SFA lesions <10 cm and when the lesion is located 7 cm or more away from the take-off of the anterior tibial artery. Use an MS cutter if the lesion is in the mid or distal popliteal artery, if the lesion is within 7 cm of the take-off of the anterior tibial, or if vessel diameter is less than 5 mm.

Make 2 to 3 cuts around the circumference and then retrieve the atherectomy catheter to confirm the absence of perforation, as debulking in the popliteal artery carries a higher risk of this complication. Consider doing Chocolate balloon angioplasty in the SFA or popliteal area if >30% residual stenosis remains after debulking with atherectomy. The balloon size must be 1 mm larger than the reference vessel diameter. When treating restenotic lesions or when concerned about increased risk of restenosis (eg, long lesions, total occlusions, complex calcified plaque, small diameter vessels), use drug-coated balloons after debulking to at least 30% or less residual stenosis.

**Treatment of 100% SFA/Popliteal Stenosis 1 cm Away from the Ostium**
After leaving the tip of the 7-Fr sheath in the proximal CFA or proximal SFA, attempt to cross the total occlusion using the Viance crossing catheter first. An alternative approach is to cross with a 4-Fr 0.035 inch × 135 cm angled stiff catheter (Navicross, angled CX1, or Quick Cross) with a straight regular glide wire (Terumo) through a 7-Fr sheath using the contralateral approach under angiographic roadmap visualization. If there is no success in crossing the total occlusion, switch the straight Terumo regular glide wire to a stiff straight 300-cm-long glide wire. If there is a “nubbin” at the site of the occlusion, come with the straight stiff glide wire and CX1 or Navicross angled glide catheters to the “nubbin.” Probe the Terumo glide wire against the proximal occlusion by pointing in the direction of the vessel trajectory. If unable to find the occluded tract of the SFA, consider using duplex ultrasound with or without fluoroscopy to cross the SFA.

Following treatment of the SFA/popliteal artery stenosis, always perform a repeat angiogram of the entire lower extremity, from distal to proximal, using low magnification, digital subtraction technique, and diluted contrast. Next, pull back the sheath gradually from distal to proximal and observe for pressure gradients and for angiographic stenosis, dissections, or any other abnormalities. Treat inflow lesion(s) if stenosis >70% and translesional pressure gradient >15 mm Hg prior to complete withdrawal of the sheath. Confirm gradient with a 4-Fr catheter, such as a Slip catheter, when possible. Exchange the Pinnacle Destination sheath for the same-size French, 10-cm-length sheath. Finish by obtaining an ACT and recording the amount of contrast used and radiation exposure.

**Protocol Variations**

**Vascular Access Site**

- Use an antegrade ipsilateral arterial access approach with 7 Fr × 65 cm Pinnacle Destination sheath if there is a difficult acute angle between the 2 common iliac arteries and the distal abdominal aorta, previous kissing stents or aorto-iliac-femoral bypass, or heavily calcified and tortuous iliac arteries; leave at least 5 cm of the sheath inside the femoral artery. Do not use this access if the SFA lesion is ostial or too proximal, because the tip of the 7-Fr sheath must be left not less than 3 cm proximal to the SFA.
stenosis. Make a “C” shape bend on the sheath and leave it over the abdomen of the patient, bringing the proximal end of the sheath into the opposite side of the femoral artery puncture site, so the endovascular procedure can be done simulating the contralateral approach. Keep the sheath secure with a large Tegaderm (3M, Maplewood, MN) taped onto the abdominal wall.

• Use the left brachial arterial access with a 6 Fr × 90 cm Pinnacle Destination sheath when the contralateral or ipsilateral antegrade approach is not technically feasible due to previous kissing stents or surgical grafts or simply because the iliac crossover is too difficult and the lesion is ostial or within 3 cm of the ostium. Most balloon shafts are 150 cm, although some tall patients may require a special 175-cm shaft balloon. The LX and LS atherectomy catheters have a working length of 113 cm and 110 cm, respectively, and the SXC is even longer at 135 cm, whereas the orbital atherectomy catheter is 150 cm long.

• Use the retrograde pedal and, less commonly, the retrograde popliteal access to cross flush occlusions or occlusions that cannot be crossed using the antegrade approach. Locate a patent pedal artery (posterior or anterior tibial) or popliteal artery by angiogram and puncture it under direct ultrasound visualization using a short micropuncture kit. Insert a 4 Fr × 12 cm sheath into the pedal or popliteal artery and advance a 4-Fr angled stiff catheter (Navicross, CX1) and a 0.035 inch × 135 cm angled regular Terumo glide wire to navigate the tibial or popliteal artery in a retrograde manner, toward the total SFA occlusion. Once at the occlusion site, follow the technique of crossing antegrade 100% occlusions described previously.

• On rare occasions, the profunda artery collaterals may be used to enter the distal SFA and then come retrograde into the occlusion using the coronary chronic total occlusion equipment and technique.

Severe Stenosis in the Path of the Contralateral Approach (Native or Stent) for SFA/Popliteal Intervention

• Treatment of the (iliac) inflow stenosis may be sufficient in patients with claudication or critical limb ischemia, even with untreated occlusive
disease left in the outflow vascular segment. If concomitant total SFA/popliteal segment occlusion is present at the same side of the iliac artery or stent restenosis, the intended outflow revascularization procedure should be staged because limb ischemia may improve significantly after treatment of the inflow segment.

- When ostial common iliac artery stenosis coexists with outflow SFA disease, the inflow stenosis must be treated first, with the treatment of the SFA generally deferred. If the decision is made to proceed with treatment of the SFA/popliteal artery, and there is an iliac stenosis in the path of the contralateral access approach, treatment must begin with balloon angioplasty of the iliac artery stenosis before placing a sheath across the stenosis to avoid ischemia on the access site limb; consider stenting the residual iliac stenosis at the end of the intended SFA/popliteal artery revascularization procedure, if angiographically significant, with a translesional gradient >15 mm Hg. An alternative approach is to balloon and stent the iliac stenosis first and to defer the revascularization of the outflow segment for 30 to 60 days.

- If there is an unplanned need to reconstruct the aortoiliac bifurcation after intervention on the outflow segment, keep the 0.035-inch contralateral Supracore wire in the contralateral proximal SFA and pull the Pinnacle Destination sheath back in the ipsilateral iliac artery. Then puncture the contralateral CFA and cross the iliac artery using the retrograde approach with a 0.018 inch × 300 cm long Steelcore wire. Use the 0.035-inch wire in the CFA as a reference for the puncture site, and leave the tip of the Steelcore wire in the thoracic aorta. Once the contralateral common iliac artery has been crossed with the Steelcore wire, exchange the contralateral 0.035-inch wire for a 0.018-inch Steelcore wire and place it in the thoracic aorta. After both common iliac arteries have been secured with wires, proceed with kissing balloons and stents.

- Restenosis of an iliac stent in the path of the contralateral approach must also be treated first, before any attempt to revascularize the outflow segment, unless the decision is made to do open surgery with an ipsilateral aortoiliac graft. If a femoral-to-femoral bypass is needed, the inflow limb of the iliac arteries must be treated with stents first.

- For totally occluded native iliac or stents, follow instructions detailed in the iliac artery disease section.
Severe Calcified Plaque Affecting Both Sides of the Wall of the SFA/Popliteal Artery Stenosis

- Perform orbital atherectomy with a 2.00-mm solid crown to modify severe calcified plaque that affects both sides of the vascular wall. Start with a 1.50-mm solid crown for tight calcified lesions. Use Emboshield filter for SFA/popliteal lesion length >3 cm.
- If there is more than 30% residual stenosis after debulking with 2.00-mm Solid Crown diamondback, use a Chocolate balloon or VascuTrak balloon at low-pressure inflations for 5 to 10 minutes. Use of a Hawk 1 could be considered before using the previously mentioned balloons.
- For restenotic lesions, use drug-coated balloons after debulking to <30% residual stenosis.
- Use a Hawk 1 for calcified lesions <10 cm long, or LX-C for calcified lesions >10 cm long, always with distal filter protection.
- Consider using a Hawk 1 if >50% residual stenosis remains after debulking with orbital atherectomy. The cost of using 2 different debulking devices should be weighed against the benefits.
- Our practice is to use orbital atherectomy first in severe vessel calcification and, if unable to reach <50% residual stenosis, to use Hawk 1 for stenosis reduction.

Thrombosis of the SFA/Popliteal Arteries

- Cross the thrombosed vascular segment with a 0.035 inch × 135 cm Quick Cross or Trailblazer catheter and a 0.035-inch exchange length glide wire, and place a filter distally to protect the trifurcation vessels.
- Perform mechanical thrombectomy with an Angiojet (Boston Scientific, Marlborough, MA) aspiration catheter or laser atherectomy, followed by treatment of the stenotic segment, if present.
- Keep the patient well anticoagulated and correct underlying thrombotic state.

Surveillance After Endovascular Revascularization of the SFA/Popliteal Artery Segment
All patients who have undergone revascularization of the SFA/popliteal arteries should have periodic outpatient visits with the treating physician to monitor for symptoms of PAD progression; the presence of femoral, popliteal, posterior tibial, and dorsalis pedis pulses; ABIs; and surveillance duplex, as follows:

- Perform duplex ultrasound of the common femoral, SFA, popliteal, and trifurcation vessels and ABI within 1 month of the procedure (baseline surveillance) and thereafter upon any subsequent new or worsening lower extremity symptoms.¹²
- Perform duplex ultrasound and ABI at 3, 6, and 12 months and annually thereafter to monitor for restenosis.

**STENOSIS OF THE TRIFURCATION VESSELS: RUNOFF DISEASE**

**Clinical Presentation**

Individually, stenosis of the tibioperoneal, anterior tibial, peroneal, or posterior tibial artery (trifurcation vessels) is not likely to cause claudication. However, when all 3 tibial vessels are severely diseased, symptoms such as numbness, foot aching, and cold feet may develop before the onset of critical limb ischemia. Disease of the trifurcation vessels is more commonly associated with chronic limb ischemia, in part due to poor compensatory collateral circulation. Critical limb ischemia is defined as PAD that results in ischemic rest pain, ischemic tissue loss, or gangrene.¹⁸ Endovascular revascularization of the trifurcation vessels is indicated when the patient has signs and symptoms of CLI or when any foot surgery is being planned and severe trifurcation disease is present.

**Vascular Testing**

- TBI <0.70 and toe pressures <40 mm Hg.
- Abnormal resting or postexercise ABIs.
- Abnormal PVR with decreased amplitude and monophasic waveform
morphology below the knee.

- Duplex ultrasound with diffuse, often calcified atherosclerotic plaque of the trifurcation vessels with monophasic waveform, spectral broadening, and elevated peak systolic velocity >100% relative to adjacent proximal segment at the site of the stenosis; may have distal tardus parvus flow.

2013 ACC/AHA Practice Guidelines (Class II)

- Stents (and other adjunctive techniques, such as lasers, cutting balloons, atherectomy devices, and thermal devices) can be useful in the femoral, popliteal, and tibial arteries as salvage therapy for a suboptimal or failed result from balloon dilatation (e.g., persistent translesional gradient, residual diameter stenosis >50%, or flow-limiting dissection). (Class IIa, Level of Evidence: C)

- The effectiveness of uncoated/uncovered stents, atherectomy, cutting balloons, thermal devices, and lasers for the treatment of infrapopliteal lesions (except to salvage a suboptimal result from balloon dilatation) is not well established. (Class IIb, Level of Evidence: C)

Emory Protocols for Endovascular Treatment

Treatment of Severe Nontotal Tibial/Peroneal Artery Stenosis

Endovascular intervention of the arteries below the knee is done using a 6-Fr sheath. However, if a combined SFA/popliteal revascularization is planned, a 7-Fr sheath is generally needed.

Choose a 65-cm-long Pinnacle Destination sheath, and leave the tip in the mid or distal SFA, if no disease is in this segment, when using the contralateral approach for below-the-knee intervention; this sheath length and position allow better angiographic images of the distal vessels with less contrast use. Cross the tibial artery stenosis using a 0.014 inch × 300 cm Spartacore wire (or your favorite wire) under angiographic roadmap visualization. Advance the 0.014-inch wire over a 0.018 inch × 135 cm long Quick Cross with either a 45° angled tip or straight tip as needed to navigate the trifurcation vessels. For patients 6 feet tall or taller, use a 150-cm Quick
Cross catheter. If the tibial artery lesion is in the distal segment, consider using the antegrade approach to avoid running out of device length.

Once the tibial artery stenosis is crossed with the 0.014 inch × 300 cm wire, advanced the Quick Cross catheter distal to the stenosis and confirm the intraluminal location of the catheter by injecting diluted contrast before exchanging the Quick Cross catheter for a balloon. Next, perform a balloon angioplasty with a Chocolate or VascuTrak balloon.

There is no need for distal filter protection in the tibial arteries unless the lesion is >5 cm and has a proximal or mid location in a vessel with a diameter >2 mm.

Consider directional atherectomy with an SXC cutter if the vessel size is 3 mm or larger, the lesion length is ≥3 cm, and the ostium of the anterior tibial artery (ATA) is not involved. Conversely, consider directional atherectomy with an SS cutter if the lesion is not ostial ATA, the vessel size is 2 to 3 mm, and the lesion is <3 cm in length. Less commonly, ostial ATA disease is encountered, which is extremely challenging. We cannot overemphasize the complexity of this lesion. If not calcified, an SS cutter may be used, and after every cut, assess the lesion with an angiogram. Once ≤50% residual is obtained, switch to Chocolate balloon. If there is any calcification, perform orbital atherectomy with a 1.5-mm standard crown with frequent lesion assessment with contrast angiography. Switch to Chocolate balloon when ≤50% stenosis is achieved. For vessels around the ankle and in the foot, consider a solid micro crown, which only comes in 1.25 mm.

If any calcium is identified, consider orbital atherectomy with 1.5-mm standard crown. Slow runoff or no reflow may develop during the procedure, especially if treating lesion lengths >5 cm with moderate to severe calcification. Shorter runs of less than 20 seconds, increased flushing between runs, and slow passes are some of the precautions to mitigate procedure-related complications.

Per standard postintervention routine for any vascular procedure, the operator should repeat the angiogram of the affected tibial artery, and, if angiographic results are good, complete the interventional procedure with an angiogram of the entire lower extremity and aortoiliac vessels with diluted contrast.

**Treatment of a 100% Tibial/Peroneal Artery Stenosis**
Use the Viance catheter and a 0.014-inch wire system as the first choice to cross 100% vessel stenosis, with the second choice being a 0.035-inch Quick Cross, CX1, or Navicross catheter with either straight or angled 0.035 inch × 300 cm glide wires. Once the artery has been crossed and the intraluminal placement of the wire confirmed, complete the steps described earlier for treatment of severe, nontotal tibial/peroneal stenosis. The option of pedal access is our preferred choice if antegrade access fails. Finally, for operators proficient in coronary chronic total occlusions, Finecross (Terumo) or similar catheters and chronic total occlusion wires (eg, Fielder [Abbott], Gya) may be tried.

Protocol Variations

Vessel Wall Calcification

• If severe calcified plaque is present in the trifurcation vessel affecting both sides of the wall, cross with the Viance, Quick Cross, or CX1 technique, and exchange the wire used for the Viper 0.014-inch wire to prepare for orbital atherectomy.
• Always confirm the intraluminal location of the wire before treatment with either balloon or debulking devices.
• Perform orbital atherectomy with 1.25-mm solid crown for ≤4-mm-diameter vessels. Alternatively, use a 1.50-mm classic crown if the vessel diameter is <3 mm, and a 1.25-mm solid micro crown if the vessel diameter is closer to 2 mm or less or if the intervention is in the plantar arch.
• If <50% residual stenosis exists without flow-limiting dissection, use a Chocolate balloon for controlled plaque modification. Size the balloon diameter 1.5:1 to vessel diameter, with expansion up to 3 to 4 atm, under direct fluoroscopic visualization. Every 30 seconds, expand the Chocolate balloon by 1 atm and keep the balloon inflated at 3 to 4 atm for a total of 5 to 8 minutes. Alternatively, a VascuTrak balloon using low-pressure inflations, increasing by 1 atm every 30 seconds, can be used for at least 5 to 8 minutes, sizing the balloon diameter 1:1 to vessel diameter and inflation pressure 3 to 4 atm.
• Drug-coated balloon sizes <4 mm are not available as of 2017.
Consider using coronary drug-eluting stents for critical limb ischemia in the tibial vessels if angiographic results from balloon angioplasty or atherectomy are suboptimal and the disease is localized.

**Ostial Anterior Tibial Artery Stenosis**

- Atherectomy to treat ostial anterior tibial artery stenosis increases the risk of vessel perforation. Downsizing the device and repeating angiograms after each pass is strongly recommended.
- Use a Chocolate or VascuTrak balloon for ostial anterior tibial or any other trifurcation vessels.

**Surveillance After Endovascular Revascularization of the Trifurcation Vessels**

Patients who have undergone revascularization of the trifurcation arteries often have nonhealing ulcers in the feet and must undergo regular follow-up appointments with wound care specialists. The interventional cardiologist should see these complex patients regularly to monitor progress with regard to limb pain and wound healing and, if gangrene occurs, make a prompt referral to the vascular surgeon for open surgery or amputation. The regular surveillance should include a thorough examination of the skin, pulses using Doppler ultrasound, ABIs, TBI, toe pressures, and duplex ultrasound of the entire limb. The treating physician should stay in close communication with the wound care specialist and be ready to reintervene if there is no improvement in wound healing or if there are worsening symptoms with signs of CLI. The vascular surveillance is summarized as follows:

- Duplex ultrasound of the trifurcation vessels and the entire limb with ABI within 1 month of the procedure (baseline surveillance) and upon any subsequent new or worsening symptoms or recurrent signs of critical limb ischemia.
- Duplex ultrasound and ABI at 3, 6, and 12 months and annually thereafter to monitor for restenosis of the trifurcation vessels. It is important to note that often foot ulcers heal even when the treated trifurcation vessel reoccludes. However, unless a nonhealing ulcer recurs or any other symptoms of critical limb ischemia arise, there is generally no need to
reintervene in the trifurcation vessels. A lower threshold for revascularization should be considered in Rutherford classification Stage 3 patients who remain symptomatic despite guideline-directed management therapy and are at high risk of progressing to CLI. Prevention of future ischemic complications in the limbs, coronary arteries, and extracerebral/intracerebral arteries is the main goal for the PAD patient.

ACKNOWLEDGMENTS

The authors acknowledge the years of advice and feedback from mentors, colleagues, and trainees who contributed their recommendations throughout this chapter. The authors also thank Bob Todd, RVT, for his technical assistance; Denise Daniels for her technical support; Drew Imhulse from Emory Media Services for his assistance with the figures and tables; and Michelle Kienholz for her editorial assistance.

REFERENCES

**MULTIPLE CHOICE QUESTIONS**

1. According to the authors, which of the following statements regarding duplex ultrasound uses for surveillance after endovascular revascularization of the femoropopliteal territory is true?
   A. Duplex ultrasound examination is warranted when claudication or signs of critical limb ischemia recur.
   B. Duplex ultrasound examination is recommended to monitor for restenosis 6 and 12 months after revascularization.
   C. Duplex ultrasound examination is recommended to monitor restenosis within 1 month after the procedure, at 3 and 6 months, and then once a year after revascularization.
   D. Concomitant ankle-brachial index (ABI) is recommended 6 and 12 months after procedure.

2. Surgical treatment of symptomatic common and external iliac artery stenosis should be considered in all of the following conditions, EXCEPT:
   A. 100% flush occlusion of the ostium of the common iliac artery with severe calcification and no “beak” at the origin of the diseased segment
   B. 6.5-cm concomitant abdominal aortic aneurysm (AAA)
   C. 100% occlusion of the distal abdominal aorta
   D. Lack of contralateral or ipsilateral femoral access

3. Distal filter protection is recommended with which of the following?
   A. Spider filter in a difficult case of calcified diffuse distal superficial femoral artery (SFA) treated with orbital atherectomy and 1-vessel runoff
B. Emboshield filter in a moderately calcified mid SFA stenosis with no vessel runoff
C. De novo and restenotic focal lesions
D. Spider filter in 100% occlusion of the SFA with 1-vessel runoff

4. Which of the following statements regarding lower extremity revascularization is true?
   A. Revascularization for asymptomatic but severe peripheral arterial disease (PAD) below the inguinal ligament has a Class IIa indication.
   B. Patients with symptomatic PAD in the critical ischemia range and Rutherford category 3 should undergo prompt revascularization to avoid amputation or to convert to limited amputation.
   C. Treatment of the inflow vascular segment may suffice if the patient with critical limb ischemia has a complete or near-complete resolution of the symptoms and signs of vascular insufficiency.
   D. An absolute variation of greater than 0.15 in the ABI and/or toe-brachial index (TBI) is considered an indication for angiogram and revascularization of the lower extremity.

5. Effort-related claudication is found in most patients with PAD.
   A. True
   B. False

**ANSWERS**

1. C

Patients undergoing lower extremity revascularization with endovascular techniques require a baseline ABI and a duplex ultrasound examination of the treated vascular segment within 1 month of the procedure. In addition to the baseline study, the authors routinely repeat the ABIs and duplex ultrasound examinations at 3 and 6 months after the endovascular intervention to monitor for patency of the target vessel site. Patients are at highest risk for restenosis during the first 6 months after the procedure, and symptoms of recurrent disabling claudication may occur too late, after (re)occlusion of the index lesion. Repeat revascularization of a completely occluded artery from restenosis is expected to be difficult and time consuming, while also exposing
both the patient and the operators to excessive direct radiation; therefore, early detection of physiologic (ABI/pulse volume recording [PVR]) or anatomic (duplex ultrasound) signs of significant restenosis will permit planning for re-intervention, before progression to a total occlusion.

2. D

Most patients with symptomatic common and external iliac artery stenosis are treated using endovascular techniques unless: (1) there is an infrarenal AAA requiring repair; (2) there is a 100% flush occlusion with no “beak” or “nubbin” at the ostium of the common iliac artery and there is severe calcification and intermediate (>5 cm) length occlusion; or (3) there is a long occlusion (>10 cm) with severe calcification.

The decision to use endovascular techniques versus open surgery should be made according to operator expertise and patient characteristics and preference after a detailed discussion of the indications, benefits and limitations, alternative treatment, and potential complications related to each procedure. Endovascular revascularization of the common and external iliac arteries can be performed using the left radial or brachial approach, generally using a 5 or 6 Fr × 90 cm long sheath.

3. D

Distal filter protection is strongly recommended when planning atherectomy in the SFA/popliteal arteries with single-vessel runoff, more than mild calcification of the vessel being treated, intermediate to long lesion length, or total occlusion. A Spider filter is used when doing directional atherectomy, and the Emboshield filter can be used in severe calcified lesions treated with orbital atherectomy. Orbital atherectomy with CSI is performed using a 0.014-inch Viper wire only and cannot be replaced by the Spider wire. Restenotic tissue is commonly soft without calcification and less likely to embolize.

4. C

An absolute variation of greater than 0.15 in the ABI/TBI is considered significant when done serially but does not mandate angiogram or revascularization. Symptoms generally mandate further testing and revascularization. Management of patients with the condition described in
answer choice A is currently debatable and should be individualized for each situation. Rutherford category 4 and above describes patients with critical limb ischemia, so answer choice B is wrong. Patients could experience resolution of the symptoms and signs of critical limb ischemia after treatment of the inflow (iliac arteries), especially if a total iliac stenosis is successfully opened; therefore, treatment of the outflow segment is not necessarily required, which is the correct answer.

5. B

Lower extremity claudication with typical effort-related limb pain occurs in only 11% of patients with PAD.
INTRODUCTION

History

The treatment of venous disease has changed dramatically in recent years with the advent of duplex ultrasound evaluation, minimally invasive treatments, and new thrombolytic drugs. For more than 100 years, the treatment of superficial disease had been limited to high ligation and stripping with limited innovation. Attempts at chemical ablation (sclerotherapy) had, historically, been hampered by serious complications and a high rate of recurrence. Deep venous treatment had been largely limited to the use of compression stockings, with occasional attempts to perform venous bypasses, valve reconstruction, or the radical Linton procedure (subfascial ligation of perforator veins), but all of these interventions had high rates of morbidity and low rates of success.

The first big step was the duplex evaluation, which greatly improved the sensitivity and specificity for the diagnosis of deep vein thrombosis (DVT), as well as reduced costs. The progress continued with improved diagnosis of superficial reflux and the mapping of incompetent veins. This greatly improved the results of high ligations and stripping and helped considerably
with the results of ultrasound-guided sclerotherapy for the chemical ablation of incompetent superficial veins. Newer techniques that use thermal ablation and improved methods of chemical ablation have furthered the improvement.

Deep venous disease treatment has also undergone a renaissance with the use of similar minimally invasive techniques, such as angioplasty, stenting, and intravascular ultrasound (IVUS).

**Epidemiology**

The prevalence of varicose veins in the Western population is greater than 20%, with about 5% of patients having the sequelae of venous edema, skin changes, or ulceration. Approximately 0.5% of patients have active ulceration. The incidence is higher in women than in men.

**ANATOMY**

**Superficial Veins**

The superficial system is defined as the portion of veins that lie between the skin and deep fascia that covers the muscles. The main veins of the superficial system are the great saphenous vein (GSV) and the small saphenous vein (SSV) (Figs. 55-1 and 55-2). The GSV starts in the foot, anterior to the medial malleolus, and courses up the medial leg to the saphenofemoral junction in the groin. The GSV runs in the saphenous sheath, which is formed from the deep fascia. In the calf, major tributaries of the GSV are the anterior and posterior arch veins. In the thigh, major tributaries of the GSV are the anterior and posterior accessory saphenous veins. The anterior accessory saphenous vein (AASV) typically joins the GSV at the saphenofemoral junction (SFJ). The SSV starts posterior to the lateral malleolus and runs in the saphenous sheath to the popliteal fossa. The termination point for the SSV is highly variable. It sometimes ends in the popliteal fossa joining the popliteal vein, or through thigh extensions ending in the thigh underneath the gluteus maximus muscle, or it courses medially and joins the GSV, also called the vein of Giacomini.
FIGURE 55-1 Schematic of the superficial veins, anterior view, which depicts the great saphenous vein. Ant, anterior; Post, posterior.
Deep Veins

The deep system includes all the veins beneath the deep fascia (Fig. 55-3). The peroneal, anterior, and posterior tibial veins are usually paired veins that course along the arteries of the same name. The posterior tibial vein joins the peroneal vein to form the tibioperoneal trunk, which joins the anterior tibial vein to form the popliteal vein in the popliteal fossa. This is paired with the popliteal artery. As the popliteal vein courses through the hunterian canal, it becomes the femoral vein (formerly known by the somewhat confusing term of “superficial” femoral vein), which is paired with the superficial femoral artery. This is one of the few times the corresponding vein and artery have different names. The femoral vein joins the profunda femoral vein to form the common femoral vein in the groin. Once the common femoral vein passes under the inguinal ligament, it becomes the external iliac vein, which joins the internal iliac vein to form the common iliac vein. The right and left common iliac veins join to form the inferior vena cava.
Perforators and Pelvic Connections

Perforating veins connect the superficial and deep systems and penetrate through the deep fascia. There are estimated to be over 150 such connections. The important perforators connect along the medial calf and thigh. Some perforating veins connect directly to the GSV and others to the posterior arch vein. There are additional important connections between the pelvic veins and the superficial venous system that sometimes lead to leg vein symptoms. These connections come from the round ligament, obturator, gluteal, and hemorrhoidal veins.

Venous Valves

Valves are critical to the healthy functioning of the venous system. Through normal opening and closing of the valves, blood is directed back to the heart.
In diseased veins, valves may not close properly, resulting in backward blood flow and pooling.

**DIAGNOSTIC EVALUATION**

**History**

The presenting complaints from patients with venous disease can range from concerns that are strictly cosmetic, with underlying psychological impact, to many vague symptoms such as pain, aching, tingling, fatigue, and heaviness, to more severe symptoms such as edema, inflammation, and ulceration (*Table 55-1*). In general, symptoms improve with rest and leg elevation and are worsened by heat and long periods of standing or sitting.

*Table 55-1 Spectrum of Chronic Venous Insufficiency*

<tr>
<td>Ulcers</td>
</tr>
</tbody>
</table>

Obtaining a thorough past history of thromboembolic events and thrombophilia as well as family history of the same is important (*Table 55-2*). Medications, particularly birth control and hormone replacement, can also increase risks of thromboembolic events. Past treatment of venous problems should be elicited.

*Table 55-2 Risk Factors*
**Physical Exam**

The physical exam should focus on signs and symptoms of venous insufficiency. The patient should be standing while being carefully examined visually and by palpation for evidence of bulging veins. Any evidence of scars from previous procedures, edema, inflammation, pigmentation, and past or present ulceration should be noted.

**Duplex Scanning**

**Deep Vein**

Duplex examination has been a major advancement in venous disease, particularly in examination for DVT. The exam can be done with the patient supine. Careful B-mode imaging with visualization of the entire vein and wall-to-wall opposition along the entire deep venous system can rule out the presence of DVT, with a very low false-negative rate. The superficial system can be examined similarly or during the standing portion of the exam.

**Iliac Inferior Vena Cava Obstruction**

If imaging of the iliac veins or inferior vena cava (IVC) is to be done, the patient should be instructed to have nothing by mouth (npo) for approximately 8 hours before the exam. Compression is not available, so careful visualization and good color flow are required to make the diagnosis.

**Reflux**
The exam to look for reflux should be done with the patient standing. The exam is conducted using a pulsed wave Doppler and 4- to 7-MHz probe. This provides enough pressure to close the valves. The superficial and deep systems are analyzed for spontaneous flow and augmented flow. In the measurement of any retrograde flow, incompetence is defined as retrograde flow greater than 500 milliseconds.

**Perforator and Pelvic Connections**

Occasionally, pathologic connections between the pelvic veins and leg veins occur. In particular, round ligament, pudendal, obturator foramen, abdominal wall, sciatic foramen, and gluteal veins can connect to the leg. These can lead to pathology in the leg. Patients may present with varicosities of the vulva or scrotum. In men, testicular varicosities can lead to infertility, and in women, ovarian varicosities can lead to pelvic congestion syndrome. Patients with these symptoms may need pelvic sonography with measurements of the gonadal veins. Veins larger than 5 mm are considered to be abnormal.

**Plethysmography**

The clinical practice guidelines of the Society for Vascular Surgery and American Venous Forum suggest that venous plethysmography be used selectively for the evaluation of patients with simple varicose veins (CEAP [clinical, etiologic, anatomic, pathophysiologic] class C₂) or advanced chronic venous disease if duplex scanning does not provide definitive information on pathophysiology (CEAP class C₃ to C₆).³

**Other Imaging**

The utility of duplex imaging of the iliac veins and the IVC can be somewhat limited. Bowel gas and body habitus can obstruct views. Occasionally, additional types of imaging may be required to identify obstruction in the iliac veins and IVC. Great strides have been made in computed tomography (CT) and magnetic resonance (MR) venography, resulting in the capability of identifying obstruction in these vessels. Traditional venography is still in use, especially when the likelihood of intervention is high. One of the major new
advances in deep venous evaluation is IVUS. This provides an ultrasound image from inside the vein that allows accurate calculation of the area and visualization of vein wall thickness and any trabeculations, frozen valves, and external compression.

**Laboratory Tests**

Routine laboratory tests are not usually required for cardiovascular disease (CVD) patients. If thrombophilia is suspected, a workup should be done to identify possible causes. A history of recurrent DVT, DVT in otherwise young healthy patients, or multiple miscarriages or strong family history should raise suspicion. Biopsy of recalcitrant ulcers may uncover an unusual etiology such as neoplasia, pyoderma gangrenosum, hydroxyurea, rheumatoid arthritis, or vasculitis.

**CEAP CLASSIFICATION**

The American Venous Forum developed the CEAP classification system for venous disease, with the name referring to clinical signs of venous disease (C), etiology (E), anatomy (A), and pathophysiology (P).

**Clinical Score**

The clinical score is determined based on the highest level of symptoms:

- \( C_0 \): no symptoms
- \( C_1 \): telangiectasias
- \( C_2 \): varicose veins
- \( C_3 \): edema from the venous insufficiency
- \( C_4 \): skin changes related to venous insufficiency
  - \( C_{4a} \): skin changes limited to inflammation
  - \( C_{4b} \): presence of lipodermatosclerosis
- \( C_5 \): history of venous ulceration but no active ulceration
C₆: active ulceration

**Etiologic Score**

The cause of the venous insufficiency is classified as congenital (Eₖ), primary (Eₚ), or secondary (Eₛ). Secondary generally refers to postthrombotic.

**Anatomic Score**

The anatomic classification identifies the type of veins affected by disease: superficial (Aₛ), perforator (Aₚ), or deep (Aₐ) veins. The anatomic score can further reflect which segment of each system is affected by disease, for example, the GSV above or below the knee (superficial veins), the internal iliac vein, the femoral vein, or the popliteal vein (deep veins), or the thigh or calf perforator veins.

**Pathophysiology Score**

The pathophysiology of venous disease can be labeled as reflux (Pᵣ), obstruction (Pₒ), or both.

**OUTCOME ASSESSMENT**

**Venous Clinical Severity Score**

The Venous Clinical Severity Score (VCSS) system was developed as an outcome assessment instrument for evaluating changes in a person’s disease severity over time and response to treatment. The score is based on the presence of pain, varicose veins, venous edema, skin pigmentation, inflammation, induration, active ulcers (number, duration, and size), and use of compression therapy. As noted by Vasquez et al, the revised VCSS, together with the CEAP, “provides a standard clinical language to report and compare differing approaches to CVD management.”
Quality-of-Life Assessment Tools

As noted in the practice guidelines of the American Venous Forum, there are several quality-of-life assessment tools designed specifically for use with venous diseases. Frequently used validated instruments include the Venous Insufficiency Epidemiologic and Economic Study of Quality of Life (VEINES-QOL/Sym) questionnaire scale, the Chronic Venous Insufficiency Questionnaire (CIVIQ), the Aberdeen Varicose Vein Questionnaire (AVVQ), and the Charing Cross Venous Ulceration Questionnaire.  

TREATMENT

Indications

The decision to treat involves a thorough discussion with the patient on the goals of treatment and realistic expectations of the results. Many patients present primarily with cosmetic concerns, while some may complain of symptoms and complications of venous disease. These symptoms include leg heaviness and fatigue, swelling, pain along the bulging veins, pruritus, and restlessness. Because these symptoms are very nonspecific, other possible causes of these symptoms should be discussed. Patients also should be advised that some of these symptoms may not improve with treatment. Patients also may exhibit other symptoms that are more obviously related to venous disease, such as superficial phlebitis, stasis dermatitis, lipodermatosclerosis, atrophie blanche, and venous ulceration.

Medical Treatment

There are a few drugs that show some promise in the treatment of symptoms related to venous insufficiency, including horse chestnut seed extract; flavonoids such as rutosides, diosmin, and hesperidin; micronized purified flavonoid fraction (MPFF); and other plant extracts, such as French maritime pine bark extract. Synthetic products such as calcium dobesilate, naftazone, and benzarone have shown some promise in treatment as well. These are venoactive drugs that improve venous tone and capillary permeability. Flavonoids appear to reduce inflammation and edema.
Pentoxifylline and MPFF have been shown in several studies to help with healing ulcers. In the clinical practice guidelines of the Society for Vascular Surgery and the American Venous Forum, Gloviczki et al\textsuperscript{3} discuss the available evidence for these various therapies.

**Compression**

Compression therapy has been a mainstay of treatment for venous insufficiency. For $C_1$ and $C_2$ disease, support hosiery ($<20\text{ mm Hg}$) has been shown to provide adequate treatment and possibly better compliance in comparison to compression stockings ($>20\text{ mm Hg}$). For more advanced disease ($C_3$-$C_6$), heavier compression ($20\text{ mm Hg}$ or greater) may be needed. Venous ulcers heal just as well with compression therapy alone as with surgery. Recurrence is reduced with corrective surgery. For intractable edema and/or ulceration, compression pumps may be necessary.

**Superficial Disease**

The treatment of superficial venous disease has changed dramatically during the past decade. High ligation and stripping (HL/stripping) was considered the gold standard but now has been replaced by endovenous thermal ablation either by radiofrequency (RF) or laser (EVLT). These can be done on the GSV, SSV, or an accessory vein as long as the veins are straight enough and not too close to the skin as to risk a burn. RF and EVLT have shown equivalent results to HL/stripping with quicker recovery and better quality-of-life scores.\textsuperscript{3,11} The difference between the thermal techniques of RF and EVLT has been minimal when comparing results, with slightly higher occlusion rates for EVLT and slightly better pain scores with RF. These numbers may have improved with both techniques because RF results have improved with the newer catheter designs and pain scores have improved with EVLT using longer wavelength lasers.

Superficial varicosities that are tortuous or too close to the skin can be treated by either stab phlebectomy or chemical ablation with sclerotherapy. Chemical ablation has also gone through dramatic improvements with the use of foam sclerotherapy. This is done by mixing a gas with a detergent sclerosant and agitating between 2 syringes, usually with a 3-way stopcock,
forming a foam solution. Most physicians use room air for the gas, but some prefer the use of carbon dioxide or a combination of carbon dioxide and oxygen. This has been shown in some studies to reduce the risk of neurologic events that have been reported with the use of foam. Studies comparing the difference between the 2 methods show slightly improved results early with phlebectomy and equivalency at 1 year. Longer term studies show a tendency toward more recurrences with sclerotherapy than phlebectomy.

Newer techniques have come to market that are allowing saphenous ablation without heat so that there is less discomfort for the patient and thus tumescent anesthesia is not required. The first technique is mechanical chemical ablation (MOCA or Clarivein). This uses a combination of a mechanical injury using a wire to damage the endothelium of the vein combined with sclerotherapy. This technique has shown comparable results to the thermal techniques in studies limiting the size of the vein generally to less than 12 mm. Recently, the US Food and Drug Administration (FDA) approved and released in the United States the polidocanol microfoam (PEM or Varithena). This is used as a chemical ablation similar to sclerotherapy introduced through a catheter. Patient-reported results have been equivalent to the thermal techniques, with ultrasound imaging showing slightly lower closures. The newest technique to get FDA approval is cyanoacrylate (glue or VenaSeal). The results from glue showed noninferiority to RF.12

Whether these new “nontumescent” techniques replace the thermal methods will depend on the long-term results and, of course, costs.13

**Perforators**

Treatment of perforator veins has also come a long way from the old Linton subfascial perforator ligation and subfascial endoscopic perforator ligation. Now with the use of ultrasound guidance, less invasive methods are available using sclerotherapy and thermal and ligation techniques to treat incompetent veins.14 Ultrasound-guided sclerotherapy using liquid solutions had the limitation of requiring direct injection into the perforator to assure treatment. This carried risks of arterial injection, since all perforators are accompanied by an artery, and a greater risk of DVT, because perforators sometimes empty directly into smaller deep veins such as the tibial veins. The use of foam has allowed remote injection and following of the sclerosant due to the visualization of foam with ultrasonography. This has led to greater use of
ultrasound-guided foam sclerotherapy for the treatment of incompetent perforator veins.

Ultrasound has also allowed thermal methods to be used for the treatment of incompetent perforators (IP). By directly accessing the perforator vein, either a laser fiber or RF device can be placed into the vein, and after tumescent anesthesia is placed around the vein, heat can be applied that ablates the vein. The FDA has only approved the RF Seps device (Medtronic, Dublin, Ireland) for this procedure, and it is primarily used in intractable venous ulceration.

Ligation can also be done by marking with an ultrasound to limit the size of the incision and cut directly down on the IP and ligate divide between ligatures. This maybe more difficult in advanced disease because of the skin changes.

**Deep Vein Reflux**

Deep venous valve failure can be a primary disorder, but much more commonly, it is secondary to DVT. Treatment has been primarily supportive with compression. Attempts at valve reconstructive surgery have been largely ineffective with a high morbidity.

**Deep Venous Obstruction**

Deep venous obstruction has been shown to be an underdiagnosed problem leading to symptoms of venous insufficiency. Risk factors include female gender, history of DVT, particularly proximal, and deep venous reflux on ultrasound examination. Diagnosis can be obtained by ultrasound, CT venography, MR venography, or standard venography, but the highest sensitivity is with IVUS. Pathologic venous occlusive disease is determined by the area calculation for the IVC, common iliac vein, and external iliac vein. An area stenosis of 50% in a symptomatic patient is considered to be pathologic and in need of angioplasty and stent. The treatment of the femoral vein and below is more controversial. The collaterals through the profunda femoral vein usually provide enough blood flow to keep the patient asymptomatic. However, now some think opening the occluded femoral and popliteal vein segments with angioplasty will increase flow and help maintain the stented iliacs and further decongest the calf.
Pelvic Varicosities

Varicosities involving the pelvic area can also extend down on the leg. Connections between the pelvis can be treated with ultrasound-guided sclerotherapy. If the patient has pelvic symptoms, then treatment of incompetent pelvic veins with embolization therapy can be considered. Gonadal vein contrast venography followed by coil embolization and/or sclerotherapy of the pelvic varicosities can be carried out.

ACKNOWLEDGMENT

The authors thank Victoria J. White for editorial assistance with this chapter.

**MULTIPLE CHOICE QUESTIONS**

1. The prevalence of varicose veins in the West is:
   A. <1%
   B. 1%-5%
   C. 5%-10%
   D. >20%

2. Which of the following statements is correct?
   A. The great saphenous vein (GSV) joins the popliteal vein to form the femoral vein.
   B. The small saphenous vein (SSV) is called the GSV above the knee.
   C. The GSV joins the femoral vein to form the common femoral vein.
   D. The GSV and SSV are deep veins of the lower extremities.
3. What is the best initial diagnostic test for chronic venous insufficiency (CVI)?
   A. Magnetic resonance venogram
   B. Duplex ultrasound
   C. Computed tomography venogram
   D. Plethysmography

4. To diagnose CVI with duplex ultrasound, the patient should be lying down.
   A. True
   B. False

5. Thermal ablation (radiofrequency or endovenous laser therapy) is best for which of the following?
   A. Deep veins
   B. Tortuous tributaries
   C. GSV or SSV
   D. For veins close to the skin

Endovascular Therapies for Abdominal Aortic Aneurysm

Ehrin J. Armstrong
John R. Laird

INTRODUCTION

Rupture of abdominal aortic aneurysms (AAAs) accounts for over 15,000 deaths per year in the United States and is the 10th leading cause of death in men older than 55 years of age (Fig. 56-1). Out-of-hospital AAA rupture is associated with a mortality of 80% to 90%. Most deaths are preventable by the early diagnosis and treatment of AAA, and as a result, more than 60,000 surgical or endovascular procedures for AAA are performed annually in the United States. Despite the excellent results of open surgical repair for the prevention of aneurysm rupture, this procedure is associated with significant morbidity and mortality, especially in high-risk patients. Endovascular aneurysm repair (EVAR), which was developed as a less invasive alternative to open surgical repair, is gaining widespread acceptance and is now performed in approximately 80% of elective aneurysm repairs. This chapter reviews the epidemiology, technical aspects, outcomes, and complications of EVAR for the treatment asymptomatic and symptomatic AAA.
FIGURE 56-1 Ruptured abdominal aortic aneurysm. Noncontrast computed tomography scan of a ruptured abdominal aortic aneurysm with extensive retroperitoneal hemorrhage.

EPIDEMIOLOGY AND NATURAL HISTORY OF ABDOMINAL AORTIC ANEURYSM

The incidence of AAA increases with age. Approximately 2.6% of men and 0.5% of women between 45 and 54 years of age have an AAA, and by 75 to 84 years of age, 19.8% of men and 5.2% of women have an AAA.\(^1\) Men are affected 4 to 6 times more frequently than women.\(^2\) AAA is also more common in Caucasian patients than in black, Hispanic, or Asian patients.\(^3\)

Approximately 15% of patients with AAA have a family history of AAA.\(^4\) Because the pathogenesis of AAA is thought to be multifactorial, including disorders of enzymes regulating connective tissue homeostasis, approximately 5% of patients with an AAA have a concomitant thoracic aneurysm and approximately 15% have either a femoral artery aneurysm or a popliteal aneurysm.\(^5\) Synchronous peripheral aneurysms are more common in
men, while synchronous thoracic aneurysms may be more common in women.\textsuperscript{6} Approximately 10\% of AAAs are juxtarenal, and iliac artery involvement occurs in up to 22\% of AAAs.

Patients with AAAs often have significant medical and cardiac comorbidities. Coronary artery disease is found in 40\% to 70\% of patients with AAAs, with evidence of prior myocardial infarction in up to 46\% of patients.\textsuperscript{7} Cerebrovascular disease is present in 25\% of patients, claudication is present in 28\%,\textsuperscript{7} hypertension is present in 55\%, and chronic obstructive lung disease is present in approximately 20\% to 25\%. A history of blunt abdominal trauma is occasionally found; this can lead to both true aneurysms and pseudoaneurysms of the abdominal aorta. Most studies have shown that AAAs are approximately 6 to 7 times more common in smokers, whereas elevated high-density lipoprotein cholesterol (HDL-C) may be protective.\textsuperscript{1} Furthermore, 23\% of patients with a AAA have some form of cancer.\textsuperscript{7} Consistent with these broad comorbidities, approximately 67\% of patients with AAAs die of a cardiovascular etiology.

The aneurysm growth rate, wall tension, and risk of rupture are dependent on aneurysm diameter. Aneurysms less than 5.5 cm in diameter grow at a median rate of 0.2 to 0.3 cm per year, whereas those greater than 5 to 6 cm expand at rates up to 3 cm per year.\textsuperscript{8} The strongest predictor of AAA rupture is aneurysm size. Aneurysms between 5.5 and 5.9 cm in diameter have an estimated annual risk of rupture of 9.4\%, those between 6.0 and 6.9 cm in diameter have an estimated annual risk of rupture of 10.2\%, and those greater than 7 cm have an estimated annual rate of rupture of 32.5\%.\textsuperscript{9} Eccentric or saccular aneurysms have considerably increased wall stress and are thought to have greater rupture risk than fusiform AAA. Patients with chronic obstructive pulmonary disease or asthma may also have a higher risk of rupture, possibly related to allergic inflammation and/or the concomitant use of bronchodilators and steroids.\textsuperscript{10} Patient age and family history of AAA are not consistent independent predictors of rupture.

**TYPES OF ABDOMINAL AORTIC ANEURYSMS**

True aortic aneurysms result from the dilation of the intima, media, and
adventitial layers of the aorta. Relatively uniform and concentric enlargement results in fusiform aneurysm formation. Saccular aneurysms result from eccentric enlargement of the aorta. As previously noted, saccular aneurysms have less uniform wall stress distribution and thus an increased risk of rupture.

Although traditionally attributed to atherosclerosis, AAAs more accurately can be attributed to a degenerative process in the arterial wall. Most AAAs result from the imbalance of connective tissue formation and degradation. Some congenital disorders such as Marfan syndrome and Ehlers-Danlos syndrome predispose to aneurysm development. Inflammatory aortitis is a rare cause of AAA formation. Pseudoaneurysms generally result from abdominal trauma or may occur at a graft anastomosis following previous aortic surgery.

Inflammatory AAAs are a subset (5%-10%) of AAAs, which commonly present as abdominal or flank pain, fever, and constitutional symptoms. On computed tomography (CT), these AAAs usually have a “halo” sign with inflammatory adventitial tissue predominately anterior and lateral to the AAA. Due to the extensive inflammation and fibrosis of surrounding structures, including the duodenum, vena cava, left renal vein, and ureters, an endovascular approach may be preferred.

Mycotic AAAs are fortunately rare. Most commonly, *Salmonella* species or *Staphylococcus aureus* are the etiologic bacteria, although fungal species or other bacteria are sometimes causative. Infected AAAs pose a significant risk to the patient and present many therapeutic challenges. The traditional surgical approach is ligation of the aorta, resection of the infected aneurysm, and extra-anatomic bypass. Antibiotic-soaked grafts or homografts may play a role. There have been case reports and small series involving the endovascular treatment of mycotic thoracic and AAAs. Although successful outcomes have been demonstrated in a few cases, the potential for infection of the endoprosthesis raises significant concerns regarding this treatment approach. Aortoenteric fistulae from AAAs have also been successfully excluded using an endograft.

**MEDICAL THERAPY OF ABDOMINAL AORTIC ANEURYSMS**
Although the basic understanding of the inflammatory and dynamic nature of AAAs has significantly advanced, there is as of yet no effective medical treatment for limiting the expansion of AAA. Based on the premise that aneurysmal growth is dependent in part on the $\delta P/\delta t$ of the aortic pulsation, $\beta$-blockers have been studied in randomized trials but have not shown any reduction in AAA growth rate or mortality.\textsuperscript{15} Angiotensin-converting enzyme (ACE) inhibitors have been shown to reduce the rate of aneurysm expansion in animal models. Some observational studies have suggested an association between ACE inhibitors and a reduced risk of aneurysm rupture,\textsuperscript{16} whereas other studies have suggested accelerated aneurysm expansion with ACE inhibitors.\textsuperscript{17} Two randomized trials of ACE inhibitors or angiotensin receptor blockers in small aneurysms are currently examining this question.\textsuperscript{18,19}

Efforts to reduce the activity of the matrix metalloproteinase (MMP) enzymes with doxycycline in patients with AAA have provided mixed results. Small pilot studies demonstrated that doxycycline reduces the levels of MMP-9 and C-reactive protein (CRP).\textsuperscript{20,21} However, a large clinical trial of doxycycline did not show any benefit in reduction of aneurysm expansion.\textsuperscript{22} Similarly, statin medications have been studied for a possible benefit in stabilization of aneurysm size by pleiotropic effects on reduction of MMP activity. Although observational studies have suggested a possible benefit of statin therapy in reducing aneurysm expansion, meta-analyses have not found a consistent benefit.\textsuperscript{23}

Despite the current lack of an adequate medical treatment for slowing the rate of AAA expansion, all patients with AAA should receive appropriate medical therapy for cardiovascular risk reduction, including smoking cessation, statin therapy, and antiplatelet therapy. Smoking cessation is associated with improved mortality after AAA repair, and smoking cessation may slow the expansion of a preexisting aneurysm.\textsuperscript{24} Treatment with a statin is associated with improved long-term survival after AAA repair, likely due to a reduction in cardiovascular mortality.\textsuperscript{25,26} Antiplatelet therapy may limit thrombus formation within the aneurysm sac, and aspirin therapy is recommended for all patients with AAA for reduction of other cardiovascular events.
REPAIR

The only proven therapy for reduction in mortality from AAA rupture is mechanical aneurysm exclusion or sealing. Elective open AAA repair is associated with a mortality of 2.7% to 7% and may be higher depending on patient comorbidities. Thus, the clinician is faced with balancing the interventional risk of AAA repair with that of continued observation and threat of rupture.

Several trials have been performed to determine the size of an AAA that optimizes the trade-off between risk of AAA rupture and perioperative mortality. These studies have suggested that aneurysms less than 5.5 cm that grow at rates of less than 0.7 cm per 6 months or 1 cm per 12 months may be safely observed. Based on the results of the United Kingdom Small Aneurysm Trial and the Aneurysm Detection and Management Trial, surgery can be reserved for aneurysms larger than 5.5 cm without increasing overall mortality or operative risk.27,28 However, these studies are prefaced on routine AAA surveillance and close patient follow-up and were performed with open surgical repair rather than widespread availability of endovascular techniques for exclusion of the aneurysm. However, one trial (the Positive Impact of Endovascular Options for Treating Aneurysms Early [PIVOTAL]) found no difference in outcomes between endovascular repair and ultrasound surveillance among patients with aneurysms measuring 4 to 5 cm.29

Despite the equivalent overall survival between surveillance and early repair for aneurysms less than 5.5 cm, caution must be used in extending these criteria to underrepresented study groups. Because women have smaller abdominal aortas than men, the criteria for diagnosis of an AAA as well as for intervention for an AAA may not be accurately applied to both genders. Some studies have suggested that a 5.0-cm diameter AAA in women has an equivalent rupture risk to that of a 6.0-cm diameter AAA in men.30 Therefore, the application of a single measurement that is not gender specific or referenced to the patient’s height may not be entirely valid.

Patients with symptomatic AAAs usually present with abdominal pain that may radiate to the flank or groin, abdominal tenderness to palpation, low back pain, or hemodynamic instability related to the retroperitoneal hemorrhage. In addition to the risk of rupture, aneurysms can be associated with a significant risk of embolic complications. Due to the presence of
thrombus or atherosclerotic material within the aneurysm sac, patients may present with evidence of atheroemboli (ie, livedo reticularis), acute renal failure, “blue toe syndrome,” or symptoms of lower extremity arterial insufficiency. Enlargement of the AAA can also cause a mass effect and obstructive symptoms. Obstructive uropathy can occur and is thought to be more common in inflammatory AAAs.

Contained or frank rupture of an AAA demands emergency intervention. Classically, there is severe pain, abdominal tenderness, and shock. The pain is generally sudden in onset and constant, and it may diffusely involve the abdomen or radiate to the flanks, groin, or legs. Occasionally, a ruptured AAA presents as a gastrointestinal hemorrhage or aortocaval fistula. Expeditious diagnosis with an imaging study (usually CT) or direct transfer to the interventional suite or operating room is necessary to reduce the attendant morbidity and mortality of a ruptured AAA.

In summary, the criteria for intervention on an AAA include an aneurysm diameter greater than 5.5 cm in men (perhaps 5.0 cm in women), rapid expansion of an aneurysm (>0.5-0.7 cm/6 months or 1 cm/12 months), or symptomatic aneurysm with either distal embolization from an AAA, aneurysmal mass effect, threatened rupture, or frank rupture.

### OUTCOMES OF ENDOVASCULAR ANEURYSM REPAIR FOR ASYMPTOMATIC ANEURYSMS

The goal of EVAR is to prevent aneurysm rupture and reduce the morbidity and mortality associated with exclusion of the AAA. Successful EVAR exclusion is associated with a progressive reduction in aneurysmal volume at a rate of approximately 3 mL per month and reduction in aneurysm diameter of 4 to 6 mm per year.\(^\text{31}\)

Four randomized trials have compared the outcomes of EVAR to open AAA repair (Table 56-1).\(^\text{32-35}\) Each of these trials enrolled patients with asymptomatic AAA who were candidates for endovascular or open repair. All 4 studies reported lower 30-day mortality with EVAR, with 30-day mortality rates ranging from 0.5% to 1.2% for EVAR and 1.3% to 4.7% for
open surgery. A subsequent meta-analysis found that EVAR is associated with significantly lower perioperative mortality compared with open surgical repair. The long-term mortality in each of the studies did not demonstrate a benefit of EVAR over open AAA repair. These findings may be a result of several factors, most significantly the competing risk of other comorbidities. However, concern has also been raised regarding the long-term implications of placing an endograft, as studies with longer-term follow-up have demonstrated an increased rate of late (>5 years) need for re-intervention and late graft failure. As a result, longer-term surveillance studies remain necessary to confirm the safety and long-term effectiveness of new devices.

Approximately 20% to 40% of patients (approximately 10%-15% per year) undergoing EVAR require subsequent re-intervention for a variety of indications, including endoleak, stent migration, graft limb occlusion, or infection. Late conversion of EVAR to open repair is necessary in approximately 2% to 3% of cases, although the frequency of late conversion may be higher in patients with larger AAAs. Open conversion often requires a more extensive operation in a higher risk patient population and thus carries a 10% to 20% mortality rate. The incidence of late rupture of an AAA after EVAR is thought to be 0.5% at 3 to 4 years and is perhaps more frequent after use of a tube graft. Rupture after EVAR carries a mortality rate similar to native AAA rupture.
ANEURYSM REPAIR FOR RUPTURED ABDOMINAL AORTIC ANEURYSMS

Despite improvements in identification and protocols for immediate treatment, ruptured AAA remains associated with an in-hospital mortality rate of 30% to 50%. Because EVAR is less invasive and may be performed using local anesthesia, the application of EVAR to acutely ill patients with ruptured AAA may reduce in-hospital mortality and minimize complications. A frequently used technique that may also improve outcomes is the immediate percutaneous placement of an aortic occlusion balloon; placement of such a balloon provides time for resuscitation efforts while a definitive decision can be made regarding EVAR versus open surgical repair.\(^4^1\)

A number of observational studies have suggested a mortality benefit of EVAR over open surgery for patients with ruptured AAA. These studies have estimated mortality rates with EVAR of 16% to 30% and of 34% to 44% for open surgery.\(^4^2\) However, criticisms of such studies include the inherent selection bias of EVAR for less critically ill patients and patients with anatomically favorable characteristics.

Compared to the observational literature, randomized studies have not demonstrated a benefit of EVAR over open surgery for ruptured AAA. The largest of these studies was the multicenter IMPROVE trial, which was conducted in the United Kingdom and Canada.\(^4^3\),\(^4^4\) In that study, 613 patients with a presumed ruptured AAA were randomized to a strategy of EVAR versus open surgical repair. At 30 days and 1 year, there was no difference in mortality between the 2 groups. However, several aspects of the study design should be considered. Most importantly, randomization was performed prior to imaging, and as a result, only 64% of patients were felt to have anatomy suitable for EVAR. Additionally, 8.9% of patients were found based on imaging and other evaluation to have a diagnosis other than ruptured AAA. In an as-treated analysis, patients treated with EVAR had numerically lower mortality (25% vs 38%). An additional analysis found that patients treated with local anesthesia had significantly lower 30-day mortality.\(^4^5\)

Based on the available data, rapid imaging can help identify patients with ruptured AAA who are anatomically appropriate for EVAR, and such patients should be approached with an “endovascular first” strategy using
local anesthesia whenever feasible. This approach may help minimize the hemodynamic stress associated with anesthesia and also minimize the postoperative complications of open surgical repair. Recent analyses using large registry data have suggested that the majority of benefit for EVAR in ruptured AAA is in low- to moderate-risk patients, whereas open surgery and EVAR have a similar benefit in high-risk ruptures. However, several barriers remain to implementation of such a strategy outside of specialized centers, including the ability to have EVAR available for unexpected anatomy and rapid availability of an endovascular suite.

ANATOMIC DEFINITIONS AND CONSIDERATIONS FOR ENDOVASCULAR ANEURYSM REPAIR

Aneurysm morphology and the status of the iliac and femoral access vessels dictate whether a patient is a candidate for EVAR. Historically, only 50% to 60% of patients with infrarenal AAAs had suitable anatomy for an endograft. Limitations of EVAR include the length of the infrarenal aortic neck; the diameter of the aneurysm neck; the location of the mesenteric arteries, particularly the celiac axis and superior mesenteric artery; and the proximal neck angulation. Distally, anatomic concerns include the size of the iliofemoral arteries, the presence or absence of calcification, the tortuosity of these arteries, and whether there is aneurysmal dilation of the iliac arteries. Successful exclusion of a common iliac artery aneurysm may require embolization of the internal iliac artery and extension of the endograft into the external iliac artery. In recent years, the development of newer endografts and branched and fenestrated endografts has addressed many of these technical limitations in the endovascular treatment of AAA, and as a result, approximately 80% of AAAs are treated with EVAR.

Aneurysm Neck

The aneurysm neck is the length from the most inferior (main) renal artery to the onset of the aneurysm. Most endografts that are commercially available in the United States are designed for suprarenal fixation, but an adequate seal
zone is necessary to exclude the aneurysm below the renal arteries. The maximal diameter of the nonaneurysmal aortic neck that can be sealed is endograft dependent. The device should be oversized by 10% to 20%. The minimal neck length tolerated is also device specific, although generally for infrarenal fixation, the neck length should ideally be at least 15 mm, especially if angulated (Fig. 56-2). An exception to this is the Ovation device from TriVascular (Santa Rosa, CA), which, due to its novel sealing mechanism, is indicated for EVAR regardless of aneurysm neck length. The angle between the suprarenal aorta and the infrarenal neck (α) and the angle of the flow axis between the infrarenal neck and the body of the aneurysm (β), in which the flow axis is the axis (line) between the distal neck/proximal aneurysm to the aortic bifurcation, should also be measured, because extreme neck angulation may limit successful aneurysm exclusion (Fig. 56-3). Calcification and thrombus of the proximal neck should also be noted, because both of these incrementally add to the morphologic complexity of EVAR.

**FIGURE 56-2** Short aneurysm neck. Left panel: Abdominal aortic aneurysm with short infrarenal aortic neck and diminished flow in the right iliac artery due to iliac
In summary, the neck length should ideally be greater than 15 mm, the neck diameter should be less than 32 mm, α or β should be greater than 150°, and the degree of calcification or thrombus greater than 2 mm thick should be less than 25% of the neck circumference. The risk of adverse outcome after EVAR is directly related to the proximal aortic neck angulation. While modern endografts have in large part addressed the anatomic limitations, studies investigating the on-label versus off-label use of endografts have found that off-label use is associated with a higher risk of long-term complications and need for re-intervention.\textsuperscript{47}

\textbf{Arterial Branches of the Abdominal Aorta}
To anticipate and prevent type II endoleak, it is also important to assess for branch arteries off the aneurysm. The lack of patent lumbar arteries, inferior mesenteric artery, or accessory renal artery off the aneurysm sac should reduce the chance of type II endoleak. However, in current practice, these branches are excluded even if patent, and pre-intervention embolization is not generally considered necessary.

**Iliac Arteries**

The anatomy of the iliac arteries is important with regard to the deliverability and proper sealing of endografts. Preoperative assessment should include measurements of the diameter of the common and external iliac arteries and length of the iliac landing zone. The external iliac artery generally needs to be at least 6 to 6.5 mm in diameter to allow passage of the majority of commercially available devices. The iliac arteries should also be evaluated for the presence of ectasia, stenosis, calcification, and tortuosity. Aortoiliac tortuosity and calcification affect device deliverability and are associated with a more complex EVAR procedure. Maintenance of patency of at least 1 of the internal iliac (hypogastric) arteries is important to preserve pelvic blood flow and to prevent buttock claudication and intestinal ischemia (see below).

**CURRENT ENDOVASCULAR ABDOMINAL AORTIC ANEURYSM DEVICES**

In 1999, the AneuRx device (Medtronic, Santa Rosa, CA) and the AnCure device (Guidant Endovascular Solutions, Menlo Park, CA) were approved by the US Food and Drug Administration (FDA) for clinical use and harkened in the era of endovascular aortic aneurysm repair. The AneuRx device was a modular, bifurcated stent graft with thin, polyester graft material fully supported by a nitinol stent framework. This device was later supplanted by newer stent graft designs from Medtronic (Talent, Endurant) and is no longer in clinical use in the United States. The AnCure stent graft was a unibody, bifurcated polyester graft that was not fully supported by stent.
More closely approximating the traditional surgical bifurcated graft, the AnCure device had a nitinol stent ring at the proximal and distal attachment sites with active fixation barbs.\textsuperscript{50} While early studies demonstrated efficacy of this device, excessive perioperative complications with AnCure led to its withdrawal from the market in 2003.

Several EVAR devices have since been approved by the FDA for the treatment of infrarenal AAA. Each device has unique features that may provide benefit in certain anatomic substrates (Table 56-2). Many of these devices incorporate a suprarenal bare stent (with or without attachment hooks/barbs) to provide secure proximal fixation and to reduce the risk of device migration. A wide array of device diameters and lengths along with aortic and iliac extender cuffs are available to customize these devices for complex and varied patient anatomy. Over the years, devices with larger aortic and iliac diameters have been approved to expand the percentage of patients who can be treated with EVAR. More recently, a fenestrated stent graft was FDA approved to facilitate treatment of patients with juxtarenal aneurysms.\textsuperscript{51} Branch grafts have also become available to help maintain patency of the internal iliac artery when there is extension of aneurysm to the iliac bifurcation.\textsuperscript{52} Continued evolution of device design has allowed for lower profile, more flexible delivery systems that can be delivered through the iliac arteries more easily, thereby reducing the risk of iliac rupture or dissection. Due to the advent of these lower profile devices, EVAR can now be performed percutaneously in a large percentage of cases.

\textbf{Table 56-2} \textbf{FDA-Approved EVAR Devices}
The Excluder stent graft (Gore and Associates, Flagstaff, AZ) was FDA approved in 2002. The Excluder device is a modular, bifurcated endoprosthesis with expanded polytetrafluoroethylene (ePTFE) graft material fully supported by nitinol stent rings. This device does not have suprarenal fixation but has an ePTFE sealing cuff and proximal nitinol anchors. A lower permeability graft material was introduced in 2004. The C3 delivery system was introduced in 2010 for more precise and controlled deployment of the device. The latest version of the Excluder is available in aortic diameters up to 35 mm and iliac limb diameters up to 27 mm. The 23- and 26-mm devices can be delivered through a 16-Fr sheath.

The Zenith stent graft (Cook Medical, Bloomington, IN) was approved by
The Zenith device is a modular, 3-piece, bifurcated endoprosthesis with woven polyester graft material fully supported by stainless steel stents. This device is distinguished by bare metal stent suprarenal fixation and proximal retention hooks. The newest version (Zenith Flex) incorporates a hydrophilic delivery sheath with trigger-wire release mechanism for precise placement. Main body diameters up to 36 mm and iliac diameters up to 24 mm are available. Smaller devices (up to 26 mm) can be delivered via an 18-Fr delivery system. An aorto-uni-iliac version of this device (Renu Ancillary Graft Converter) is available and may facilitate secondary endovascular intervention in patients who have received prior endovascular repair. The Zenith Fenestrated EVAR device was more recently approved by the FDA for treatment of challenging neck anatomy that is unsuitable for a conventional, nonfenestrated graft. The Zenith Fenestrated device incorporates up to 3 holes (fenestrations) and cutouts from the proximal margin of the graft material to maintain patency of the renal arteries and superior mesenteric artery when sealing with the stent graft across the juxtarenal segment of the aorta.

The Powerlink stent graft (Endologix, Irvine, CA) was approved by the FDA in 2004. This is a unibody, bifurcated endoprosthesis with ePTFE graft material fully supported by a cobalt-chromium stent. The most recent iteration of this device is the AFX endovascular system. The AFX device is differentiated from other EVAR devices by its unique delivery mechanism, unibody design, and method of fixation. Fixation is not achieved by the usual mechanism of suprarenal bare metal stent and attachment hooks but rather is achieved by buttressing the bifurcation of the AFX device at the native aortoiliac bifurcation. Maintaining the native aortoiliac bifurcation has the advantage of preserving options for future contralateral access for the treatment of lower extremity occlusive disease. The AFX device is available in aortic diameters up to 32 mm and iliac diameters up to 20 mm. The main body can be delivered via a 17-Fr delivery sheath.

The Talent stent graft (Medtronic) was approved by the FDA in 2008. The Talent device is a modular, bifurcated design consisting of polyester graft material fully supported by nitinol stent rings and full-length connecting bar. There is a bare metal proximal stent for suprarenal fixation. This device was supplanted by the next-generation stent graft from Medtronic, the Endurant, which was FDA approved in 2010. The Endurant is also a 2-piece, modular, bifurcation stent graft with proximal bare metal stent and
anchor pins from suprarenal fixation. The most recent iteration of this platform is the Endurant II stent graft system, which is available in 2-piece and 3-piece modular configurations (Endurant IIs). The Endurant II device is available in aortic diameters up to 36 mm and iliac diameters up to 28 mm. Main body diameters up to 28 mm can be delivered via an 18-Fr delivery system. An aorto-uni-iliaic version of the device is also available.

The Ovation stent graft (Trivascular, Santa Rosa, CA) was approved by the FDA in 2012. The Ovation device has a unique modular, bifurcated design with ePTFE graft material and polymer sealing rings in the main body along with proximal bare metal stent with attachment hooks for suprarenal fixation. The iliac limbs are fully supported by nitinol stent rings. The main body O-rings fill with a conformable polymer and are designed to achieve a watertight proximal seal without chronic outward force on the infrarenal aortic neck. Another unique feature of the Ovation device is the low-profile, flexible delivery system. The majority of sizes can be delivered via a 14-Fr delivery system. The Ovation device is available in aortic diameters up to 34 mm and iliac diameters up to 28 mm.

The Aorfix endovascular stent (Lombard Medical, Oxfordshire, United Kingdom) was approved by the FDA in 2013. The Aorfix is a modular, bifurcated endoprosthesis with polyester graft material and a unique nitinol framework that combines circular and helical structures to provide added flexibility and conformability in tortuous anatomy. The Aorfix has a unique approval from the FDA for treatment of aneurysms with up to 90° of neck angulation. The Aorfix device is available in aortic diameters up to 34 mm and iliac diameters up to 20 mm. The main body is delivered via a 22-Fr delivery system.

Investigational Devices

Continued device development and technologic advances will lead to lower profile versions of the current EVAR devices (eg, Zenith LP) as well as newer low-profile stent graft systems. The Incraft device (Cordis, Freemont, CA) is a low-profile stent graft that is currently undergoing clinical investigation in the United States. Incraft is a modular, bifurcated stent graft that is delivered via a low-profile, 14-Fr integrated sheath. In addition to incremental improvements in device profile, efforts will continue to be directed toward expanding the reach of endovascular AAA repair to patients.
with suboptimal or inadequate infrarenal aortic neck anatomy. There will be alternative branched graft and fenestrated technologies to allow noncustomized, simpler, off-the-shelf solutions for patients who are not candidates for traditional infrarenal fixation.

Current and future approaches to the endovascular treatment of AAA may shift the focus to treating the aneurysm sac. The Nellix system (Endologix, Irvine, CA) is the first such device that focuses on filling the aneurysm sac rather than the traditional approach of relying on proximal neck fixation with subsequent aneurysm sac exclusion and depressurization. This system incorporates 2 balloon-expandable ePTFE-covered cobalt-chromium alloy stents surrounded by a set of 2 thin-walled polyester polymer–filled endobags that are designed to completely fill the aneurysm sac and freeze the sac in a definitive and permanent manner. Such an approach has the potential to reduce or eliminate the possibility of type II endoleak and reduce the need for secondary interventions. Initial experience with this device has been promising, and it is currently undergoing clinical investigation in the United States.

Parallel Grafts, Chimneys, Periscopes, and Snorkels

A variety of innovative techniques have been developed in order to expand the patient population with AAA that can be successfully treated by an endovascular approach. It has been estimated that roughly 60% of patients with AAA can be treated with commercially available EVAR devices according to the FDA-approved indications in the instructions for use (IFU). A common limitation for traditional EVAR devices is the lack of an adequate infrarenal neck for proximal fixation. Although fenestrated and branched devices have been developed to overcome the limitations of currently available devices, fenestrated devices may not be practical or possible to use in many cases. In particular, customized fenestrated grafts cannot be used in urgent or emergent settings, as they require time for manufacture. Greenberg and colleagues were the first to describe a “chimney” or “snorkel” graft technique to preserve renal artery flow when a proximal seal zone above the renal artery origin was required (Fig. 56-4). Subsequent publications have documented the safety and efficacy of this approach for a wide variety of clinical scenarios and anatomic substrates. A chimney or snorkel procedure involves deployment of stent grafts into 1 or more aortic visceral
branches and deployment of an aortic endograft such that the proximal parts of the visceral stents are placed parallel to the main aortic endoprosthesis (between the wall of the aorta and the aortic stent) and extend above or beyond it to ensure perfusion of the visceral organs. This technique is also commonly referred to as the “parallel graft” technique. The parallel graft technique is possible using a variety of off-the-shelf technologies, including commercially available EVAR devices and either balloon-expandable (Atrium iCAST; Atrium Medical, Hudson, NH) or self-expanding (Viabahn; WL Gore, Flagstaff, AZ) covered stents.

Moulakakis and colleagues published a review of the early experience with the chimney graft technique in 2012. They reviewed 15 reports that included 93 patients, of whom 24.7% were treated in an urgent setting. A total of 134 chimney grafts were implanted. Primary technical success was
achieved in all cases. A total of 13 patients (14.0%) developed a type I endoleak. Three were detected and treated during the index procedure. Four additional patients required a secondary intervention in the postoperative period. The 30-day in-hospital mortality rate was 4.3%. During a mean follow-up of 9.0 months, 97.8% of the chimney grafts remained patent.

A larger, multicenter registry (PERICLES Registry) provided additional insight regarding the safety and effectiveness of this approach. A total of 517 patients treated over a 6-year period at centers in the United States and Europe met the criteria for enrollment in the registry. The most common endografts employed were the Endurant and Zenith devices. Overall, 898 chimney grafts were placed in 694 renal arteries, 156 superior mesenteric arteries, and 50 celiac arteries. A mix of 49.2% covered balloon-expandable stents, 39.6% self-expanding covered stents, and 11.2% balloon-expandable bare metal stents were deployed. A type I endoleak was noted intraoperatively in 7.9% of cases. In 2.9% of cases, there was persistence of the type I endoleak despite corrective measures, resulting in a technical success rate of 97.1%. The 30-day mortality rate was 4.9%. At a mean follow-up of 17.1 months, primary patency of the grafts was 94%, and secondary patency (patency following reintervention) was 95.3%. Overall survival in this high-risk patient population at latest follow-up was 79%.

These reports suggest that a parallel graft or chimney EVAR approach is a reasonable option for patients presenting with a juxtarenal or pararenal aneurysm, particularly in urgent or emergent situations where a customized fenestrated graft is not an option. This strategy provides an off-the-shelf solution that is reasonably safe and effective, with satisfactory mid-term patency rates for the parallel grafts. Although the frequency of type I endoleak appears acceptably low, the potential for “gutter leaks” around the parallel graft and questions about the long-term durability of this approach lead many to favor a fenestrated graft solution when feasible.

**Fenestrated Grafts**

There is currently 1 fenestrated stent graft available in the United States for clinical use (Zenith Fenestrated Graft; Cook Medical), with numerous other fenestrated devices in various stages of clinical investigation (Fig. 56-5). As previously noted, the Zenith Fenestrated device incorporates up to 3 holes (fenestrations) and cutouts from the proximal margin of the graft material to
maintain patency of the renal arteries and superior mesenteric artery when sealing with the stent graft across the juxtarenal segment of the aorta. This device received FDA approval in 2012 based on results from a multicenter prospective clinical trial.\textsuperscript{51} A total of 67 patients were enrolled at 14 centers in the United States from 2005 to 2012. A total of 178 visceral arteries required incorporation with 118 small fenestrations, scallops in 51, and large fenestrations in 9. All were aligned by stents. Technical success was achieved in 100\% of cases. The 30-day mortality rate was 1.5\%. No aneurysm ruptures or conversions occurred during a mean follow-up of 37 ± 17 months. At 5 years, patient survival was 91\% ± 4\%, and primary and secondary patency of targeted renal arteries was 81\% ± 5\% and 97\% ± 2\%, respectively.

\textbf{FIGURE 56-5} Fenestrated endovascular aneurysm repair graft. A. The Zenith fenestrated graft with 2 fenestrations for the renal arteries and scallop for the superior mesenteric artery. B. Schematic showing deployment of the fenestrated graft across the renal arteries with renal stents implanted through the fenestrations.

The remarkably good results from this early experience with fenestrated grafts (high technical success, low 30-day mortality, no conversion or rupture, and high secondary renal artery patency) provide support for this approach to the treatment of patients with juxtarenal aneurysms and stand in stark contrast to results with traditional open surgical repair. Comparisons between the 2 approaches have shown that endovascular repair with fenestrated grafts is associated with significantly reduced mortality,
morbidity, and renal dysfunction compared to open repair.\textsuperscript{68,69} Tsilimparis and colleagues\textsuperscript{69} reported that open repair was associated with a 5-fold increase in mortality (5% vs 1%) and 2-fold increase in complications (40% vs 20%) compared to fenestrated EVAR. Current limitations to a fenestrated graft approach include the need to customize the fenestrated graft based on precise measurements from the CT scan with resultant delays in treatment pending manufacture of the device. Current fenestrated graft approaches are not feasible in the setting of ruptured aneurysm or other acute aortic syndromes. In addition, technical expertise is required for these cases, and fenestrated EVAR procedures are often long, difficult, and associated with significant radiation exposure for the operator and the patient.

**PROCEDURAL OUTLINE**

**Preintervention Imaging**

Preintervention imaging with contrast-enhanced CT with CT angiography is crucial for preoperative planning. To adequately visualize the aneurysm and make the appropriate measurements, 1- to 2-mm cuts are required. CT angiography can rapidly acquire high-resolution images, which can be postprocessed, producing 3-dimensional reconstructions. Other valuable procedural data, including aneurysm dimensions, angles, thrombus content, extent of calcification, and iliofemoral artery dimensions, can be obtained. Propriety software programs provide very accurate measurements of vessel diameter by reformatting raw data to create slices perpendicular to blood flow. Accurate length measurements are obtained via a computer-generated centerline. Vessel angulation is also easily calculated. With modern reconstruction techniques, it is often possible to plan the specific device sizes and lengths prior to starting the procedure. This detailed preprocedural planning also allows for consideration of alternative strategies or treatment approaches in the event of an intraprocedural complication.

Other methods for imaging AAAs include magnetic resonance (MR) imaging/angiography, digital subtraction angiography (DSA), and intravascular ultrasound (IVUS). MR imaging/angiography has the advantage of using the less nephrotoxic contrast agent gadolinium. However, MR imaging/angiography does not adequately visualize calcification of the
aneurysm wall, and image acquisition time is much longer. IVUS has also been used as an alternative or adjunct to other imaging modalities. IVUS allows precise diameter measurements, accurate assessment of the quality of the aortic neck (eg, thrombus, calcification, confirmatory length measurements), and precise evaluation of the degree of calcification in the iliac arteries. Angiography (or DSA) can define the aneurysm length and side branches but cannot adequately define the aneurysm size, extent of thrombus, or calcification. Duplex examination has a very limited role in endovascular planning. Before intervention, ultrasound is best used for diagnosis, whereas after intervention, it has a role in identification of endoleaks and measurement of aneurysm size and pulsatility.

The Endovascular Suite

Depending on the capabilities of a given institution, EVAR may be performed in an interventional radiology suite, cardiac catheterization laboratory, or operating room. An endovascular suite should have the capabilities of a standard operating theater, including utilization of special air filtration systems and laminar flow. An anesthesiologist and equipment should also be available to provide patient sedation for the procedure and in the event of emergent conversion to an open repair. Nurses and technologists capable of functioning as scrub nurses and circulators must be available for operative assistance.

The endovascular suite also needs to provide optimal radiographic imaging. The image intensifier should provide at least a 12-inch field of view; in cases of complex anatomy, a more magnified view may be desirable. The image-processing equipment should be capable of DSA and road mapping, and a power injector needs to be available for aortography. Whether the endovascular suite is in the cardiac catheterization laboratory, radiology department, or operating room, catheters, guide wires, balloons, stents, and other equipment necessary for successful EVAR should be readily available. In particular, an aortic occlusion balloon should be available in the event of vessel perforation or aneurysm rupture. These balloons are elastomeric and capable of rapidly and relatively atraumatically occluding distal aortic flow, providing temporary control of the situation.
Preintervention Hypogastric Artery Exclusion Procedures

A significant percentage (20%-30%) of AAAs extend beyond the aortic bifurcation to involve the iliac arteries. To minimize the chances of type II endoleak at the distal attachment site in the iliac artery, it is occasionally necessary to extend the graft into the external iliac artery. To provide for complete exclusion of the iliac/aortic aneurysm, it is necessary to occlude the ipsilateral hypogastric artery prior to doing so. Some practitioners have taken the approach of occluding (coils or plug) the internal iliac artery prior to the endograft deployment procedure. Such a staged approach may allow collaterals to develop and gives the interventionist the chance to observe the patient’s response to the hypogastric artery embolization. For those cases in which bilateral common iliac artery aneurysms are present and the patient is clearly not a candidate for open surgical repair, staged occlusion of both hypogastric arteries has been performed. Alternative techniques for hypogastric preservation include use of an additional self-expanding stent to “snorkel” the internal iliac inflow, as discussed earlier. A branched iliac device was also recently approved by the FDA and will have an important role in the treatment of AAA with concomitant iliac aneurysm.

With unilateral hypogastric artery occlusion, there is a 13% reduction in the penile brachial index, up to a 38% incidence of erectile dysfunction, and a 39% to 50% chance of hip or buttock claudication. The occlusion of bilateral hypogastric arteries is associated with a 28% to 55% incidence of pelvic ischemia. Bilateral hypogastric artery embolization results in a 39% reduction in the penile brachial index, a 50% incidence of erectile dysfunction, and an approximately 50% chance of hip or buttock claudication. Most patients have improvement or resolution of these symptoms over time, but this may occur over several months (mean, 14 months). Other reported complications after bilateral internal iliac artery embolization include scrotal skin sloughing, sacral decubitus ulceration, and intestinal ischemia. Having a diseased profunda femoris artery with a stenosis greater than 50% is associated with a higher rate of complications.

If the hypogastric artery cannot be spared, and buttock claudication or pelvic ischemia develops, several steps can be taken to help mitigate the symptoms. As noted earlier, it is possible that if the profunda femoris artery is diseased, profundoplasty may improve symptoms. Regular exercise should be a mainstay of therapy. Cilostazol has not been adequately studied in this

---

70

---
setting but may be of benefit. Finally, treatment of a diseased contralateral hypogastric artery may be necessary. Surgical hypogastric artery reimplantation via a retroperitoneal incision may also become necessary in recalcitrant settings. In the event that both hypogastric arteries need to be occluded, sufficient staging should be performed, with at least 3 weeks between each embolization.

Covering the hypogastric artery with the endograft limb without coil embolization is another option if there is no aneurysmal involvement of the distal common and proximal external iliac arteries. By covering but not coiling the hypogastric artery, the chances of distal embolization into the small branches of the hypogastric artery are reduced and the likelihood of maintaining collaterals is enhanced. There is a trend toward both a reduced rate and severity of complications with this approach. Adequate sealing zones both in the distal common iliac artery and the proximal external iliac artery are necessary. In suitable patients, type II endoleak is similar between covering and embolizing the hypogastric artery. Other procedures such as surgical bypass and proximal ligation of the internal iliac artery, using an aorto-uni-iliac endograft, and occlusion of the contralateral common iliac artery in conjunction with a femoral-femoral bypass (allowing for retrograde perfusion of the internal iliac artery) are also considerations.

**Arterial Access**

For the vast majority of endografting procedures for AAA, a bilateral femoral approach is used. Depending on the common femoral access and the size of the device being used, a surgical cutdown may be necessary. There are 2 basic types of incisions for the femoral cutdown—vertical and oblique. Small oblique incisions can be used in the great majority of cases and are associated with a lower risk of wound complications. The wound complication rate has been reported to be as high as 7% to 18% for vertical incisions and 0% to 2.8% for oblique incisions. In addition, subsequent femoral access or reoperation is more easily achieved following an oblique incision.

Fully percutaneous EVAR is increasingly performed in many centers. In the majority of cases, the “preclose” technique is used with the Perclose closure device (ProGlide or Prostar XL; Abbott Vascular, Santa Clara, CA). Either the ProGlide or Prostar XL devices may be used for percutaneous large-bore sheath closure. The ProGlide closure device is a 8.6-Fr device with
2 needles and a single monofilament suture with a pretied knot. It is FDA approved for closure of up to 21-Fr sheaths. Two ProGlide devices are generally required for each large-bore sheath closure. The Prostar XL is a 12-Fr device that has 4 needles and 2 braided sutures. The operator ties the knot (usually a fisherman’s knot). The Prostar XL is approved for closure of 10-Fr sheaths in the United States and 24-Fr sheaths in Europe. When percutaneous EVAR is planned, anterior wall puncture of a nondiseased segment of the common femoral artery is essential. This is best performed with ultrasound guidance, but can be performed using fluoroscopic or angiographic landmarks. Using the double ProGlide technique, initial access is gained to the common femoral artery using a smaller 6-Fr sheath. The first ProGlide device is deployed, and then a second device is inserted 45° to 90° to the first to avoid duplicate suture entry sites. The arteriotomy is then progressively dilated, and the endograft delivery sheath is finally inserted. The contralateral limb is generally deployed through a smaller sheath, which can be closed with either 1 or 2 sutures depending on the sheath size. At the time of removal of the large sheath, closure can initially be performed over a 0.035-inch guide wire. If adequate hemostasis is not achieved, a third ProGlide device can be used. If the Prostar XL technique is employed, usually only 1 device is required for each access site. The Prostar XL is more cumbersome and challenging to use, but has been associated with high technical success rates and a low rate of conversion to surgical closure. A large prospective multicenter study and a smaller randomized trial have evaluated both percutaneous closure techniques and found them to have success and complication rates comparable to surgical cutdown.\textsuperscript{74,75} Advantages to a fully percutaneous procedure include less bleeding, earlier recovery, no incision, and perhaps earlier ambulation.\textsuperscript{76,77} This approach requires proper patient selection, with particular attention paid to femoral artery size and the degree of calcification of the femoral artery. Failure of the percutaneous closure mandates prolonged manual compression and possible surgical exploration.

\textbf{Intraoperative Imaging}

Good-quality intraoperative fluoroscopy and angiographic technique is required for precise endograft deployment. Accurate localization of the mesenteric and renal arteries is necessary to avoid inadvertent occlusion of these vessels and to document the proximal extent of the aneurysm. This is
generally accomplished by placement of an angiographic catheter via the contralateral femoral artery or radial/brachial artery. A pigtail or similar multihole angiographic catheter is inserted and advanced to a juxtarenal position. From this position, angiograms are taken during the deployment process to guide precise endograft positioning just below the renal arteries. Use of an angiographic “road map” or bony landmarks may be helpful, but neither method is sufficient for precise deployment. Another useful technique is to trace on the monitor with a marker the outline of the aorta and its major branches to serve as a guide. As long as the patient and image intensifier do not move, this method can assist in positioning of the endograft.

Postdeployment imaging is important to establish if the aneurysm is successfully excluded, to evaluate the patency of the renal and hypogastric arteries, and to evaluate for evidence of dissection of the external iliac arteries. Because the delivery sheaths are large relative to the common femoral artery, they may impede antegrade flow to the lower extremities, and adequate visualization of the iliac and femoral arteries may prove difficult. A retrograde sheath injection may be helpful. Another technique to allow for adequate opacification of the iliac arteries is to attach a 50-mL syringe to both sheath side ports. During aortography, as the contrast is injected, 2 operators manually aspirate from the syringes. This creates enough antegrade flow in the iliac arteries to allow for adequate visualization. The aspirated blood can then be returned to the patient.

Inadvertent renal artery occlusion is a rare complication of EVAR. Covering the renal artery during endograft deployment or as a result of subsequent endograft migration across a renal artery can lead to azotemia and ischemic nephropathy. Partial obstruction of the renal artery can be treated by insertion of a balloon-expandable stent into the renal artery. If complete renal artery occlusion occurs following endograft deployment, the options for salvage of the kidney are limited. If the endograft is not completely deployed, either resheathing or manually pulling the graft caudally may be sufficient to uncover the renal artery. Once the endograft is fully deployed, one option is to use the “dental floss” technique to displace the graft caudally. This will not be a good option if there is suprarenal fixation with attachment hooks/barbs. With the dental floss technique, a guide wire is advanced across the bifurcation of the endograft, snared from the contralateral iliac artery, and then externalized through the contralateral sheath. Traction on both ends of the wire may be sufficient to pull the endograft down and thus uncover the
renal artery. Placing a catheter over the wire across the bifurcation of the graft and pulling on the catheter may reduce the potential for damage to the graft by the guide wire.

**Postprocedure Surveillance Imaging**

Long-term endograft surveillance is required to document continued exclusion of the aneurysm by the endograft (Fig. 56-6). Imaging protocols vary depending on the institution. Following an uncomplicated EVAR, imaging is usually performed at 1 month, 6 months, and 12 months after procedure, and annually thereafter. If an endoleak is detected, immediate intervention may be required (as in the case of a type I or III endoleak), or the surveillance protocol may need to be modified. If a type II endoleak is identified or there is an endoleak of undetermined type, imaging every 6 months or sooner may be necessary.
FIGURE 56-6 Aneurysm regression after endovascular exclusion. A and B. Baseline computed tomography of large abdominal aortic aneurysm with minimal mural thrombus. C. Successful result following endovascular aneurysm repair with flow in main body and iliac limbs without evidence of endoleak. D. Follow-up abdominal ultrasound shows evidence of sac shrinkage.

Helical CT with intravenous contrast and thin slices is the preferred method of post-EVAR imaging. The techniques for CT in this setting are well established and standardized. The equipment is readily available in almost all centers, and extensive literature supports its use. Delayed imaging may be necessary to detect endoleaks in some cases.

Color Doppler ultrasound (CDU) has the advantage of being less expensive than CT and avoids radiation exposure and the use of nephrotoxic contrast agents. The sensitivity of CDU for detecting endoleak ranges from
77% to 97% and may be increased by the use of ultrasound contrast agents. Furthermore, CDU can assess physiologic parameters of the aneurysm such as pulsatility and can provide accurate measurements of the aneurysm sac dimensions and circumference. However, CDU is operator and patient dependent, and its major limitation is the inability to consistently provide adequate diagnostic images.

With the increasing use of EVAR and the need for long-term surveillance, one problem is a lack of necessary patient and physician follow-up. In a recent study, 50% of patients who had undergone EVAR were lost to follow-up after 5 years and were therefore not undergoing necessary surveillance imaging.  

**COMPLICATIONS OF ENDOVASCULAR ANEURYSM REPAIR**

*Endoleak*

Endoleak is the persistent flow of blood into the aneurysm sac after EVAR. There are 4 types of endoleak.  

1. Type I endoleak results from flow into the sac due to inadequate seal at either the proximal (type IA) or distal (type IB) attachment sites.
2. Type II endoleak occurs as a result of retrograde flow into the sac through a branch vessel (eg, accessory renal artery, lumbar artery, internal iliac artery, median sacral artery, gonadal artery, or inferior mesenteric artery).
3. Type III endoleak refers to a leak through the graft itself—either at the junction of modular components or because of a defect in the graft material.
4. Type IV endoleak is not truly an endoleak at all. This instead refers to the tendency of some grafts to be porous for a short period of time after insertion in the body. CT scans in the early postoperative period may demonstrate contrast in the aneurysm sac due to extravasation of contrast through the interstices of the stent-graft.

Endoleaks can be further categorized as primary or secondary. Primary
Endoleaks occur in the first 30 days after EVAR, whereas secondary endoleaks are detected more than 30 days after EVAR.

Endoleak results in continued pressurization of the aneurysm sac and may increase the risk of rupture following an otherwise successful EVAR. Between 20% and 40% of patients develop endoleaks after EVAR. The rate of endoleaks for aorto-uni-iliac endografts may be as high as 52.3%. Type I and III endoleaks are thought to result in the highest sac pressures and thus necessitate immediate intervention. Type II endoleaks are generally more benign and can be observed. Many type II endoleaks resolve spontaneously. Close attention must be paid to the size of the type II endoleak as well as the diameter and volume of the aneurysm sac. If there is growth of the aneurysm sac, consideration should be given to treatment of the type II endoleak. In rare cases, type II endoleaks can result in continued aneurysm pressurization, growth, and ultimate rupture.

**Type I Endoleak**

Type I endoleak can occur early after EVAR due to failure to achieve an adequate proximal or distal seal at the time of the procedure. Delayed type I endoleak may occur due to morphologic changes in the aorta or iliac arteries. Over time, there may be continued dilation of the proximal aortic neck or iliac arteries such that stent graft apposition to the vessel wall may be lost. In addition, as the aneurysm sac diameter and volume decrease, the resultant morphologic changes may lead to endograft migration.

Failure of stent-graft apposition at the proximal or distal attachment sites leads to repressurization of the aneurysm sac, with aneurysmal enlargement and possible rupture. Risk factors for the development of type I endoleak include a short proximal neck (<15 mm), the use of proximal extender cuffs, AAA diameter greater than 5.5 cm, severe neck angulation (<120°), and proximal neck calcification. Oversizing of the proximal endograft by at least 10% to 20% is thought to reduce the rate of type I endoleak.

There may be differences in the significance of proximal attachment endoleaks (type IA) depending on whether the endograft is supported or unsupported. Type IA endoleaks in fully supported endografts are unlikely to spontaneously resolve and should be treated if present at the time of endograft implantation. Treatment of type IA endoleak can be initially attempted with balloon dilation of the proximal attachment site. If this fails,
then deployment of a proximal extension cuff or balloon-expandable stent is necessary. There are reports of selectively coiling the gap between endograft and the arterial wall for type I endoleak. This technique should be reserved for cases in which there is an inadequate landing zone for an extension cuff and use of an uncovered stent is not appropriate.

Distal attachment site endoleaks (type IB) occur more commonly in the setting of iliac tortuosity, iliac artery ectasia, or iliac artery calcification. Regardless of the type of endograft (supported or unsupported), type IB endoleaks should be treated at the time of their discovery. Treatment of type IB endoleaks is generally accomplished with either the placement of an uncovered stent or endograft extension.

The use of devices with suprarenal fixation has been recommended for patients with short or angulated infrarenal aortic necks. Such devices do not appear to confer a lower type I endoleak rate if the aortic neck anatomy is favorable. For those with inadequate neck length, however, suprarenal fixation may be preferred to minimize the risk of late graft migration. Proximal aneurysm neck dilation (>3 mm) occurs in up to 28% of EVAR in the midterm (2 years), although only 20% of these require intervention. An increased risk of proximal aneurysm neck dilation is related to circumferential thrombus within the neck, pre-EVAR neck diameter, and pre-EVAR AAA diameter.\(^3\) Treatment for neck enlargement includes continued observation unless there is endoleak or suspicion of endotension. In such cases, either proximal extension cuffs are used or the patient may need to undergo conversion to open repair. The initial oversizing of the proximal endograft by 10% to 20% is perhaps the most important preventive strategy to reduce the chances of type I endoleak if aneurysm neck dilation does occur.

**Type II Endoleak**

As previously described, if there is stabilization or reduction in aneurysm volume, then intervention for type II endoleak is usually not required. In cases where a higher likelihood of type II endoleak is anticipated, some experts have advocated pre-EVAR embolization of branch arteries, use of thrombogenic AAA sac packing at the time of EVAR, or laparoscopically assisted side branch ligation. When prophylactically or primarily treating type II endoleak, it should be kept in mind that type II endoleak is generally
benign; its treatment should not be at an excessive risk of morbidity and mortality to the patient.

The diagnosis of type II endoleak can sometimes be challenging. If contrast-enhanced CT imaging is used to identify type II endoleak, it is important to recognize that branch flow into the aneurysm sac can be slow, necessitating delayed enhancement images. Contrast-enhanced ultrasound scanning is accurate in detecting endoleak and identifying the source artery. Spontaneous sealing often occurs within 12 months. Type II endoleak can be treated with selective arterial coiling, laparoscopic ligation, or translumbar embolization (Fig. 56-7). Successful treatment of type II endoleak is associated with a reduction in aneurysm surface area.

**FIGURE 56-7** Type II endoleak. Left panel: Type II endoleak caused by retrograde flow through the inferior mesenteric artery (arrow). Right panel: The endoleak is resolved following coil embolization of the inferior mesenteric artery near its origin (arrow).

**Type III Endoleak**

Type III endoleak can occur after EVAR due to separation of the modular components (IIIA) or late failure of the graft material (IIIB). Treatment of type IIIA endoleak at the junction of endograft components often requires
insertion of an iliac limb or extension cuff within the original graft (Fig. 56-8). Similarly, a hole in the endograft material can be patched from the inside with another iliac limb or cuff. If there is complete separation of the endograft limb from the main body, the endograft limb may be pushed into the aneurysm sac and a new limb inserted. More commonly, the disjointed endograft limb is recannulated and extension cuffs are placed to connect the limb and main body.

**FIGURE 56-8** Type III endoleak. A type III endoleak occurs due to late failure of the graft material.

During the procedure of placing new endograft extension cuffs, it is critical to confirm intraluminal placement.

**Type IV Endoleak**

Until the graft becomes impregnated and coated with platelets and fibrin, there may be some contrast “blush” seen in the AAA sac on aortography or contrast CT scan. Type IV endoleak from graft porosity generally resolves within a few weeks after EVAR. It is essential to distinguish graft porosity (type IV endoleak) from type III microleak. The presence of even very small
holes (type III endoleak) in the graft material results in systemic pressurization of the aneurysm sac. The use of color flow duplex imaging can help differentiate these microleaks (type III endoleak) from graft porosity (type IV endoleak).

**ENDOGRAFT LIMB OCCLUSION**

Any endograft deformity, kinking, or stenosis at the time of implantation requires a thorough investigation. Balloon angioplasty of graft limbs, either with standard angioplasty balloons or compliant balloon catheters should be utilized to minimize the risk of subsequent limb occlusion. IVUS may be helpful to evaluate the adequacy of iliac limb expansion. Intraoperative evaluation of endograft limbs by IVUS may result in significantly higher utilization of additional interventions but potentially fewer long-term complications.

Limb thrombosis most commonly (but not always) occurs within 2 months of endograft implantation. Patients can present with atypical leg discomfort, new-onset claudication, or acute limb ischemia. The decision to intervene on the limb depends on the patient’s limitations and the acuity of symptoms. Acutely thrombosed endograft limbs may be treated with open surgical embolectomy (care must be taken to avoid dislocation of modular components during passage of the Fogarty balloon), catheter-directed thrombolysis, or percutaneous thrombectomy with a device such as the Angiojet Rheolytic Thrombectomy catheter (Boston Scientific, Marlborough, MA). After reestablishing flow through the endograft limb, careful evaluation and treatment of predisposing factors such as limb kink, stenosis, or distal dissection are necessary. Risk factors for developing iliac limb occlusions include smaller limb diameter, limb stenosis, unsupported endografts, and the extension of the graft into the external iliac artery.

A cautionary note to the use of aorto-uni-iliac endografts with femoral-femoral bypass is the dependence of the entire lower extremity arterial circulation on the inflow from the endograft. Acute occlusion of this graft results in bilateral lower extremity ischemia with its attendant morbidity, risk of reperfusion syndrome, and mortality.
ENDOGRAFT MIGRATION

Endograft migration occurs in up to 15% to 45% of patients depending on the time frame of evaluation and the definition used for endograft migration (usually, 5-10 mm). The likelihood of endograft migration increases with time, with most occurring at a mean of 20 months after EVAR. Nearly 50% of patients with endograft migration require repeat interventions, including the placement of proximal extension cuffs. Risk factors for endograft migration include neck dilation of 10% or more and pre-EVAR AAA diameter greater than 5.5 cm. The potential for endograft migration emphasizes the need for routine imaging follow-up in patients after EVAR.

CONCLUSION

The endovascular treatment of AAAs has been shown to reduce the morbidity and early mortality associated with aneurysm repair compared with a traditional open surgical approach. EVAR has become the most common method for treatment of AAA, despite the recognition that the long-term outcomes of EVAR are similar to those of open surgery. There has been continuous evolution of devices and techniques for EVAR, and EVAR outcomes will likely continue to improve. Percutaneous EVAR can now be performed in the majority of cases, further reducing the morbidity associated with aneurysm repair. Novel techniques such as chimney, snorkel, and parallel grafts have made it possible to treat juxta- or pararenal aneurysms with an endovascular approach. The development of fenestrated and branched graft devices will further expand the patient population that can be treated successfully with EVAR. Future innovations will include alternative techniques for sac management to reduce the rate of endoleak and the need for late reintervention. Despite the successes of EVAR, it must be kept in mind that lifelong surveillance is required to reduce the risk of late complications such as endoleak or late aneurysm rupture.

**MULTIPLE CHOICE QUESTIONS**

1. What have randomized trials of open surgery versus endovascular aneurysm repair (EVAR) shown for the treatment of patients with asymptomatic abdominal aortic aneurysms (AAAs)?
   A. Similar operative mortality and long-term outcomes for both open surgery and EVAR
   B. Decreased operative mortality for EVAR, but similar long-term mortality for both open surgery and EVAR
   C. Decreased operative and long-term mortality with EVAR
   D. Increased operative mortality and long-term mortality with EVAR

2. A 67-year-old man with a past medical history of smoking undergoes abdominal aortic ultrasound. The ultrasound demonstrates a 5.1-cm aneurysm with a clear infrarenal neck. One year ago, the patient’s aneurysm was 3.5 cm. What is the recommended treatment at this time?
A. Endovascular or open surgical repair of the aneurysm
B. Repeat ultrasound in 6 months
C. Repeat ultrasound in 1 year
D. Reassurance that his aneurysm is not yet large enough to treat and unlikely to grow further

3. A 72-year-old man undergoes endovascular aortic repair for a 5.6-cm infrarenal aortic aneurysm. During follow-up, computed tomography imaging reveals a type II endoleak originating from an inferior mesenteric artery, but the aneurysm sac has shrunk to 4.7 cm. What is the most appropriate management of the endoleak?
   A. Coil embolization of the inferior mesenteric artery via collaterals
   B. Conservative management; no intervention indicated at this time
   C. Surgical explant of the endovascular graft with open surgical repair of the aneurysm
   D. Placement of additional stent graft material in the main body of the graft to exclude possible concomitant type III endoleak

4. A patient who underwent endovascular aortic aneurysm repair 4 years ago undergoes a surveillance computed tomography (CT) scan. This scan demonstrates dislodgement of the left iliac limb relative to the main body component. What type of endoleak is this considered?
   A. Type I endoleak
   B. Type II endoleak
   C. Type III endoleak
   D. Type IV endoleak

5. A 69-year-old man is diagnosed with a 4.1-cm AAA. Which of the following medical interventions has been shown to reduce aneurysm sac expansion among patients with moderate-size aneurysms?
   A. Doxycycline
   B. Angiotensin-converting enzyme inhibitors
   C. β-Blockers
   D. There is no definite benefit of medical therapy in reducing aneurysm expansion.
ANSWERS

1. B
Four randomized trials have compared the outcomes of EVAR to open AAA repair. Each of these trials enrolled patients with asymptomatic AAA who were candidates for endovascular or open repair. All 4 studies reported lower 30-day mortality with EVAR, with 30-day mortality rates ranging from 0.5% to 1.2% for EVAR and 1.3% to 4.7% for open surgery. The long-term mortality in each of the studies did not demonstrate a benefit of EVAR over open AAA repair, likely due to death from other comorbidities.

2. A
The patient has rapid expansion of his aneurysm and should undergo aneurysm repair. The criteria for intervention on an AAA include an aneurysm diameter greater than 5.5 cm in men (perhaps 5.0 cm in women), rapid expansion of an aneurysm (>0.5-0.7 cm/6 months or 1 cm/12 months), or symptomatic aneurysm with either distal embolization from an AAA, aneurysmal mass effect, threatened rupture, or frank rupture.

3. B
If there is stabilization or reduction in aneurysm volume, then intervention for type II endoleak is usually not required. In cases where a higher likelihood of type II endoleak is anticipated, some experts have advocated pre-EVAR embolization of branch arteries, use of thrombogenic AAA sac packing at the time of EVAR, or laparoscopically assisted side branch ligation. When prophylactically or primarily treating type II endoleak, it should be kept in mind that type II endoleak is generally benign; its treatment should not be at an excessive risk of morbidity and mortality to the patient.

4. C
Endoleak is the persistent flow of blood into the aneurysm sac after EVAR. There are 4 types of endoleak. Type I endoleak results from flow into the sac due to inadequate seal at either the proximal (type IA) or distal (type IB) attachment sites. Type II endoleak occurs as a result of retrograde flow into the sac through a branch vessel (eg, accessory renal artery, lumbar artery,
internal iliac artery, median sacral artery, gonadal artery, or inferior mesenteric artery). Type III endoleak refers to a leak through the graft itself—either at the junction of modular components or because of a defect in the graft material. Type IV endoleak is not truly an endoleak at all. This instead refers to the tendency of some grafts to be porous for a short period of time after insertion in the body. CT scans in the early postoperative period may demonstrate contrast in the aneurysm sac due to extravasation of contrast through the interstices of the stent-graft.

5. D

Although the basic understanding of the inflammatory and dynamic nature of AAAs has significantly advanced, there is as of yet no effective medical treatment for limiting the expansion of AAA. Despite the current lack of an adequate medical treatment for slowing the rate of AAA expansion, all patients with AAA should receive appropriate medical therapy for cardiovascular risk reduction, including smoking cessation, statin therapy, and antiplatelet therapy.
CAROTID ARTERY INTERVENTION

The era of percutaneous or endovascular revascularization techniques was ushered in by Dotter in 1964, and then advanced by Gruentzig with the invention of the balloon angioplasty catheter. The technique of percutaneous transluminal angioplasty (PTA) has been used in both peripheral and coronary vessels to great success and, in many circumstances, has largely replaced surgical therapy as the treatment choice. The use of PTA in the extracranial carotid circulation began in Europe. In a worldwide survey of carotid intervention published in 1998, the specialty of cardiology was dominant, responsible for more than 60% of all the reported cases. Cardiologists have continued to lead this field with the development of embolic protection devices (EPDs); initially proven in saphenous vein graft intervention, cardiologists are already comfortable using this technology.

Pathophysiology

The majority of cerebral ischemic events are a focal manifestation of a systemic disease, atherosclerosis. Extracranial atherosclerotic carotid artery disease accounts for slightly more than half of the 731,000 strokes per year in the United States. Stroke is the third leading cause of death after coronary
artery disease and cancer in the United States, and it is the leading cause of
disability. In the Framingham study, 70% of all stroke patients had
hypertension, 70% had coronary artery disease, and 30% had peripheral
vascular disease.

There are 2 main types of stroke: ischemic and hemorrhagic. Ischemic
stroke results from a reduction of blood flow due to emboli, thrombosis, or
hypoperfusion. Hemorrhagic stroke includes primary cerebral hemorrhages
or hemorrhage secondary to an ischemic event. Atherosclerotic carotid artery
stenoses most often cause symptoms due to emboli events. A minority of
ischemic strokes are caused by thrombotic occlusion, which is in contrast to
acute coronary syndromes, which are usually due to thrombotic vessel
occlusion.

Anatomically, the 2 internal carotid arteries and 2 vertebral arteries come
together at the base of the skull to form the circle of Willis (Fig. 57-1), which
is an ideal anastomotic network. In theory, a single vessel could supply the
circulatory needs of the entire brain. However, although a circle of Willis is
present in every brain, there is a huge amount of individual variability, and
fewer than half are complete anastomotic networks.
Stroke Prevalence, Demographics, and Etiology

The third leading cause of death in the United States is stroke, with more than three-quarters of a million strokes per year. Stroke is a leading cause of functional impairment in adults with approximately 20% of survivors requiring institutional care and up to one-third having a permanent disability. More worrisome, however, is the fact that as the population ages, the number of patients experiencing strokes appears to be increasing.

The majority of strokes are ischemic and are caused by atherosclerotic emboli from the carotid artery or the aortic arch; more rarely, they are related to thromboembolism from the heart chambers. The incidence of asymptomatic extracranial carotid stenosis (≥50%) in persons >65 years of age is estimated to be between 5% and 10%, with fewer than 1% of patients having a critical stenosis (>80%). The annual risk of stroke is between 1% and 4.3% for asymptomatic patients with ≥50% stenosis of the carotid artery. The asymptomatic patients at highest risk of stroke are those with severe stenoses or those with progressive carotid narrowing. Unfortunately, the majority (~80%) of strokes have no warning symptoms. Therefore, identifying asymptomatic patients at highest risk for stroke is extremely important.

The current evidence supporting revascularization (carotid endarterectomy [CEA] or carotid artery stenting [CAS]) in asymptomatic patients is dated, with more current evidence creating debate among experts. The strongest evidence favoring revascularization comes from randomized clinical trials (Asymptomatic Carotid Artery Surgery [ACAS] and Asymptomatic Carotid Surgery Trial [ACST]) that were performed prior to the widespread availability of modern multimodality medical therapy, particularly statins. The most conservative estimate is that the current incidence of an asymptomatic carotid stenosis leading to a stroke is <1% per year, which, if true, would make it difficult for revascularization to provide additional benefit for patients. Unfortunately, there is little evidence upon which to base a treatment recommendation for patients with severe asymptomatic carotid stenosis. This has led to a proposal for a second Carotid
Revascularization Endarterectomy Versus Stenting Trial (CREST-2), which will randomize asymptomatic patients with significant carotid lesions to revascularization (CEA or CAS) versus multimodality medical therapy.

Pending the outcome of new trials, there continues to be reasons to consider revascularization of asymptomatic patients with significant carotid artery stenosis (>60%), such as prior to heart surgery to protect the brain from intraoperative hypoperfusion, rapidly progressing stenoses, patients with contralateral carotid occlusions, or patients with ulcerated or other high-risk plaque features that increase the incidence of stroke. Because the majority of strokes occur without warning, patient-centered care demands giving the asymptomatic patient’s preferences for revascularization (CAS or CEA), in the hands of an experienced team with proven quality outcomes, consideration.

Symptomatic patients have a worse prognosis compared to asymptomatic patients. The risk of atheroembolic stroke is directly related to the severity of carotid artery stenosis and the presence of symptoms. A transient ischemic attack (TIA), a neurologic event lasting <24 hours, predicted a 15% risk of stroke at 1 month and a 30% risk of recurrent TIA, stroke, or death within 3 months. In the North American Symptomatic Carotid Endarterectomy Trial (NASCET), the stroke rate was 16.2% among those with moderate (50%-69%) stenosis and 25.1% with a 70% to 99% carotid stenosis (Table 57-1). Patients with the very tightest lesions, near occlusions, which were defined in the European Carotid Surgery Trial (ECST) as a severe stenosis with evidence of reduced flow in the distal carotid artery and evidence of narrowing of the poststenotic carotid artery, did not benefit from CEA.

**Cerebrovascular Symptoms**

Symptomatic cerebrovascular events are classified as TIAs, if they
completely resolve within 24 hours, or as strokes, if they leave a permanent
deficit. Patients with minor strokes include those who symptoms resolve
within 7 days or those with minimal disability (National Institute of Health
Stroke Scale [NIHSS] ≤). Symptoms may be “hemispheric,” meaning they
are related to a single carotid distribution, causing contralateral hemiparesis
or hemiparesthesias, aphasia, and/or ipsilateral monocular blindness
(amaurosis fugax), or they may be “nonhemispheric,” with symptoms of
vertebrobasilar insufficiency (VBI) such as dysarthria, diplopia, vertigo,
syncope, and/or transient confusion.

**Noninvasive Imaging**

Doppler ultrasound or duplex imaging of the extracranial carotid arteries is
cost-effective, accurate, and reproducible. Duplex imaging of the carotids
provides information about the location, extent, and severity of disease.
Blood flow velocity measurements are translated into categories that have
clinical relevance. There is controversy regarding the ability of ultrasound
imaging to serve as the sole imaging criterion to determine suitability for
carotid revascularization. A recent trial suggested that although ultrasound is
an excellent screening tool, its accuracy in a community setting was not
sufficient to replace angiography. As the resolution and speed of magnetic
resonance angiography (MRA) and computed tomographic angiography
(CTA) rapidly improve, they are being used to noninvasively image the
extracranial carotid arteries and intracerebral vessels (Fig. 57-2). The cross-
sectional images can be reconstructed into noninvasive angiograms that have
the very important advantage of imaging the circle of Willis with excellent
resolution and clarity.
FIGURE 57-2 A. Computed tomography angiography (CTA) image of an internal carotid artery stenosis (arrow). B. Magnetic resonance angiography (MRA) image of an internal carotid artery stenosis (arrows). MIP, maximum intensity projection; MPR, multiplanar reconstruction.

**Invasive Angiography**

All of the revascularization trials upon which carotid artery treatment decisions have been based have used angiographic criteria for patient selection. Invasive angiography is the “gold standard” for the diagnosis of vascular pathology of the aortic arch, cervical, and cerebral vessels (Fig. 57-3). The major drawback for invasive angiography has been the risk of adverse events associated with the procedure. In the ACAS trial, there was a 1.2% risk of stroke related to angiography performed by radiologists. More
recently, we have reported a much lower stroke rate (0.5%) for experienced interventional cardiologists performing carotid angiography. Clinical volume, technical skills, and patient selection are important elements in minimizing the risk for diagnostic angiography.

FIGURE 57-3 Digital subtraction angiogram of critical internal carotid artery stenosis (arrow). The asterisk denotes an artifact from dental fillings.
**Stroke Prevention with Pharmacologic Therapy**

Both primary and secondary stroke prevention require aggressive risk factor modification, specifically lipid management, blood pressure control, and smoking cessation. Aspirin therapy (81 mg daily) results in a 25% relative risk reduction compared to placebo. There is no evidence that doses of aspirin greater than 75 to 325 mg per day are more effective for stroke prevention. The CAPRIE (Clopidogrel Versus Aspirin in Patients at Risk of Ischemic Events) trial, comparing clopidogrel to aspirin, demonstrated a significant benefit for clopidogrel for the combined endpoint of ischemic stroke, myocardial infarction, or vascular death, but it did not show a reduction in stroke risk with clopidogrel compared to aspirin alone. The MATCH (Management of Atherothrombosis With Clopidogrel in High-Risk Patients) trial showed no stroke reduction benefit for aspirin and clopidogrel compared to clopidogrel alone, although the bleeding risk was increased with combination therapy. Despite isolated data from a single trial regarding secondary prevention, the preponderance of evidence is that the addition of dipyridamole to aspirin alone for primary or secondary stroke prevention is of marginal benefit. With the exception of patients with atrial fibrillation, there are no data to support the role of anticoagulation with warfarin to reduce the risk of stroke.

Primary prevention has consisted of primarily blood pressure control, tobacco cessation, and aspirin therapy, but recently, the Justification for the Use of Statins in Prevention: An Intervention Trial Evaluating Rosuvastatin (JUPITER) trial demonstrated significant risk reduction for stroke with statins. Several other lipid-lowering trials in patients at increased risk for stroke due to cardiovascular disease have also shown efficacy for statin therapy to reduce stroke. Both the 4-S (Scandinavian Simvastatin Survival Study) trial with simvastatin and the CARE (Cholesterol and Recurrent Events) trial with pravastatin demonstrated a 30% relative risk reduction for stroke compared to placebo. Of note, the stroke benefit did not appear in these trials until after 3 years of therapy.

**Surgical Treatment**

CEA has been established as the surgical procedure of choice for stroke prevention in patients with extracranial carotid artery disease (see Table 57-1; [Table 57-1](#)).
Table 57-2) to prevent stroke for usual or average surgical risk symptomatic patients with ≥50% carotid stenosis\textsuperscript{6,11,12} and average risk asymptomatic patients with ≥60% carotid stenosis\textsuperscript{7,13,14} compared to medical therapy.

ACAS, Asymptomatic Carotid Atherosclerosis Study; ACST, Asymptomatic Carotid Surgery Trial.

The applicability of clinical trial results to everyday patients has been questioned. Wennberg and colleagues\textsuperscript{15} demonstrated that the perioperative mortality rate for trial hospitals was 1.4% (95% confidence interval [CI], 1.2%-1.7%) and that the perioperative mortality rate was higher in nontrial hospitals (high volume: 1.7%; 95% CI, 1.6%-1.8%; average volume: 1.9%; 95% CI, 1.7%-2.1%; low volume: 2.5%; 95% CI, 2.0%-2.9%; \(P\) for trend <.001; \textbf{Fig. 57-4}). Patients undergoing CEA at trial hospitals had a mortality risk reduction of 15% (95% CI, 0%-31%) compared with high-volume nontrial hospitals, 25% (95% CI, 7%-40%) compared with average-volume hospitals, and 43% (95% CI, 25%-56%) compared with low-volume hospitals (\(P\) for trend <.001). The authors concluded that the perioperative mortality following CEA as practiced in the communities is substantially higher than that reported in the trials, even in those institutions that participated in the randomized studies. Caution is advised in translating the efficacy of carefully controlled studies of CEA to effectiveness in everyday practice.
FIGURE 57-4 Mortality rates for carotid endarterectomy (CEA) in Medicare patients are increased compared to symptomatic (NASCET) and asymptomatic (ACAS) clinical trial patients.15

Variability in the reporting of CEA results makes interpretation and comparison of studies difficult (Table 57-3). In a meta-analysis of CEA in symptomatic patients (n = 51 studies), the strongest predictor of stroke or death was who (neurologist or surgeon) performed the postoperative assessment.16 When a neurologist evaluated postoperative patients, the risk of stroke and death was 7.7%; however, when a single author surgeon performed the evaluation, the risk was reported as 2.3%.

The clinical benefit of CEA must be balanced against the perioperative risk associated with the procedure. An expert consensus panel suggested that
CEA was beneficial if the perioperative risk of stroke and death did not exceed 3% for asymptomatic patients and 6% for symptomatic patients. However, an increased risk of perioperative stroke and death rates has been reported for repeat CEAs (10.9%) and in patients with contralateral carotid occlusions (14.3%). There is consensus among experts that there is a population of patients who are at increased risk of complications with CEA due to a variety of unfavorable anatomic features and/or medical comorbidities (Table 57-4). The comparative benefit of CEA in patients treated with modern anti-atherosclerotic therapy has not been established.

### Carotid Artery Stenting

Extracranial CAS placement has evolved over the past 20 years to become an
accepted method for revascularizing patients with selected carotid lesions (Fig. 57-5). Because the extracranial carotid artery is subject to external compression and rotation, self-expanding stents are used to avoid stent deformation. Concern over the potential release of cerebral emboli led to the development of EPDs. These protection systems fall into 3 categories: (1) distal balloon occlusion with aspiration, (2) proximal occlusion with aspiration, and (3) distal filter systems.

FIGURE 57-5 Left panel: Tight internal carotid stenosis (arrow). Right panel: After stent placement (arrow).

CAS is the preferred revascularization strategy in patients at increased risk for surgical complications of CEA if they have suitable anatomy (see Table
The SAPPHIRE trial randomized high surgical risk patients to CEA or CAS in a large multicenter trial. The investigators clearly demonstrated noninferiority (CAS = 12.2%, CEA = 20.1%; \( P = .004 \) for noninferiority) across the entire cohort at 1 year for major adverse events. In patients at increased risk for complications of CEA, randomized trial data (SAPPHIRE\(^{18} \)) and pivotal registry evidence (ARCHer, \(^{19}\) SECuRITY, \(^{20}\) MAVerIC, \(^{21}\) SPIDERX, \(^{22}\) PRIAMUS, \(^{23}\) BEACH, \(^{24}\) CREATE, \(^{25}\) CAPTURE, \(^{26}\) CASES-PMS, \(^{27}\) CABERNET, \(^{28}\) EXACT, \(^{29}\) CAPTURE-2, \(^{29}\) ARMOUR, \(^{30}\) EPIC, \(^{31}\) EMPIRE, \(^{32}\) and PROTECT\(^{33} \)) support CAS as an alternative to CEA (Fig. 57-6). The durability of CAS relative to CEA was maintained out to 3 years of follow-up.\(^{34} \)

**FIGURE 57-6** Outcomes of improvement in carotid artery stenting: results for high surgical risk patients over time.\(^{19-33}\)

The current multisocietal guidelines recommend CAS as an alternative to CEA for treating symptomatic patients at increased risk for complications of CEA, if performed by an experienced operator and an experienced team, with expected 30-day morbidity and mortality outcomes similar to those observed in clinical trials (4% to 6%).\(^{35,36}\) This category of CAS patient (symptomatic
with ≥70% carotid artery stenosis and at high risk of CEA complications) represents the only group eligible for noninvestigational Centers for Medicare and Medicaid Services (CMS) reimbursement.

There have been 3 international randomized controlled trials comparing CEA to CAS (SPACE, EVA-3S, and ICSS), each of which, unfortunately, had seriously flawed trial designs by failing to provide quality control for CAS operators and not requiring the use of an EPD, which is the standard of care in the United States. The single common denominator among these trials was allowing inexperienced operators to participate in order to accelerate enrollment. These inexperienced operators were challenged by the additional complexity of using an EPD with CAS, leading many of them to abandon this important step and sacrificing patient safety.

The largest trial comparing CAS and CEA in average surgical risk patients was CREST, which enrolled 1321 symptomatic patients (53%) and found no difference for the primary end point of stroke, myocardial infarction (MI), or death from any cause during the periprocedural period or any ipsilateral stroke within 4 years after randomization between CEA (8.4% ± 1.2%) and CAS (8.6% ± 1.1%). A potentially disabling cranial nerve palsy occurred in 5.5% (n = 36) of the CEA group. After 4 years of follow-up, there was no difference in stroke occurrence for either symptomatic or asymptomatic patients (Fig. 57-7).

**FIGURE 57-7** Data from the 4-year follow-up of any periprocedural stroke or postprocedural ipsilateral stroke showing no statistical difference for carotid artery
stenting (CAS) versus carotid endarterectomy (CEA).

CREST is the only source of modern randomized comparative data for 1181 asymptomatic patients at average risk for complications with CEA.\textsuperscript{41} There was evidence of equipoise between CEA and CAS for the primary end point of stroke, MI, or death from any cause during the periprocedural period or any ipsilateral stroke within 4 years after randomization (CAS 5.6% ± 1.0% vs CEA 4.9% ± 1.0%; $P = .56$). There was a 1 in 25 risk for a potentially disabling cranial nerve palsy in these asymptomatic patients undergoing CEA. The multisocietal guideline\textsuperscript{36} recommends considering CAS in asymptomatic average-risk patients (Class IIb) but cautions that the benefit of revascularization versus medical therapy is not well established.

**CAS Procedural Risk**

Clinical and anatomic conditions that put patients at increased risk for CEA complications should influence the treatment recommendations given to patients. Factors that place patients at increased risk for complications from CAS should also be considered when recommending CAS.\textsuperscript{42} CAS procedural risk assessment can be based on patient medical comorbidities, such as their symptom status or age; patient anatomic characteristics, such as a type III aortic arch (Fig. 57-8) or severe carotid artery tortuosity; and procedural factors, such as operator and team experience (Table 57-5). Experts agree that patients with anatomic features that prolong catheter manipulation, make crossing a carotid stenosis difficult, or make using an EPD or deploying a stent difficult should be avoided if possible. Other characteristics that make endovascular therapy more difficult or more risky and that should prompt consideration of CEA are compromised vascular access, severe iodinated contrast reactions, and chronic kidney disease, which puts the patient at risk for contrast-induced nephropathy.
Operator and team experience may be the most important factor in determining which patients are better suited for CEA or CAS. A proven track record of good results, with a team that can provide a safe environment during and after the procedure, is very important. One of the unintended
consequences of CMS’s restricted reimbursement policy for CAS has been to severely constrain the volume of CAS in the United States and limit the development of experienced centers outside those performing clinical trials.

There is little overlap among risk factors or patient characteristics that increase the periprocedural risk after CAS or CEA with a few notable exceptions (see Tables 57-4 and 57-5). Some are supported by clinical evidence such as the finding that echolucent plaques are associated with a higher event rate with CAS, whereas others are based on expert consensus such as high bleeding risk.

The risk for a CAS complication increases when catheter/guide wire manipulation is prolonged in the aortic arch, makes lesion crossing more difficult, decreases the successful deployment or retrieval of an EPD, or makes stent placement difficult. The most difficult anatomic features for CAS were a complex aortic (type III) arch (Fig. 57-9), circumferential lesion calcification, severe angulation of the internal carotid artery, severe atherosclerotic disease of the aortic arch, and a tortuous common carotid artery. Other features that may increase the risk of CAS include patients with dementia due to multiple lacunar strokes, cerebral microangiopathy with diminished vascular reserve, increased risk of bleeding or coagulation disorders, difficult vascular access, and kidney disease.
An increased complication rate for CAS in the elderly (≥75/80 years) has been clearly demonstrated. Younger patients (≤69 years old) were shown to have lower event rates with CAS compared to CEA in two large randomized trials. Elderly patients (>80 years) are more likely to have tortuous vessels, unfavorable aortic arches, and more complex carotid lesions. Despite these facts, it has been clearly shown that with experience and careful patient selection, excellent CAS outcomes are attainable even in the very elderly.

The experience of CAS operators and hospital volumes have a direct impact on procedure outcomes. The lead-in patients for the CREST trial
demonstrated that catheter-based subspecialties (radiology and cardiology) experienced half the number of complications as the vascular surgeons, which was statistically significant (Fig. 57-10). After successful completion of lead-in cases, which ensured operator competence, the final CREST results reported that the quality gap for the vascular surgeons had been closed.

**CREST Lead-In Specialty Outcomes**

- Neuro Surg [OR = 1.66; 95% CI 0.66 – 4.16]
- INR [OR = 0.39; 95% CI 0.13 – 1.15]

**FIGURE 57-10** CREST lead-in results showing statistically inferior results for the vascular surgeons, the least experienced group. INR, interventional neuroradiology; IR, intervention radiology; OR, odds ratio.

Although EPD use with CAS has never been subjected to a randomized controlled trial, most experienced operators believe that embolic protection is necessary with CAS; in addition, the US Food and Drug Administration approved the devices without randomized evidence, and Medicare will not reimburse for a CAS procedure in which an EPD has not been used. A meta-analysis of 4747 patients in 24 CAS studies found a significant benefit for protected procedures with a relative risk reduction of 0.59 (95% CI, 0.47-0.73). New brain lesions detected by magnetic resonance diffusion-weighted imaging (DWI) correlate with complex aortic arch vessels, more contrast usage, and longer fluoroscopic times during diagnostic cerebral angiography. The appearance of new contralateral-hemisphere DWI lesions is compelling evidence that some cerebral emboli are caused by catheter manipulation in
the aortic arch and explains why 20% of all strokes associated with CAS affect the contralateral hemisphere. Quantitatively, fewer transcranial Doppler (TCD) embolic signals and fewer DWI brain lesions occur with an EPD in place compared to no EPD used with CAS. When comparing a distal balloon occlusion EPD to a filter EPD during CAS, no difference was found between the devices, with new cerebral lesions detected in 40% of both groups; however, TCD has shown fewer embolic signals with a proximal embolic occlusion (PEO) device compared to a filter EPD.

There is continuing debate regarding the effect of stent type (open cell vs closed cell) on the occurrence of CAS complications. Open-cell stents are typically more flexible and conformable in tortuous lesions, whereas closed-cells stents offer better lesion coverage. Several authors have observed an increase in CAS complication rates with open-cell stents, particularly in symptomatic patients and those with echolucent plaques. Complications in these symptomatic patients correlate with the “free cell area” of the stents. However, a large CAS series failed to show any relationship of stent type with CAS complications, with the authors pointing out that without a randomized controlled trial, lesion morphology, which drives stent choice, may confound the observed outcomes. For example, open-cell stents are preferred in more complex angulated lesions, which are more likely to cause complications, whereas closed-cell stents are preferred in straighter lesion segments, introducing a bias in favor of closed-cell stents.

Earlier intervention (≤14 days) after a symptomatic event has become recommended therapy for CEA given the high recurrent event rate for symptomatic patients. It is unclear whether the timing of CAS following a symptomatic event is beneficial or carries an increased risk of complications. In the symptomatic (stroke or TIA) subset of the multicenter CAPTURE (Carotid ACCULINK/ACCUNET Post Approval Trial to Uncover Rare Events) trial (n = 482), there was an increase in complications associated with CAS performed within 2 weeks of the symptomatic event (P = .0047; odds ratio, 2.52; 95% CI, 1.33-4.78). However, in 320 symptomatic CAS patients treated at 2 high-volume European centers, early intervention (≤14 days from onset of symptoms) with CAS was not associated with increased complications. Clarification of the risk-to-benefit ratio for early CAS intervention in symptomatic patients with CAS will require better controlled clinical trials.
VERTEBRAL ARTERY INTERVENTION

The vertebrobasilar system (VBS) accounts for approximately 25% of all ischemic strokes. Atherosclerotic occlusion or thrombosis of the VBS carries a poor prognosis, with mortality rates approximating 80%. Symptomatic posterior circulation lesions that are refractory to medical therapy carry a 10% incidence of stroke or death at 1 year. Patients with peripheral vascular disease have a 40% incidence of vertebral artery stenosis (VAS), whereas symptoms of posterior circulation ischemia correlate with a 25% to 40% incidence of VAS.

VBS symptoms (Table 57-6) are frequently unrecognized and underdiagnosed. Noninvasive ultrasound imaging of the proximal portion of the vertebral artery is often difficult. Noninvasive angiography (MRA or CTA) or invasive angiography is the best way to demonstrate the stenosis in this proximal location, which is the most common location for disease to occur in this vessel.

Vertebrobasilar Anatomy

The vertebral artery originates at a 90° angle as the first branch of the subclavian artery and is divided into 4 segments defined by the bony landmarks illustrated in Figure 57-11. These 4 segments are designated V₁ to V₄, and the ostium is designated as V₀. The ostium and V₁ segment are the most frequent locations of disease in this vessel treated with percutaneous intervention (Fig. 57-12).

FIGURE 57-11 Vertebral artery anatomy. (Reproduced with permission from Silva JA, White CJ. Peripheral vascular intervention. In: Kern MJ. The Interventional Cardiac
The $V_1$ segment courses between the longus colli and scalenus anterior muscles until it enters the transverse foramina of either the fifth or sixth cervical vertebra and becomes the $V_2$ segment. The $V_1$ segment can be treated percutaneously with ease provided it is not tortuous or redundant.

The $V_2$ segment begins as it enters the transverse foramina of C5 or C6, courses through the bony canal of the transverse foramina of C6 to C2, and ends when it exits the transverse foramina of C2. The $V_2$ segment is also easily treated with percutaneous intervention due to favorable anatomic features such as its short distance from the subclavian artery and a straight course through the transverse foramina of the cervical vertebra.
The V3 segment begins as it exits the transverse foramina of C2 and ends as the vessel penetrates the dura mater through the foramen magnum and becomes an intracranial vessel. Percutaneous intervention in the V3 segment is more difficult as this segment is extremely tortuous and does not allow mobility of the atlantoaxial and the atlanto-occipital joints. Balloon-expandable stents should be avoided in this flexible joint region. Avoiding extreme tortuosity and use of short self-expanding stents increase success in this segment.

The V4 segment extends along the inferior portion of the pons and joins the contralateral vertebral artery to form the basilar artery. Anterior spinal communicator arteries originate from the V4 segments bilaterally, join in the midline, and perfuse the anterior two-thirds of the spinal cord. Therefore, percutaneous intervention in V4 segment is extremely risky and is rarely attempted except for acute stroke intervention or severe symptoms unresponsive to medical therapy. Occlusion of the anterior spinal communicators can cause major deficits and brainstem infarcts.

There are several anatomic variants to consider when performing selective vertebral artery angiography. The left vertebral artery origin is anomalous in 5% to 10% of the population, arising from the aortic arch just proximal to the left subclavian artery or from the proximal left subclavian artery. The right vertebral artery arises from the aorta distal to the left subclavian artery or from the right carotid artery in 0.18% of the population. Hypoplasia of 1 vertebral artery with congenital absence of the V4 segment and termination in the posterior inferior cerebellar artery occurs in 6% or the population.

**Indications for Intervention**

Patients with VBS symptoms (see Table 57-6) that are refractory to medical therapy should be considered for vertebral artery intervention. Therapy for symptomatic VBI is reasonable in patients with bilateral vertebral stenosis ≥70%, unilateral vertebral stenosis ≥70% in the presence of an occluded or hypoplastic contralateral vertebral artery, or evidence of artery-to-artery embolism even in the presence of a unilateral stenosis and if vertebral angioplasty would increase total cerebral blood flow to patients with diffuse atherosclerotic disease involving occlusions of both carotid arteries. Revascularization of the vertebral artery should not be attempted if the vessel
Clinical Results

Since the first successful treatment of a vertebral artery stenosis with balloon angioplasty in 1980, multiple case reports and case series have been reported describing the successful use of endovascular techniques to treat posterior circulation atherosclerotic disease. Unfortunately, there is no level 1 evidence from multicenter clinical trials to guide clinical decision making. Endovascular treatment of vertebral artery atherosclerosis still remains a major challenge today due to a lack of randomized controlled trials and a nonpayment decision by Medicare in 1984. Despite these challenges, review of previous studies demonstrates that endovascular treatment of the vertebral artery is safe, feasible, and durable with high technical success rates and low clinical complication rates (Table 57-7).

Abbreviations: CVA, cerebrovascular accident; N/A, not applicable; SSYLVIA, Stenting of Symptomatic Atherosclerotic Lesions in the Vertebral or Intracranial Arteries; TIA, transient ischemic attack.

In a Cochrane Review, 173 cases of VAS stenting were identified out of 313 cases of vertebral artery intervention. Meta-analysis of these 20 studies
found a 30-day major stroke and death rate of 3.2% and a 30-day TIA and nondisabling stroke rate of 3.2%. These data would suggest that VA stenting is comparable to CAS\textsuperscript{47} in selected patients. In a meta-analysis of 300 proximal vertebral artery interventions at a mean follow-up of 14.2 months, the risk of death was 0.3%, the risk of periprocedural neurologic complications was 5.5%, and the risk of posterior stroke was 0.7%. After a mean of 12 months (range, 3-25 months), restenosis occurred in 26% of cases (range, 0%-43%) but did not correlate with recurrent symptoms.

Endovascular treatment of the ostial and proximal portion of the vertebral artery is a safe and effective technique for alleviating symptoms and improving cerebral blood flow to the posterior circulation. Vertebral artery angioplasty can be performed with high technical and clinical success rates, low complication rates, and durable long-term results. The durability of vertebral artery angioplasty is evidenced by low restenosis rates in multiple large series reported in the literature. Endovascular stenting of vertebral artery atherosclerotic disease in patients who fail medical therapy should be considered first-line therapy for this disease despite the absence of randomized trials demonstrating superiority of endovascular therapy due to the major difficulty and high morbidity of open surgical revascularization.

**SUMMARY**

CAS is one of the most studied medical procedures of all time, and in contrast, vertebral artery intervention is one of the least well studied. Surgical options for vertebral revascularization are not available, making endovascular stenting the best option available to patients facing a grim natural history for symptomatic lesions that have failed maximal medical therapy. For both symptomatic and asymptomatic patients, the largest randomized clinical trial to date (CREST\textsuperscript{41}) confirms equipoise for CAS and CEA when these procedures are performed by experienced operators with experienced teams supporting them. In recognition of this extensive evidence base, there is a multisociety expert consensus document\textsuperscript{48} and 2 professional society guidelines endorsed by 14 of the major stakeholder professional societies, including cardiology, vascular surgery, neurology, radiology, nursing, and neurosurgery, recommending that CAS be considered an alternative to CEA in average surgical risk patients.\textsuperscript{35,36}
Patients at risk for stroke from their carotid artery disease should be encouraged to discuss their treatment options, including revascularization with their physician. As of 2014, there remained uncertainty regarding the value proposition for revascularization (either CEA or CAS) in asymptomatic patients as a strategy to prevent stroke, and asymptomatic vertebral lesions should not be intervened upon. Investigation continues in an attempt to identify subsets of patients with carotid plaque at higher risk of causing strokes, but until those data are available, physicians and patients should continue to strive for value-based care—the best outcomes at the lowest cost and fewest complications, with the best information that is currently available. When considering revascularization of an asymptomatic patient, it is important to acknowledge that as the population lives longer, there is a cumulative benefit of freedom from stroke that ensues if the revascularization procedure is uncomplicated. However, the relative benefit of revascularization in asymptomatic patients over the long-term compared to multifactorial medical therapy, including antiplatelet agents, blood pressure control, and lipid-lowering therapy, is not known.

No one can know exactly what the future holds for carotid or vertebral stenting, but there are several reasonably safe bets. The first is that less invasive CAS will eventually replace the more invasive CEA, despite CMS’s intransigence on payment equality for CEA and CAS. This change will be largely driven by the acceptance of CAS by younger, endovascularly trained vascular surgeons, who will replace senior surgeons (not endovascularly trained), who have fought so hard and so effectively to protect their turf and influence Medicare. The second is that far fewer asymptomatic patients will undergo carotid revascularization to prevent stroke, as multimodality medical therapy continues to improve.

At some point, government regulators and third-party payers will realize that percutaneous CAS is a reasonable less morbid option to open surgical CEA and will expand reimbursement to be equal to that of CEA, returning clinical decision making to the patients and their physicians. This expansion of CAS cases, as a percentage of total carotid revascularization procedures, will drive further technical enhancements and procedural evolution that will result in continued improvements in CAS safety and efficacy.

**MULTIPLE CHOICE QUESTIONS**

1. What is the most common pathophysiology for acute stroke?
   A. Carotid artery occlusion
   B. Rupture of an intracranial vessel with hemorrhage
   C. Atheroembolic occlusion of a cerebral artery
   D. Thrombotic embolization to a cerebral artery

2. Which of the following is true regarding patients with asymptomatic carotid artery stenosis?
   A. Revascularization is not indicated for <50% stenosis.
   B. The annual risk of stroke is 5% per year.
   C. At the end of 4 years of follow-up in the CREST trial, there were more strokes in the stent group compared to the surgical group.
   D. Ulcerations of atherosclerotic carotid plaque double the risk of stroke.

3. Which of the following statements is true regarding carotid artery disease?
   A. Symptomatic patients are at greater risk than asymptomatic patients.
   B. An asymptomatic patient with a >80% carotid stenosis has a 10% per year risk of stroke.
   C. Dual antiplatelet therapy is more effective in preventing strokes than aspirin therapy.
   D. Aspirin doses of 325 mg/d are more effective than 81 mg/d for stroke prevention.
4. Which of the following characteristics puts a patient with carotid stenosis undergoing carotid stenting at the highest risk?
   A. Age >80 years
   B. Heavily calcified artery
   C. Lesion ulceration
   D. Tortuosity of the aortic arch (type III)

5. In which of the following circumstances is carotid stenting recommended as a superior option over carotid surgery for stroke prevention in a patient with carotid stenosis?
   A. A patient younger than age 60
   B. A patient with restenosis after prior carotid surgery
   C. A patient who had coronary bypass surgery 1 month ago
   D. A patient with moderate aortic stenosis

**ANSWERS**

1. C

   The most cause of acute ischemic stroke is atheroembolism, usually vessel-to-vessel embolization.

2. A

   There is no indication for revascularization of mildly narrow carotid arteries. The annual risk of stroke is estimated at 1% per year. There was no statistical difference between stent or surgery for all strokes at the end of 4 years. Ulcerations increase the risk of stroke by 30%.

3. A

   Symptomatic patients are at much greater risk than asymptomatic patients. The risk of stroke for a >80% stenosis on modern medical therapy is not known. Neither dual antiplatelet therapy nor doses of aspirin higher than 81 mg/d are more effective at stroke prevention.

4. D
The highest risk for stent complications is excessive tortuosity of the aortic arch.

5. B

Patients at increased risk with surgery are preferred for stenting. None of the other options have been identified as placing patients at increased risk with surgery.
Part V  Complications and Management

58  Risk Stratification in Interventional Cardiology
59  Bleeding Risk Scores
60  Stent Thrombosis
61  Coronary Artery Perforation
62  Embolization and No-Reflow During Percutaneous Coronary Intervention
63  Emergency Surgery Following Percutaneous Coronary Intervention
64  Emergency Resuscitation Measures
The field of interventional cardiology has evolved since the introduction of balloon angioplasty by Andreas Gruntzig, with current high procedural success rates and low attendant periprocedural complications. Percutaneous coronary intervention (PCI) and transcatheter aortic valve replacement (TAVR) are now preferred in many high-risk subgroups in whom they were previously contraindicated.

Evaluation of risk-benefit ratios and risk stratification are important elements in optimizing care for an individual undergoing PCI or TAVR. Various models for prediction of risks can help physicians, patients, and their families better comprehend attendant risks and provide an objective basis for the most suitable treatment option. It is paramount for clinicians to become familiar with the available risk scores and apply them in clinical practice. This chapter focuses on the strengths and weaknesses, ease of applicability, and use of risk prediction models to estimate the risk of mortality and major adverse cardiac events (MACE) in the current environment of interventional cardiology.
PREDICTION MODEL: STATISTICAL CONSIDERATIONS

A good predictive model should be accurate and able to discriminate between different levels of risk. An accurate model, on average, is not biased toward over- or underprediction. If the true average risk of an event in a population is 5%, one could achieve accuracy by predicting 5% risk for every patient. Such estimates would lack precision, however, because the same prognosis is given for both low- and high-risk patients. Discriminatory ability is related to precision (distinguishing high- from low-risk patients).

In the context of this chapter, a “prediction” is the probability that an event will occur. A high-risk patient may have a predicted risk of 0.50, but he or she will not suffer a half-event. This may be why assessment of these models tends to focus more on discriminatory ability than accuracy.

Logistic regression is the standard statistical analysis employed for binary outcomes. Harrell and colleagues recommend that the number of explanatory variables considered should not exceed one-tenth of the number of events. This set of variables should be determined without knowledge of their relationship to the outcome in the modeling data set. Clinical expertise is essential at this stage of model development. After candidate explanatory variables are chosen, the final model may be determined using automatic selection or bootstrap methods. These methods are intended not only to simplify the model, but also to avoid overfitting. Overfitting occurs when a model reflects anomalous associations specific only to the model-building data, resulting in suboptimal performance in other data sets.

Once a final model is chosen, the Hosmer-Lemeshow goodness-of-fit test may be used to determine if the model adequately reflects the observed data. A significant test result indicates an inadequate fit. Accuracy may be internally validated using data-splitting, cross-validation, or bootstrap methods. However, external validation is more valuable than these methods. Comparison of the observed number of events in the external data set against the events predicted by the model determines the model accuracy.

The discriminatory ability of a model may be quantified by the c-statistic (c stands for concordance). The c-statistic, or area under the receiver operating characteristic (ROC) curve, is the proportion of times that the
model correctly ranks the risks for a pair of subjects. That is, if 2 patients are selected, only 1 of whom will have an event, it is the rate at which the model assigns a higher level of risk to the patient with the event. Thus, a c-statistic of 0.50 indicates the model performs as well as assigning risk by the toss of a coin. Perfect discrimination results in a c-statistic of 1.00.

The simplification of the statistical model to an additive integer-scoring tool may be useful for patient counseling. The goal is to assign integer coefficients to risk factors significantly associated with an event so that the physician may quickly sum the coefficients for a numerical ranking of the patient’s risk. Once the logistic regression model is finalized, the simplified scoring tool may be defined by selecting integer coefficients roughly proportional to the log-odds ratio coefficients (ie, parameter estimates) of the logistic regression model variables.

RECENT RISK MODELS PREDICTING COMPLICATIONS FOLLOWING PERCUTANEOUS CORONARY INTERVENTIONS

Multiple models have been developed that incorporate demographic features, existing comorbidities, and angiographic characteristics to predict in-hospital and long-term outcomes of patients undergoing PCI. Of these, the Mayo Clinic Risk Score, American College of Cardiology National Cardiovascular Data Registry (ACC-NCDR) CathPCI risk score, and SYNTAX (Synergy Between Percutaneous Coronary Interventions With Taxus and Cardiac Surgery) score models are the most commonly applied in practice. These models are usually used in synergy and complement prognostic information; the Mayo Clinic and NCDR CathPCI scores stratify patient risk based on bedside clinical variables and PCI urgency (Table 58-1), while the SYNTAX score can further refine the overall risk and success of PCI based on the angiographic complexity and extent of coronary artery disease (CAD). Nine models that predict the risk of in-hospital and 30-day mortality and MACE have been described in the recent literature. They are listed below and compared in Table 58-1 and Table 58-2.

In general, these risk models have good predictive capability (c-statistic, approximately 0.9). Their discrimination ability is reduced in high-risk populations. A recently described enhanced NCDR CathPCI model is effective in determining survival in patient undergoing urgent PCI with high-risk clinical features, such as cardiogenic shock or cardiac arrest. Based on the model, survival to hospital discharge after urgent PCI was 35% for patients with sustained shock and cardiac arrest, whereas patients who had transient shock without cardiac arrest had 85% chance of survival.\textsuperscript{17}

\textsuperscript{*Odds ratio from logistic regression models.}

Abbreviations: ACC-NCDR, American College of Cardiology-National Cardiovascular Data Registry; AML, acute myocardial infarction; CHF, congestive heart failure; EF, ejection fraction; IABP, intra-aortic balloon pump; LM, left main; LVEF, left ventricular ejecion fraction; NNE, Northern New England; NYHA, New York Heart Association; PCI, percutaneous coronary intervention; PVD, peripheral vascular disease; SCAI, Society for Cardiac Angiography and Interventions; VD, vessel disease.
All the models incorporate similar demographic features, existing comorbidities, and lesion variables (with the exception of NY State) (see Table 54-2). In general, the risk factors associated with in-hospital complications can be divided into the following broad categories: age, left ventricular function, acuity of presentation, high-risk angiographic features, and additional high-risk demographics, such as congestive heart failure, New York Heart Association class, renal failure, diabetes, chronic obstructive pulmonary disease, peripheral vascular disease, and other variables.

**Age**

Advancing age is an important risk factor for PCI complication and is universally present in the risk models. Possible explanations for increased risk include reduced cardiac reserve, presence of multivessel disease, and increased prevalence of comorbidities. In all the risk scores, there was a graded increase in the mortality risk with advancing age. Thus, an octogenarian has 2.7 times the risk (Michigan model) as compared with patients between 50 and 59 years of age. The Mayo Clinic risk and NY state risk scores extend these observations to composite end points, with an unadjusted odds ratio for these complications of 6.03 and 4.7, respectively, in a person older than 80 years of age who undergoes PCI, as compared with a younger patient. Age was considered a binary variable in a recent simplified scoring system. This dichotomous cutoff of age might underestimate risks from PCI in the very elderly.

**Left Ventricular Function**

Assessment of left ventricular function is an important variable with prognostic implications during PCI. Various models have measured this risk variable differently. Cardiogenic shock resulting from severe left ventricular systolic dysfunction is the single most important predictor of PCI complications. The mortality in patients presenting with shock in various risk scores ranged from 28% (ACC-NCDR) to 33% (Michigan). In the Cleveland and Mayo Clinic models, the odds ratios of in-hospital complications in patients with shock were 12.7 and 4.95, respectively. Moreover, in the enhanced NCDR CathPCI model, sustained shock is associated with higher unadjusted in-hospital mortality than transient shock.
In the NY State model, reduced ejection fraction and congestive heart failure were independent predictors of death during or after angioplasty. Increased risk of death was associated with patients presenting with New York Heart Association (NYHA) class greater than or equal to III in the Mayo model, in the NCDR CathPCI risk model, and in the NNE cardiovascular study group, with an ejection fraction of 40% of less. Similar conclusions were derived from other risk score models. Therefore, it is important to have clinical or objective assessment of left ventricular function at the time PCI is performed.

**Acuity of Presentation**

Acute myocardial infarction (especially within 24 hours), cardiac arrest, hemodynamic instability with cardiac arrhythmia, and cardiogenic shock are important clinical variables that influence the acuity of presentation and adversely affect the outcome of the procedure. In the NCDR CathPCI database, the overall in-hospital mortality after PCI was 1.27%, ranging from 0.65% in nonurgent PCI to 4.81% in ST-segment elevation myocardial infarction (STEMI). Use of intra-aortic balloon pump during an urgent procedure is an important marker for increased mortality risk as seen in the NY State, ACC-NCDR, and NNE models. The odds ratio estimate for complications in urgent or emergent procedures in the Mayo Clinic risk score was 2.13. Similarly, mortality with emergent PCI procedures was high in the other study populations, with rates between 5.8% and 6.35% in the ACC-NCDR and NNE groups, respectively.

**High-Risk Angiographic Features**

Multivessel disease had a higher odds ratio for complications during PCI: 1.54 per extra vessel in the Michigan model, 1.86 in the Mayo Clinic model, and 1.32 per extra vessel in the Cleveland Clinic model. Multivessel angioplasty was a risk factor in the NY State model (odds ratio, 1.82) and can influence the prognosis of the patient. Other angiographic risk factors of importance are presence of thrombus (Mayo Clinic and Michigan models), American College of Cardiology/American Heart Association (ACC/AHA) type C lesion classification (ACC-NCDR, NNE, and Cleveland Clinic models), and left main coronary artery disease (ACC-NCDR and Mayo
Clinic models) or left main intervention (Brigham and Women’s model).

**Additional High-Risk Demographics**

**Renal Failure**

Renal failure has been found to be an important predictor of in-hospital complications following PCI.\(^{33,34}\) The Michigan model had an odds ratio of 5.5 for mortality in patients undergoing PCI who have a creatinine level of more than 1.5 mg/dL. Similar findings were noted in all other models except the Cleveland Clinic model. Despite differences in the definition of renal failure, the presence of renal insufficiency clearly increases the risk of complications during PCI. Assessment of renal function before PCI not only helps in prevention and management of contrast-associated acute kidney injury, but also adds this variable to the profile of the patient.

**Peripheral Vascular Disease**

Peripheral vascular disease is linked to higher mortality with the NNE, Michigan, and Beaumont models. Similar observations were noted in the NY State model (the odds ratio for mortality in patients with femoral popliteal disease was 1.775). This is an important diagnosis and is readily available from history and clinical examination. Peripheral vascular disease is not clearly defined in most of the risk scores; however, femoral popliteal disease (NY State model), claudication, amputation, peripheral bypass surgery, angioplasty, aortic aneurysm, and history of transient ischemic attacks, stroke, or carotid stenosis (Michigan model) add to the risk of the patient undergoing PCI.

**Frailty**

Although not included in the previously mentioned risk models, the role of frailty has recently been recognized because frail patients have poor in-hospital and long-term outcomes. Frailty can help estimate the biological age and clinical vulnerability of elderly patients. Frail patients have an odds ratio for in-hospital mortality of 4.6 after urgent PCI.\(^{35}\) Adding frailty to the Mayo
Clinic Risk Score improved the discriminability for adverse long-term outcomes (mortality and myocardial infarction) following PCI.\textsuperscript{36} Frailty is increasingly recognized as an important variable that determines not only eligibility but also prognosis of elderly subjects evaluated for high-risk percutaneous procedures, such as TAVR. There is still no consensus on the definition; however, uniform evaluation with existing definitions is strongly encouraged, especially as the age of the patients referred to cardiac catheterization laboratory continues to increase. In the PARTNER trial, for example, frailty was assessed using a composite of 4 markers (serum albumin, dominant handgrip strength, gait speed, and Katz activity of daily living survey), which were combined into a frailty score.\textsuperscript{37}

**Other Variables**

Other predictors (eg, diabetes mellitus [NY State and Beaumont models] and female sex [NY State, Cleveland Clinic, Michigan, and Beaumont models]) are not consistent across all the risk models and have a generally lower, weaker relationship with procedural complications.

**AMERICAN COLLEGE OF CARDIOLOGY/AMERICAN HEART ASSOCIATION LESION AND SYNTAX CLASSIFICATIONS**

Percutaneous angioplasty techniques have evolved rapidly since the original proposal of this classification in 1986 and its subsequent modification in 1990.\textsuperscript{38,39} It is still the most widely used system to scorecard the individual operator and the institution. More recently, in a new classification system, 2 variables (nonchronic total occlusion and degenerated saphenous vein grafts) were significantly correlated with death, non–Q-wave myocardial infarction, and the need for emergency coronary artery bypass grafting (CABG).\textsuperscript{40} The Society for Cardiac Angiography and Interventions (SCAI) proposed a simpler classification, collapsing ACC/AHA lesions A, B1, and B2 lesions into non-C category, and then stratifying the lesion by patency (SCAI I =
non-C/patent; SCAI II = C/patent; SCAI III = non-C/occluded; SCAI IV = C/occluded), resulting in better, but modest, discrimination (c-statistic, 0.665) for prediction of major in-hospital complications as compared with ACC/AHA lesion classification (c-statistic, 0.624). ACC/AHA type A is associated with a 2% risk of complications, whereas the risk of complications increases to 21% with type C lesions.

Investigators compared the Mayo Clinic risk score with ACC/AHA lesion classification for prediction of complications following PCI. The ACC/AHA lesion classification was inferior to the Mayo model in predicting the complications from the procedure. In other studies, procedural success was adversely affected by type C lesions. Among the type C lesions, chronic total occlusion and extreme tortuosity are significant lesion variables affecting procedure outcome. Type C lesion was one of the significant variables predictive of the need for emergency CABG following PCI.

Prior studies that relied on the ACC/AHA classification could not demonstrate value of adding angiographic variables toward assessment of prognosis. More recently, SYNTAX score derived from comprehensive angiographic information of patients enrolled in the SYNTAX trial clearly demonstrated its utility in not only providing prognostic information but also in selecting the mode of revascularization in patients with multivessel disease. SYNTAX score, a score based solely on angiographic extent and complexity of CAD, can predict the risk of complications with PCI based on the extent of CAD (eg, length of segment), complexity of CAD (eg, bifurcation/trifurcation disease, thrombus, calcification), and myocardium at risk (eg, left main disease, CAD dominance; http://www.syntaxscore.com/calc/start.htm; Fig. 58-1). The score divides patients undergoing revascularization into low (score <22), intermediate (23-32), and high (>32) risk, with corresponding 1-year major adverse cardiovascular and cerebrovascular events (MACCE) of 14.7%, 16.7%, and 23.7%, after PCI, respectively. SYNTAX has strong discriminative ability in various clinical presentations including left main and multivessel disease, non-STEMI, STEMI, and elective procedures. The score is frequently used in complex disease (eg, left main/multivessel disease) to assess the most appropriate revascularization strategy (PCI vs coronary artery bypass surgery), where patients with low-intermediate scores can be offered PCI (AHA/ACC class IIa indication). Newer hybrid models integrating
SYNTAX score with clinical variables, such as Global Risk Classification (GRC) and clinical SYNTAX score, can be used to increase the discriminative power in patients with significant comorbidities\textsuperscript{52,53} and underscore the importance of clinical and demographic information in calculating risk.

\begin{figure}
\centering
\includegraphics[width=\textwidth]{syntax_score.png}
\caption{SYNTAX (Synergy Between Percutaneous Coronary Interventions With Taxus and Cardiac Surgery) score. Angiographic complexity and extent of coronary artery disease are computed to calculate SYNTAX score. A higher number of diseased vessels and the presence of each of the listed variables increases the risk of complications after percutaneous coronary intervention. (Based on Sianos G, Morel MA, Kappetein AP, et al. The syntax score: an angiographic tool grading the complexity of coronary artery disease. \textit{Eurointervention}. 2005;1:219-227.)}
\end{figure}

\textbf{PITFALLS IN THE CURRENT RISK SCORE MODELS}

Outcome analysis following PCI is an important tool for quality control. However, benchmarking of outcome data is complicated by variations in the
case mix, referral patterns, procedural techniques, and operator and hospital volume (Table 58-3). The models that address the prediction of complications following PCI have several limitations.\textsuperscript{20,22-27,54} With the exception of the ACC-NCDR Registry and SYNTAX models, the other risk scores are derived from either regional (NNE and Michigan Consortium) or single-institution databases (Mayo Clinic, Beaumont, and Brigham and Women’s), limiting their generalizability. Some data sets antedate current state-of-the-art interventional practice. Important outcome measures, such as myocardial infarction, stroke, or need for emergency CABG, can significantly contribute to morbidity, length of hospital stay, and cost and are not considered in most available models except the hybrid SYNTAX, Mayo Clinic, Cleveland Clinic, and Brigham and Women’s Hospital models. Similarly, operator volume, an important variable predicting outcome following PCI, was not used in most models.\textsuperscript{21,55}

Table 58-3 \textbf{Drawbacks of Available Risk Models for Prediction of Complications Following Percutaneous Coronary Interventions}

- Different definitions of included variables.
- Risk scores derived from single-center, regional databases have reduced generalizability.
- Outcome measures other than mortality (myocardial infarction, stroke, and emergency coronary artery bypass surgery) are ignored.
- Operator and institutional coronary angioplasty volume is not tested.
- Often-used ACC/AHA lesion classification has only modest discriminatory accuracy for prediction of complications.
- A lower incidence of events would require an even larger size of the database from which the model is derived.
- Time elapsed between collection of data and analysis compromises applicability of score to contemporary current practice.
- Newer models, including current definitions of myocardial infarction, are unavailable.
- Influence of referral bias.

Abbreviation: ACC/AHA, American College of Cardiology/American Heart Association.
WHICH MODEL TO CHOOSE FOR PREDICTION OF COMPLICATIONS?

The properties of an “ideal” predictive model are highlighted in Table 58-4. All the models described in this chapter have excellent predictive accuracy, with c-statistics varying from 0.89 in Mayo Clinic score model to 0.93 in NCDR CathPCI. The c-statistic for combined end points for the Cleveland Clinic model was, however, modest (0.648). The prediction is not a crystal ball; the vast majority of high-risk patients would not have any complication from the procedure. However, the aim of the risk score should be to correctly risk-stratify a patient into low-, moderate-, or high-risk categories. Most of the risk scores with the exception of new Mayo Clinic Risk models, NCDR, and NY State use both clinical and angiographic variables and, hence, cannot be used electively for risk stratification at the time of first contact in a patient with unknown angiographic variables. SYNTAX can further tailor procedural success and risk of complications based on the angiographic complexity of revascularization. It can enhance decision making when it comes to optimal revascularization technique (eg, PCI vs CABG) based on the risk of procedural complications. For example, patients with low or intermediate SYNTAX score will have good results with PCI. Also, in patients with unprotected left main disease at ostial and mid-body location, PCI can be recommended if the overall SYNTAX score is low.

Most of the mortality models have been externally validated. Holmes and colleagues\textsuperscript{57} applied 5 of these risk models—including NY State, Cleveland Clinic, Michigan, NNE, and ACC-NCDR, developed from different data sets—to patients undergoing PCI in the National Heart, Lung, and Blood Institute Dynamic Registry. Three models (NY State, Cleveland Clinic, and NNE) predicted in-hospital mortality rates that were not significantly different than those previously observed. NY State and Mayo Clinic models can be used to predict the 30-day mortality as two-thirds of patients die within 30 days after hospital discharge.\textsuperscript{58} In both high- and low-risk subgroups, however, the Michigan model slightly underpredicted mortality, and the ACC-NCDR Registry predicted significantly higher mortality than that observed. Potential reasons for this discrepancy were misclassification of renal disease and nonavailability of higher-risk variables (eg, cardiac arrest was the strongest prediction in the Michigan model) in the ACC Dynamic Registry. Omission of variables not included in the Dynamic Registry will lead, by default, to underestimation of the mortality risk. Additional limitations are related to clinical definitions, missing data, and how other variables such as renal failure and ejection fraction are handled.

The NCDR CathPCI, Mayo Clinic, Michigan Consortium, Brigham and Women’s, and Beaumont hospital studies\textsuperscript{14,15,17,24,25,31,59} have developed risk scores that are easy for an interventionalist to apply at the bedside for rapid risk scoring of the patient. These scores help the physician to triage the patient for the best treatment option, stratify the risk for the PCI procedure, counsel patient and family, and benchmark the outcomes in a more consistent and uniform fashion (Figs. 58-2 to 58-4 and Table 58-5).
Mayo Clinic risk score for major adverse cardiovascular events after percutaneous coronary intervention. Complication rates rise with increase in the risk score (horizontal axis). Estimated rates of procedural complications for the integer scoring system are depicted. The integers are proportional to the estimated continuous coefficient from the logistic model. Percentages at risk are shown for each of the 5 risk categories: <2% is very low risk for complications with coronary angioplasty; 2% to <4%, low risk; 4% to <10%, moderate risk; 10% to 20%, high risk; and more than 20%, very high risk. If left ventricular ejection fraction (LVEF) is not available, add 1 when patients present with congestive heart failure (CHF); otherwise, enter 0. If creatinine is not available, add 1 for man or patient presenting with CHF; enter 0 for woman without CHF. MI, myocardial infarction. (Reprinted from Singh M, Rihal CS, Lennon RJ, et al. Bedside estimation of risk from percutaneous coronary intervention: the new Mayo Clinic risk scores. Mayo Clin Proc. 2007;82:701-708, Copyright © 2007 with permission from Mayo Foundation for Medical Education and Research.)
FIGURE 58-3 National Cardiovascular Data Registry bedside risk score. This model divides patient into 8 groups (horizontal axis) based on their predicted risk for in-hospital mortality. The percutaneous coronary intervention (PCI) patient can be classified into one of the groups by adding points based on patient’s age, clinical characteristics (eg, prior congestive heart failure, cardiogenic shock, chronic lung disease, New York Heart Association functional class IV, peripheral vascular disease, glomerular filtration rate), and PCI urgency. Group 1 (score 0-0.5) has the lowest probability for in-hospital mortality, while group 8 (score 30+) has the highest probability of in-hospital mortality, approaching 45%. (Reprinted from Peterson ED, Dai D, DeLong ER, et al. Contemporary mortality risk prediction for percutaneous coronary intervention: results from 588,398 procedures in the National Cardiovascular Data Registry. J Am Coll Cardiol. 2010;55:1923-1932, Copyright © 2010, with permission from American College of Cardiology Foundation.)
FIGURE 58-4 Michigan risk score. This score is only for in-hospital mortality and is read similar to the Mayo Clinic risk score. To estimate risk, calculate the total score by adding individual scores if comorbidity is present. For number of diseased vessels, add 0.5 for each major epicardial vessel with more than 70% stenosis. Identify the total score on the horizontal axis of the plot and corresponding probability on the vertical axis. Scores of 2.5 or less are associated with risk of death less than 0.8%, whereas scores higher than 7 are associated with risk of death greater than 40%. (Reproduced from Moscucci M, Kline-Rogers E, Share D, et al. Simple bedside additive tool for prediction of in-hospital mortality after percutaneous coronary interventions. Circulation. 2001;104:263-268.)

Table 58-5 Michigan Risk Score
Since the introduction of its use in patients with aortic valve stenosis (AS) who have prohibitive surgical risk, TAVR is now used widely for treatment of severe AS in patients with high surgical risk and has recently been approved for valve-in-valve procedures. The heterogeneity of the population undergoing TAVR, the presence of multiple medical comorbidities, and the rapid advancement in the technical aspects of the procedure hindered the development of TAVR-specific risk models. Nevertheless, previously applied surgical models have been used for initial risk stratification and patient selection for TAVR, including Society of

Thoracic Surgeons (STS) risk estimate and European System for Cardiac Operative Risk Evaluation (EuroSCORE).\cite{6,7,60,61} Despite their wide use, these surgical derived scores have limited discrimination and calibration in the TAVR patient population.\cite{64,65} In addition, assessment of frailty,\cite{66} comorbidities\cite{67} (Charlson Index, CAD index), certain high-risk anatomic features (eg, proximity of coronary arteries ostium to aortic annulus, calcification of left ventricular outflow tract\cite{68}), and baseline echocardiographic variables (eg, low-flow aortic valve stenosis and severe mitral valve regurgitation\cite{69-72}) are essential to determine best access route, treatment approach, and potential outcomes in patients with severe AS (Fig. 58-5).

**FIGURE 58-5** Proposed algorithm for best treatment approach in severe aortic stenosis (AS). Society of Thoracic Surgeons (STS) score can be used as a screening tool and help classify patients into low to high surgical risk. Additional comorbid conditions (eg, frailty, hostile chest, end-stage liver disease) can prevent candidates from surgery. These patients can be offered transcatheter aortic valve replacement.
(TAVR). In patients with significantly elevated STS >15%, significant comorbid conditions (eg, oxygen dependency, wheelchair bound), or reduced life expectancy, balloon valvuloplasty can be offered as part of palliative therapy. COPD, chronic obstructive pulmonary disease; LAA, left atrial appendage; MMSE, mini-mental status exam; SAVR, surgical aortic valve replacement. (Reprinted from Walsh JA III, Teirstein PS, Stinis C, et al. Risk assessment in patient selection for transcatheter aortic valve replacement. *Intervent Cardiol Clin*. 2015;4:12, Copyright © 2015, with permission from Elsevier.)

A recent risk prediction model (OBSERVANT risk score) has been developed that displays improved discrimination and calibration compared with the STS score. Seven variables were combined to predict 30-day mortality in patients undergoing TAVR (glomerular filtration rate <45 mL/min [6 points], critical preoperative state [5 points], NYHA class IV [4 points], pulmonary hypertension [4 points], diabetes mellitus [4 points], previous balloon aortic valvuloplasty [3 points], and left ventricular ejection fraction <40% [3 points]; Figs. 54-6 and 54-7). The model showed good discrimination (c-index, 0.73). However, the model risk score need further validation in other TAVR cohorts.

---

**FIGURE 58-6** OBSERVANT risk scoring system for prediction of 30-day mortality after transcatheter aortic valve replacement (TAVR). Left side: Bedside chart from which a total OBSERVANT risk score is calculated. Right side: Risk score (horizontal axis) with its corresponding estimated 30-day mortality percentage. Scores of 0 to 6 are associated with 2.4% 30-day mortality after TAVR, scores of 7 to 14 are associated with 7.8% 30-day mortality, and scores ≥14 are associated with steep increase in 30-day mortality (28%). Dotted line corresponds to confidence interval (CI). BAV, balloon aortic valvuloplasty; GFR, glomerular filtration rate; LVEF, left ventricular ejection fraction.

A simple risk tool (the observant score) for prediction of 30-day mortality after transcatheter aortic valve replacement. *Am J Cardiol*. 2014;113:1851-1858, Copyright © 2014, with permission from Elsevier.)

**FIGURE 58-7** Comparison of observed and predicted 30-day mortality rates by OBSERVANT model and logistic EuroSCORE after stratification by quartiles. OBSERVANT risk score has better discriminative power (c-statistic, 0.71) than logistic EuroSCORE (c-statistic, 0.66), especially in patients in the highest risk quartile for 30-day mortality after transcatheter aortic valve replacement (TAVR). OBSERVANT risk score needs further validation in other TAVR cohorts. (Reprinted from Capodanno D, Barbanti M, Tamburino C, et al. A simple risk tool (the observant score) for prediction of 30-day mortality after transcatheter aortic valve replacement. *Am J Cardiol*. 2014;113:1851-1858, Copyright © 2014, with permission from Elsevier.)

**SUMMARY**

The risk models described in this chapter predict in-hospital and 30-day mortality or MACE following PCI or TAVR. All the models are robust and represent current practice in interventional cardiology. Based on the description of strengths and limitations of the currently available models, physicians should be better able to counsel patients and their families about the risks involved in undergoing interventional procedures.

The focus of future studies should be on the uniformity and consensus
regarding the definitions of variables used, the outcomes measured, inclusion of postprocedure variables (elevation of cardiac enzymes, stroke, emergency CABG) and operator volume, and a strong national effort to streamline these measures.

MULTIPLE CHOICE QUESTIONS

1. Which risk model has the highest discrimination and calibration for 30-day mortality after transcatheter aortic valve replacement (TAVR)?
   A. European System for Cardiac Operative Risk Evaluation (EuroSCORE)
   B. Society of Thoracic Surgeons (STS) risk score
   C. OBSERVANT risk score
   D. PARTNER novel risk score

2. Which of the following variables is not included in all of the clinical risk models?
   A. Age
   B. Acuity of presentation
   C. Cardiogenic shock
   D. Sex

3. Which of the following 2 models can be used to predict 30-day mortality
after PCI?
A. NY State and Mayo Clinic
B. NCDR CathPCI and Mayo Clinic
C. Michigan and NCDR CathPCI
D. NY State and NCDR CathPCI

4. Which of the following statements is true about Synergy Between Percutaneous Coronary Interventions With Taxus and Cardiac Surgery (SYNTAX) and ACC/American Heart Association (AHA) lesion scores?
A. The ACC/AHA lesion classification was superior to the Mayo Clinic risk model in predicting the complications from the procedure.
B. SYNTAX score is frequently used in complex disease intervention to assess the most appropriate revascularization strategy.
C. ACC/AHA type C is associated with 2% risk of complications during PCI.

5. Which of the following is not needed to estimate frailty?
A. Handgrip strength
B. Serum albumin level
C. Gait speed
D. Katz activity
E. Renal function

ANSWERS

1. C

EuroSCORE and STS risk models were developed for risk stratification of surgical procedures and have low discrimination and calibration for outcomes in TAVR (STS risk score c-statistic, 0.58). They are mainly used to decide best interventional approach for severe aortic valve stenosis: surgical aortic valve replacement (SAVR), TAVR, or balloon valvuloplasty. OBSERVANT risk model was shown to have high discrimination and calibration abilities (c-statistic, 0.73) when compared to EuroSCORE. However, this model needs to be validated in other cohorts. The PARTNER novel risk model was developed to predict poor outcome including 6-month mortality and Kansas
City Cardiomyopathy Questionnaire–Overall Summary Scale (KCCQ-OS) score less than 45 after TAVR. This risk model has moderate discrimination (c-statistics, 0.66).

2. D

Most of the clinical risk models are derived from similar variables, including age, acuity of presentation, left ventricular function, and periprocedural shock. Age is a universal risk marker for prediction of complications after percutaneous coronary intervention (PCI). For instance, patients old than 80 years have 6.03 and 4.3 unadjusted odds ratios for mortality in Mayo Clinic and New York (NY) State risk scores. Acuity of presentation, including cardiac arrest at presentation, cardiogenic shock, and ST-segment elevation myocardial infarction (STEMI), is associated with higher complication rates. For example, the overall in-hospital mortality after PCI was 0.65% in nonurgent PCI and 4.81 in STEMI in the National Cardiovascular Data Registry (NCDR) CathPCI model. Other predictors (eg, diabetes mellitus [NY State and Beaumont models] and female sex [NY State, Cleveland Clinic, Michigan, and Beaumont models]) are not consistent across all the risk models and have a generally lower, weaker relationship with procedural complications.

3. A

American College of Cardiology (ACC)-NCDR CathPCI, Michigan, Cleveland Clinic, Northern New England (NNE), and Brigham and Women’s models can predict the in-hospital mortality. NY State and Mayo Clinic risk models can be used to predict 30-day mortality. Both models have high discrimination abilities (NY State c-statistic of 0.89 and Mayo Clinic c-statistic of 0.9 for 30-day mortality).

4. B

ACC/AHA and SYNTAX score are 2 of the most common classifications used to determine lesion complexity during PCI intervention. An ACC/AHA type A lesion is associated with 2%, type B1 with 4%, type B2 with 10%, and type C with 21% risk of in-hospital complications. However, the discrimination ability is modest (c-statistic, 0.624). The Mayo Clinic risk score was superior to ACC/AHA lesion classification in predicting in-
hospital complications from PCI (c-statistic difference 95% confidence interval, 0.05-0.15). SYNTAX score is based solely on angiographic extent, complexity of coronary artery disease, and myocardium at risk. The score is frequently used in left main and multivessel disease intervention to assess the most appropriate revascularization strategy (PCI vs coronary artery bypass surgery). Patients with low-intermediate scores can be offered PCI (AHA/ACC class IIa indication).

5. E

Frailty is an estimate of biological age that can help assess the eligibility and vulnerability of elderly patients in high-risk percutaneous procedures. Frail patients have an odds ratio for in-hospital mortality of 4.6 after urgent PCI. There is no consensus on the definition of frailty. Common markers that have been used to calculate frailty score include serum albumin, dominant handgrip strength, gait speed, and Katz activity of daily living. Renal function is not used to calculate frailty score.
INTRODUCTION

Advances in the catheterizations techniques, stent designs, and pharmacotherapeutics have reduced adverse ischemic event rates such as cardiovascular death, ST (stent thrombosis), recurrent myocardial infarctions, and revascularizations in patients with coronary artery disease undergoing elective or acute percutaneous coronary intervention (PCI). However, the same antithrombotic regimens also increase bleeding risk, and a cornerstone of contemporary cardiovascular interventions is balancing ischemic and bleeding events in order to optimize the net benefit for the individual patient.

Bleeding complications in patients undergoing cardiovascular interventions have previously been underappreciated. Over the decade, however, awareness has gradually raised that adverse bleeding outcome after PCI carries substantial hazard comparable to that of post-PCI myocardial infarction associated with mortality. A growing number of studies showing the impact of bleeding on short- and long-term mortality have promoted bleeding end points to a pivotal metric, increasingly applied as a single and combined primary end point in randomized controlled trials (RCTs). The composite end point of net adverse clinical events (NACE), assessing both ischemia and bleeding in the same outcome measure, was conceived to investigate the balanced effect of novel therapeutic agents or clinical
strategies in antithrombotic treatment regimens.

However, understanding the full impact of bleeding on outcome is still challenging. While ischemic adverse events are mostly narrowly adjudicated by widely accepted consensus definitions such as ST by the academic research consortium or myocardial infarction (MI) by the global definition of MI, bleeding assessment has been based on a large and very heterogeneous palette of definitions, often arbitrarily modeled as per-protocol criteria for specific clinical trials.

In the following, we will summarize the existing bleeding risk scores, their comparability, and their effect on clinical outcomes, as well as highlight their importance in contemporary clinical decision making and clinical trial design.

BLEEDING EPIDEMIOLOGY IN INTERVENTIONAL CARDIOLOGY

Bleeding is the most common noncardiac complication after PCI and leads to incremental increase in costs of health care. Rao et al\(^1\) recently published an updated bleeding model based on the US National Cardiovascular Data Registry (NCDR) in order to predict the risk of postprocedure major bleeding complications among patients undergoing PCI. Bleeding was defined as adverse events occurring within 72 hours after PCI or before hospital discharge, and the criteria are described in Table 59-1. In contemporary clinical practice describing more than 1 million procedures from over 1000 invasive US centers, this report identified over 60,000 PCI procedures, with postprocedure bleeding comprising an incidence of 5.8% in this cohort. Among the bleeding events, 32% related to a specific anatomic location; 44.6% were detected due to a pre- to postprocedure hemoglobin decrease, 21.8% by a blood transfusion, and 1% by cardiac tamponade; and 0.6% were intracranial hemorrhage events.\(^1\) Approximately half of bleeding events occur at the arterial site and may cover a large spectrum of clinical importance from uncomplicated subcutaneous access site hematoma to fatal retroperitoneal bleeding.

</tbody>
</table>
Subherwal et al.² has described the temporal trends of the incidence of bleeding among 1.7 million patients undergoing PCI between 2005 and 2009.
The finding of a nearly 20% reduction in post-PCI bleeding over time was largely due to temporal changes in antithrombotic strategies, as bivalirudin use increased from 17% to 30% and any heparin plus glycoprotein IIb/IIIa inhibitor decreased from 41% to 28%, while PCI by radial access and the use of vascular closure devices remained similar among all-comer PCI.2

Bleeding varies according to the clinical setting of PCI. In ST-segment elevation MI (STEMI) patients, the usage of fibrinolysis and the hectic preprocedural phase with the associated risk of misdosing anticoagulant regimen and a potentially less thorough assessment of individual bleeding risk, as well as the urgent need to gain vascular access, are all likely contributors to the well described increased incidence of major bleeding complications. Several registries have reported elevated bleeding rates in STEMI patients ranging from 6.5% to 11%.3,4 Intensified antiplatelet and antithrombotic pharmacotherapy in non–ST-segment elevation MI (NSTEMI) patients also makes this subset of patients particularly susceptible to bleeding complications, and the CRUSADE (Can Rapid Risk Stratification of Unstable Angina Patients Suppress Adverse Outcomes With Early Implementation of the American College of Cardiology [ACC]/American Heart Association [AHA] Guidelines) registry has reported major bleeding rates of almost 12%.

However, the reported bleeding incidence and the associated mortality risk are greatly dependent on the circumstance (RCT vs observational registry with either retrospective or prospective data collection), patient risk presentation (eg, elderly, acute coronary syndrome [ACS], vs non-ACS), and the bleeding criteria applied.

BLEEDING DEFINITIONS

A large number of bleeding definitions exist (see Table 59-1). This is a challenge as bleeding end points are given an increasingly pivotal role as safety end points in clinical randomized trials, but the comparability is low because the criteria may be quite different. For instance, The TIMI (Thrombolysis in Myocardial Infarction) bleeding classification is a laboratory-based scale, while the GUSTO (Global Utilization of Streptokinase and Tissue Plasminogen Activator for Occluded Coronary Arteries) bleeding classification is a clinically based scale that does not
consider clinical chemistry data. More than 15 different bleeding criteria are currently applied to various degrees and originate from datasets highly differing in setting and inclusion period (see Table 59-1). They are based on RCTs or observational registries or defined by consensus in research consortiums (Table 59-2), originate from treatment periods in the early 1990s to present day, and assess highly varying clinical entities (eg, intracranial hemorrhage or hemoglobin drop) in order to define major bleeding. It is well known that variations in bleeding criteria used to define major bleeding have led to differences in reported rates.5

<td>Bleeding that is not actionable and patient does not have unscheduled studies, hospitalization, or treatment by a healthcare professional</td>
</tr>
</tbody>
</table>
| 2 | Any clinically overt sign of hemorrhage that is actionable but does not meet criteria for type 3, 4, or 5 bleeding, meeting at least 1 of the following criteria:  
1. Requiring medical or percutaneous intervention guided by a healthcare professional, including (but not limited to) temporary/permanent cessation or reversal of a medication, coiling, compression, or local injection  
2. Leading to hospitalization or an increased level of care  
3. Prompting evaluation defined as an unscheduled visit to a healthcare professional resulting in diagnostic testing (laboratory or imaging) |
| 3 | Clinical, laboratory, and/or imaging evidence of bleeding with specific healthcare provider responses |
| 3a | Any transfusion with overt bleeding  
Overt bleeding plus hemoglobin (Hb) drop ≥3 to <5 g/dL<sup>4</sup> (provided Hb drop is related to bleeding) |
| 3b | Overt bleeding plus Hb drop ≥5 g/dL<sup>5</sup> (where Hb drop is related to bleed)  
Cardiac tamponade  
Bleeding requiring surgical intervention for control (excluding dental/nasal/skin/hemorrhoid)  
Bleeding requiring intravenous vasoactive drugs |
| 3c | Intracranial hemorrhage (does not include micro bleeds or hemorrhagic transformation; does include intrasinal). Subcategories: confirmed by autopsy, imaging, or lumbar puncture  
Intraocular bleed compromising vision |
| 4 | Coronary artery bypass graft-related bleeding  
Perioperative intracranial bleeding within 48 hours  
Reoperation following closure of sternotomy for the purpose of controlling bleeding  
Transfusion of ≥5 units of whole blood or packed red blood cells within a 48-hour period  
Chest tube output ≥2 L within a 24-hour period |
| 5 | Categorized further as either definite or probable:  
5a: Probable fatal bleeding is bleeding that is clinically suspicious as the cause of death, but the bleeding is not directly observed and there is no autopsy or confirmatory imaging  
5b: Definite fatal bleeding is bleeding that is directly observed (either by clinical specimen—blood, emesis, stool, etc—or by imaging) or confirmed on autopsy |

<sup>a</sup>Hemoglobin drop should be corrected for intravenous transfusion in which 1 unit of packed red blood cells or whole blood would be expected to increase hemoglobin by 1 g/dL.<br>Adapted from Mehran R, Rao SV, Bhatt DL, et al. Standardized bleeding definitions for cardiovascular clinical trials: a consensus report from the Bleeding Academic Research Consortium. Circulation. 2011;124:2736-2747.

Intuitively, major bleeding criteria such as the GUSTO criteria, which
only consider clinical variables such as intracranial hemorrhage, hemodynamic compromise, or intervention/clinically significant disability, identify much less major bleeding but convey a much higher mortality prediction than the more recent and sensitive per-protocol bleeding criteria, which in some cases adjudicate major bleeding already at a liberal use of any blood transfusion with overt bleeding, such as the ACUITY (Acute Catheterization and Urgent Intervention Triage Strategy), REPLACE-2 (The Randomized Evaluation in PCI Linking Angiomax to Reduced Clinical Events), or STEEPLE (Safety and Efficacy of Enoxaparin in PCI Patients, an International Randomized Evaluation) criteria. Logically, the latter scores will entail higher estimates of major bleeding, but with less associated mortality hazard (see Table 59-1).

Another example of large differences between major bleeding criteria comes from the REPLACE-2 study investigating bivalirudin with provisional glycoprotein IIb/IIIa inhibitor (GPI) versus heparin with planned GPI in patients undergoing elective or urgent PCI. Bleeding complications were evaluated by the TIMI criteria and the per-protocol REPLACE-2 criteria. When the TIMI major bleeding criteria were used, no difference in bleeding was found; however, when the REPLACE-2 major bleeding criteria were applied, significantly less bleeding was seen in the bivalirudin group. A crucial difference between the TIMI bleeding criteria and the REPLACE-2 bleeding criteria is that a drop in hemoglobin concentration ≥3 g/dL is considered major bleeding in the REPLACE-2 bleeding criteria, but only minor bleeding in the TIMI bleeding criteria (see Table 59-1).

A similar example is found in the STEEPLE trial evaluating 2 different doses of enoxaparin with unfractionated heparin in patients undergoing elective PCI. Again, the TIMI major bleeding criteria were used without finding a difference between any of the groups. Conversely, when the per-protocol STEEPLE major bleeding criteria were used, there was significantly more bleeding in the unfractionated heparin group than in any of the enoxaparin groups. Also in this case, the STEEPLE criteria adjudicate major bleeding when a drop in hemoglobin concentration ≥3 g/dL occurs in the presence of overt bleeding, a finding that only qualifies for minor bleeding according to the TIMI criteria. Furthermore, the STEEPLE criteria consider any transfusion of ≥1 unit of packed red blood cells in the scenario of overt bleeding as pathognomonic for major bleeding, which adds additional variability to the bleeding adjudication as transfusion standards vary
considerably across institutions and regions.

An obvious reason for this large number of per-protocol bleeding criteria is that the earliest major bleeding definitions, such as GUSTO and TIMI, only consider clinically major bleeding and are not very sensitive to other bleeding that requires clinical action and increases treatment items for the patient as well as the length of hospital stay and cost and thus constitutes a sensible end point to measure. Less sensitive bleeding criteria decrease statistical power, thereby augmenting the need for large sample sizes in RCTs. This is especially an issue in the constantly improving environment of the pharmacotherapeutic and technical interventional advances in PCI with consequently decreasing adverse event rates. Less sensitive bleeding criteria have therefore become increasingly less attractive to clinical trial investigators.

Adding to the lack of generalizability of bleeding criteria is the circumstance of their origin (ie, whether they were defined or evaluated in clinical trials with rigorous prospective data collection by clinical coordinators and individual event adjudication by clinical event committees, or whether the outcome was evaluated retrospectively by chart review in observational registries, possibly resulting in underreporting of adverse events). In contrast, bleeding criteria and outcomes from clinical trials can be harder to extrapolate to different clinical settings due to the often narrow inclusion criteria of the trial, whereas registries tend to provide a more accurate image of outcomes in real-world clinical practice.

Finally, large differences in concomitant antiplatelet and anticoagulant regimens, as well as highly variable interventional techniques, have been applied over the years and in publications reporting bleeding outcome from the different criteria.

For all of these reasons, in an effort to harmonize bleeding criteria, standardized bleeding definitions for cardiovascular clinical trials were designed and resulted in a consensus report from the Bleeding Academic Research Consortium (BARC), defining the BARC bleeding criteria, which have recently been validated in an independent population (see Table 59-2).\(^8\) Ndrepepa et al\(^8\) found in this patient-level pooled analysis of 12,459 patients recruited in 6 randomized trials of patients undergoing PCI that BARC class ≥3 was associated with a significant and similar adjusted 1-year mortality hazard of 3.19 (95% confidence interval [CI], 2.34-4.35), compared to TIMI (major + minor; 3.64; 95% CI, 2.62-5.07) and REPLACE-2 (major; 3.14;
95% CI, 2.30-4.29). The European Society of Cardiology Working Group on Thrombosis has stated in their latest issued position paper that bleeding should be reported using at least 2 bleeding scales and 1 of these should be the BARC bleeding criteria.9

**BLEEDING AND OUTCOMES**

The best clinical evidence of the association between bleeding and mortality in ACSs comes from 2 prominent examples in large-scale randomized trials, in which the ischemic end points between the treatment groups were very similar but major bleeding differed significantly, resulting in a mortality benefit associated with the reduced bleeding. This effect was evident in the HORIZONS-AMI (The Harmonizing Outcomes with Revascularization and Stents in Acute Myocardial Infarction) trial at 30 days and 1 year of follow-up in STEMI patients treated with bivalirudin compared to patients treated with unfractionated heparin and GPs.10 Patients undergoing primary PCI and treated with bivalirudin had a significantly reduced primary end point defined by the non–coronary artery bypass graft (CABG)–related major bleeding rate of 4.9% versus 8.3% in patients treated with heparin plus a provisional GPI, resulting in a significant decrease in death as a result of cardiac cause from 2.8% to 1.8%. At the same time, ischemic outcome in terms of reinfarction, revascularization stroke, and all ST (acute and subacute) did not differ, indicating that the survival benefit is attributable to the improved bleeding profile of bivalirudin at 30 days of follow-up. This difference between groups widened even more in the time period between 30 days and 1 year after PCI. Cardiac death and reinfarction occurred less frequently in patients treated with bivalirudin. This long-term reduction might have been attributable to the prevention of iatrogenic hemorrhagic complications. The rates of all-cause mortality, cardiac mortality, and stroke were each 5-fold higher in patients with major bleeding compared to those without major bleeding, while the rate of reinfarction was 2 times higher.11

A similar effect of decreased major bleeding associated with improved survival has also been reported in patients without STEMI. While the rates of death, MI, or refractory ischemia through day 9 after hospitalization were equal between groups, non–ST-segment elevation ACS patients randomized to fondaparinux treatment had a lower rate of major bleeding at 9 days and
significantly improved 6-month survival compared with patients assigned to enoxaparin.\textsuperscript{12} The OASIS-5 (Organization for the Assessment of Strategies for Ischemic Syndromes) trial therefore constitutes another example of a survival benefit attributable to an improved bleeding profile. Since then, several other substudies in cohorts originating from RCTs have confirmed that major bleeding is a powerful independent predictor in ACS populations of 30-day\textsuperscript{13} and 1-year mortality\textsuperscript{14} regardless of the bleeding criteria used. Major bleeding has also been associated with ischemia end points and ST.\textsuperscript{13}

In observational data from over 3 million all-comer procedures in the NCDR CathPCI Registry performed in the United States between 2004 and 2011, a propensity-matched analysis revealed that postprocedural bleeding events were associated with increased risk of in-hospital mortality and that approximately 1 out of 8 deaths was related to bleeding complications. Major bleeding was associated with increased in-hospital mortality with a number needed to harm (NNH) of 29. The association between major bleeding and in-hospital mortality was observed in all strata of preprocedural bleeding risk, although NNH decreased substantially across NCDR bleeding risk strata (high: NNH = 21; intermediate: NNH = 39; and low: NNH = 69). Although both access site (NNH = 117) and non–access site bleeding (NNH = 16) were associated with increased in-hospital mortality, the mortality risk associated with access site bleeding was substantially lower than for non–access site bleeding.\textsuperscript{15} Both access and non–access site bleeding events occurring within 30 days of PCI were also independently associated with an increased long-term risk of mortality at 1-year follow-up. Non–access site bleeding has recently been confirmed to be a stronger correlate of mortality than access site bleeding, and it improves the discriminatory power of models for mortality prediction.\textsuperscript{16}

In patients with MI, nuisance bleeding (BARC 1) is common in the following year, related with ongoing use of dual antiplatelet therapy (DAPT) and independently associated with worse patient perception of quality of life.\textsuperscript{17} Whether or not premature DAPT cessation after PCI due to nuisance bleeding is associated with increased rates of ST or MI is not well described. Improved selection of patients for prolonged DAPT may help minimize the incidence and adverse consequences of nuisance bleeding. Bleeding outcomes in relation to criteria, patient presentation, and circumstance of data collection are summarized in Table 59-3. The clinical variables defining the
various bleeding criteria are summarized in Table 59-4.

### Table 59-4 Summary of Clinical Variables Defining the Various Bleeding Criteria
PATHOPHYSIOLOGIC TIES BETWEEN BLEEDING AND MORTALITY

Several possible mechanisms explaining the association between bleeding and mortality exist. First, considerable overlap between bleeding and ischemic risk factors has been described, and bleeding has been suspected to act as a mere marker of increased mortality risk, rather than inferring a causal relationship. Conversely, consequences of bleeding are consistently reported to be independently associated with increased short- and long-term survival and constitute pathologic mechanisms that convey proven and biologically very meaningful risk indices of mortality. These mechanisms are likely to be multifactorial, but obvious consequences of bleeding include the rare cases of truly life-threatening or fatal bleeding, such as intracranial hemorrhage, as well as the consequences of blood loss entailing volume depletion, anemia, and hypotension. These mechanisms might be especially relevant in vulnerable STEMI patients with coronary artery disease susceptible to supply and demand mismatches, leading to possible deterioration with arrhythmias, hypovolemic instability, and shock, which
occur either directly as a result of decreased oxygen delivery to target organs or as part of a vicious circle of hypotension and myocardial ischemia entailing decreasing cardiac output, organ hypoperfusion, and cardiogenic/hypovolemic shock.

Another direct consequence of bleeding is disruption of antiplatelet therapy, which potentially puts the patient at increased risk of adverse ischemic outcomes by allowing aggregation of new thrombus material on uncovered stent struts without neoendothelialization: DAPT disruption in patients treated with drug-eluting stents has been found to convey a 12-fold adjusted hazard for major adverse cardiovascular events within the first 7 days after disruption. In addition, those with major bleeding have longer in-hospital stays and undergo more procedures, which may increase the chances of an adverse outcome, such as nosocomial respiratory, gastrointestinal, or blood infections or procedural complications.

Bleeding is often approached with a common and liberal use of transfusion, even though the effect of transfusions on mortality in many patients with coronary artery disease is at best neutral, as no positive effect could be identified in patients with a hematocrit >30%. Rao et al showed in a pooled analysis of 24,112 patients from clinical trials that even after adjusting for the propensity to receive blood and other confounders, transfusion was associated with a 4-fold hazard for 30-day death. Furthermore, a transfusion hemoglobin threshold of 7 or 8 g/dL, compared with higher hemoglobin thresholds, is associated with fewer red blood cell units transfused without adverse associations with mortality, cardiac morbidity, functional recovery, or length of hospital stay. Many potential mechanisms for the adverse effects of transfusion have been described, including activation of inflammatory cascades, platelet activation and aggregation, impaired delivery of oxygen and nitric oxide, vasoconstriction, and subsequently thrombosis and tissue ischemia. All of these could lead to paradoxical decreases in tissue oxygenation. However, it has to be stated that all of these data connecting transfusion to poorer outcome in patients with coronary artery disease are retrospective and have to be interpreted with caution.

Considerations regarding transfusion thresholds are important for the assessment of bleeding criteria, as the above pathologic considerations related to transfusion create different transfusion strategies in different health care
systems and are subject to change over time as new evidence regarding blood transfusion in coronary artery disease patients emerges. Therefore, bleeding criteria, such as the GUSTO score, that only apply clinical findings and do not incorporate hemoglobin or hematocrit levels will be less generalizable.

**RISK FACTORS PREDICTING BLEEDING**

In clinical practice, balancing the ischemic and bleeding risk is of utmost importance. It has been argued that comorbidity accounts for the excess mortality seen in patients with major bleeding, and that although bleeding may be causally related to adverse outcomes in some patients, it is often merely a marker for patients at higher risk for adverse events. Therefore, balancing ischemic and bleeding risk can seem like an unmanageable task, as both risk realms occur in the same type of patients. Nevertheless, numerous studies report that non–CABG-related bleeding within 30 days is strongly and independently associated with an increased risk of subsequent mortality at 1 year in patients undergoing PCI for all indications. In addition, Pocock et al have demonstrated that prognostic modeling of individual patient risk of ischemic and hemorrhagic complications and their mortality impact within 30 days in the ACUITY trial has identified several independent predictors that differ for MI and major bleeding. Independent predictors of MI were elevated biomarkers, family history of coronary artery disease, age, ST-segment elevation $\geq 1$ mm, and previous MI. Age and ST-segment elevation $\geq 1$ mm were also predictors for bleeding; however, importantly, female sex, anemia, serum creatinine, white blood cell count, previous cerebrovascular accident, previous PCI, bivalirudin plus GPI as opposed to lone bivalirudin treatment, and upstream GPIs as opposed to deferred GPIs all predicted major bleeding, but not ischemic events, on an individual basis. Some of these bleeding predictors were also identified in the CRUSADE bleeding score, namely female sex, anemia, creatinine clearance, and previous vascular disease (others were hypotension, tachycardia, signs of congestive heart failure at presentation, and diabetes mellitus). Mehran and colleagues subsequently built a risk score based on the ACUITY and HORIZONS-AMI trials, with female sex, serum creatinine, and anemia being the central
demographic risk contributors. Despite matching for age, body mass index, and type of antithrombotic therapy, bleeding risk after PCI remains significantly higher in women than in men. Bleeding is associated with increased risk of 1-year mortality with no bleeding-by-sex interaction, which illustrates that bleeding is as detrimental for 1-year survival in women as in men, but occurs more frequently in women. Female sex, low body mass index, and renal insufficiency have been consistent independent predictors of major bleeding, which is important knowledge for bleeding avoidance strategies.

It follows that although considerable overlap exists between risk predictors of bleeding and ischemic outcome, consideration of the individual risk profile for patients undergoing PCI and the relative treatment effects of alternative antithrombotic pharmaceutical regimen permits personalized decision making to optimize therapy of patients with ACS.

The clinical risk factors comprising the 3 most commonly applied bleeding risk scores are summarized in Table 59-5.

Abbreviations: ACS, acute coronary syndrome; CHF, congestive heart failure; GPI, glycoprotein IIIb/IIIa inhibitor; PCI, percutaneous coronary intervention; UFH, unfractionated heparin.
PCI-related bleeding may be avoided by different strategies such as the use of bivalirudin, radial access, vascular closure devices, and attention to appropriate dosing.

Compared with unfractionated heparin and provisional GPIs, bivalirudin has been shown to reduce bleeding in the setting of STEMI, both when administered in the prehospital phase\textsuperscript{25} as well as immediately before and during primary PCI.\textsuperscript{10} Bivalirudin also reduced major bleeding after subacute PCI in non–ST-segment elevation ACSs\textsuperscript{26} and after elective PCI in stable coronary artery disease.\textsuperscript{6} However, in both the HORIZONS-AMI and EUROMAX (European Ambulance Acute Coronary Syndrome Angiography) trials, conducted in the STEMI setting, the use of bivalirudin was associated with an increased risk of acute ST. Balancing bleeding and ischemic risk in these patients should therefore involve rigorous upstream antiplatelet therapy with early loading doses of P2Y\textsubscript{12} inhibitors, which in combination with bivalirudin do not seem to increase bleeding.\textsuperscript{27}

The beneficial bleeding profile of bivalirudin has recently been contested due to the evolution of pharmacoinvasive strategies in PCI. The HEAT-PPCI trial presented at the ACC 2014 meeting in Washington, DC, showed that primary PCI patients treated with weight-adjusted (low-dose) unfractionated heparin had similar outcomes than patients treated with bivalirudin regarding the end point of major bleeding (3.1\% vs 3.5\%), whereas patients treated with unfractionated heparin had significantly better results in terms of the composite of major adverse cardiac events (5.7\% vs 8.7\%) driven by a 4-fold higher rate of definite or probable ST (0.9\% vs 3.4\%), particularly acute ST. Both groups had similar use of bailout GPIs (15.5\% vs 13.5\%). This is the third study indicating an increased risk of acute ST (within hours of the end of primary PCI) in bivalirudin-treated STEMI patients, which has previously been reported in HORIZONS-AMI\textsuperscript{10} and EUROMAX.\textsuperscript{25} Only the HORIZONS-SWITCH protocol has so far indicated a way to mitigate this early ST risk, which occurs if heparin is given at the time of very first patient contact.\textsuperscript{28} Therefore, STEMI patients should be indeed treated with an anticoagulant as early as possible (eg, ambulance, emergency room, hospital floor), regardless of the final anticoagulant strategy and without waiting for sophisticated therapies to get started in the interventional suite.

The BRAVE-4 trial, presented at the same convention, showed that non–CABG-related bleeding was numerically higher in primary PCI patients
treated with prasugrel plus bivalirudin compared with patients treated with clopidogrel plus unfractionated heparin (14.1% vs 12.0%; \( P = .54 \)), while the primary composite end point of death, MI, unplanned revascularization of the infarct-related artery, ST, stroke, or major bleeding did not differ. There was a trend toward higher use of GPIs in the clopidogrel plus unfractionated heparin arm. However, BRAVE-4 was terminated early due to slow recruitment and was thus underpowered to test its primary hypothesis. Both trials have been subject to much controversy as they have given the indication that the beneficial bleeding profile of bivalirudin seen in previous trials is in fact due to the higher use of GPIs in the unfractionated heparin comparator groups.

Both HEAT and BRAVE-4 were conducted using potent oral as opposed to parenteral antiplatelet agents, thereby indicating once again how multidimensional the field of combination pharmacologic therapy has become in the treatment of STEMI PCI. This field will continue to evolve, and new studies will shed light on the new set of questions that has arisen.

The benefit of the radial approach in terms of adverse ischemic and bleeding outcome is controversial. In the RIVAL trial (Radial Versus Femoral Access for Coronary Intervention) in ACS patients, the rate of death, MI, or stroke at 30 days did not differ between patients randomized to PCI by radial or femoral access.\(^{29}\) In addition, the rate of non–CABG-related major bleeding at 30 days was similar in both groups. However, there was an overall significantly lower rate of large hematomas and pseudoaneurysms needing closure in the radial group. In prespecified subgroup analyses, those benefits in vascular complications were observed in all types of centers, whereas a beneficial effect of the radial approach for death, MI, or stroke was found only in high-volume centers and in STEMI patients.

The data regarding a mortality benefit associated with radial access in STEMI patients as found in the RIVAL subanalysis are disputed. In the multicenter randomized STEMI-RADIAL trial, patients treated with primary PCI by radial access by operators experienced in both access sites had a significantly lower incidence of major bleeding, fewer access site complications, shorter intensive care stay, and less contrast utilization; however, no survival benefit with radial access was shown at the 30-day follow-up.\(^ {30}\) Conversely, a recent meta-analysis of RCTs also indicated a significantly decrease mortality hazard associated with radial access in STEMI patients.\(^ {31}\)
The benefits of vascular closure devices (VCD) were investigated in the ACUITY trial. Access site bleeding was defined as requiring interventional or surgical correction, hematoma ≥5 cm at the access site, retroperitoneal bleeding, or hemoglobin drop ≥3 g/dL with ecchymosis or hematoma <5 cm, oozing blood, or prolonged bleeding (>30 minutes) at the access site. Almost 40% of patients received a VCD; rates of major access site bleeding were lower with VCD compared with no VCD and were lowest in patients treated with bivalirudin monotherapy and a VCD.32

Appropriate dosing of antiplatelet and anticoagulant treatment is an obvious strategy to reduce bleeding. The magnitude of misdosing has been highlighted in data from the CRUSADE registry.33 In this observational study, Alexander et al33 showed that more than 40% of the patients who were administered antithrombotic agents received at least 1 dose outside the recommended range and that bleeding increased relative to the degree of excess dose and to the number of agents administered in excess, which in turn translated into higher mortality and longer length of stay among patients administered excess dosing. The authors estimated that 15% of major bleeding in this particular cohort may have been attributable to excess dosing. Elderly patients with ACS33 and women with ACS34 are more likely to be overdosed with antithrombotic agents. Consequently, taking age, gender, body weight, and renal insufficiency into consideration when dosing antithrombotic agents is a crucial step to reduce bleeding in PCI populations.

Finally, appropriate operator techniques for proper arterial puncture at access site and technical developments such as smaller sheath sizes contribute to bleeding reduction. Fluoroscopy will help to locate the middle third of the femoral head as a landmark for identifying an optimal puncture site in the common femoral artery above the bifurcation but below the inferior epigastric artery. Arteriotomy at the appropriate anatomic location will reduce the risk of bleeding and retroperitoneal hematomas.35

Surprisingly, although bleeding avoidance strategies have been associated with significantly lowering bleeding rates, these strategies are paradoxically less often used among higher risk patients.36

Indeed, incorporation of preprocedural routine estimates of individualized bleeding risk affects physicians’ utilization of bivalirudin during PCI and might change the risk-treatment paradox in which patients at highest risk for bleeding are least likely to receive bleeding avoidance strategies. In 6491 PCI
procedures, Rao et al\textsuperscript{37} demonstrated that overall bivalirudin use significantly increased in the postimplementation period in intermediate (27%-35\%) and high bleeding risk patients (25%-43\%), and decreased in low-risk patients (30%-25\%).\textsuperscript{37} As women continue to have an almost 2-fold greater rate of bleeding following PCI compared with men, the use of effective bleeding avoidance strategies is particularly important in women.\textsuperscript{38}

Bleeding avoidance strategies are summarized in Table 59-6.

**TREATMENT OF BLEEDING**

Symptoms of hypervolemia such as unconsciousness, altered consciousness with confusion, anxiety or agitation, general weakness, cool and clammy skin and pallor, rapid breathing, decreased or no urine output, hypotension, and tachycardia should all evoke an acute diagnostic workup for seeking bleeding sources. In the absence of (or in addition to) overt hematomas and oozing from puncture sites, urgent diagnostic imaging in order to exclude cardiac tamponade (transthoracic echocardiography), intracranial hemorrhage (computed tomography [CT] of brain), or retroperitoneal bleeding (CT angiography) should be performed. In major overt bleeding, PCI-related antithrombotic therapy should be discontinued temporarily, which obviously will increase the risk of acute adverse ischemic events. Bleeding is often approached with a liberal use of transfusion; however, it should be
considered that in absence of overt life-threatening bleeding, the effect of transfusions on mortality is at best neutral in coronary artery disease patients with a hematocrit >30%, and a transfusion hemoglobin threshold of 7 or 8 g/dL appears recommendable. In case of life-threatening bleeding, treatment with inotropes and vasopressors might be needed.

BLEEDING COMPlications AFTER TRANsCATHERETER AORTIC VALVE REPLACEMENT

Bleeding complications are also an important end point measure in other percutaneous interventions. Patients undergoing transcatheter aortic valve replacement (TAVR) are an elderly and high-risk population undergoing femoral access site puncture with a large size French sheath and often lengthy procedures. Criteria for bleeding complications in TAVR have been standardized in the Valve Academic Research Consortium (VARC) Bleeding Definitions (Standardized Endpoint Definitions for Transcatheter Aortic Valve Implantation Clinical Trials) and are based on the BARC bleeding criteria (Table 59-7).

*Given that 1 unit of packed RBCs typically will raise the hemoglobin concentration by 1 g/dL, an estimated decrease in hemoglobin will be calculated.

Larger sheath sizes are a well-known predictor of bleeding complications.
in percutaneous cardiac interventions. In contrast to the Edwards Sapien Valve, which requires either large 22- or 24-Fr sheaths for delivery, the CoreValve is delivered through an 18-Fr sheath. The newer Edwards Sapien XT Valve can also be delivered through an 18-Fr sheath. Currently, therefore, bleeding complications are a natural element of treating patients with transfemoral TAVR and had a 30-day incidence of 11% in the PARTNER-I trial. Recently, VARC major in-hospital bleeding was described to occur with an in-hospital incidence of 3.5% in observational data from 7710 patients undergoing TAVR, gathered in the US national registry (the Society of Thoracic Surgeons [STS]/ACC Transcatheter Valve Therapy [TVT] Registry).

A purely empirical DAPT strategy is commonly used; however, 2 smaller studies have recently shown that a strategy using aspirin alone has been shown to reduce life-threatening bleeding without increasing the risk of stroke or MI. A trial testing whether a procedural anticoagulant strategy with bivalirudin improves bleeding outcomes compared with unfractionated heparin is currently enrolling.

### BLEEDING IN PATIENTS WITH ATRIAL FIBRILLATION UNDERGOING PCI

Anticoagulation with vitamin K antagonist (VKA) agents has been the standard of care for several decades and has been considered superior to DAPT in preventing stroke and thromboembolism in atrial fibrillation (AF) patients who do not undergo PCI. Conversely, in patients in need of PCI, DAPT with aspirin and a thienopyridine has been shown to be more beneficial in preventing ST than oral anticoagulation alone.

The current AHA guidelines on AF for patients undergoing PCI are nonspecific because they recommend “low-dose aspirin (less than 100 mg per d) and/or clopidogrel (75 mg per d), which may be given concurrently with anticoagulation to prevent myocardial ischemic events, but these strategies have not been thoroughly evaluated and are associated with an increased risk of bleeding. (Class IIB; Level of Evidence: C).” Recently, 1 European and
North American consensus paper stated that triple therapy (TT) with warfarin, aspirin, and thienopyridine should be preferred for AF patients undergoing PCI with stenting and with a CHADS₂ score >1. The length of TT in these patients is dependent on stent type and the assessment of ischemic and bleeding risk. Simultaneously, it is well recognized that the benefits of TT come with a significant 3-fold increase in bleeding risk compared to warfarin monotherapy and a 5-fold increase compared to DAPT, and these hazards increase further with longer durations of TT. For this reason, the guidelines indicate that the choice of discharge therapy should be dependent on balancing the risk of bleeding and thromboembolism in each individual patient.

These consensus statements have recently been challenged by the WOEST trial, which found that in patients undergoing PCI and on an anticoagulant therapy (69% indication AF, 88% CHADS₂ >1), the use of clopidogrel without aspirin was associated with a significant reduction in bleeding complications and no increase in the rate of thrombotic events, as compared to TT. A recent Danish nationwide retrospective study based on dispensed drug prescriptions in real-life AF patients hospitalized with an MI and/or undergoing PCI in the period from 2001 to 2009, oral anticoagulant therapy plus clopidogrel was equal or better than TT regarding both benefit and safety outcomes, essentially confirming the WOEST trial.

Estimating major bleeding risk in patients with AF undergoing PCI is performed with the HAS-BLED score. The HAS-BLED bleeding risk score is an AF-specific score based on hypertension, abnormal renal function (dialysis, renal transplantation, or serum creatinine >200 mmol/L) and liver function (chronic hepatic disease or biochemical evidence of significant hepatic derangement, bilirubin >2 times upper limit of normal, in association with aspartate aminotransferase/alanine aminotransferase/alkaline phosphatase >3 times upper limit of normal), stroke, bleeding (history or bleeding predisposition), labile international normalized ratio (INR; unstable INR or poor time in the therapeutic range <60%), elderly status (eg, age >65 years), and use of drugs or alcohol (Table 59-8). Major bleeding was defined in the HAS-BLED study as intracranial, requiring hospitalization, involving hemoglobin decrease >2 g/L, and/or requiring transfusion, and major bleeding was assessed at 1 year.
### HAS-BLED Bleeding Risk Score Criteria

<table>
<thead>
<tr>
<th><strong>Hypertension</strong></th>
<th>1 point for uncontrolled high systolic blood pressure (SBP) with a SBP ≥160 mm Hg</th>
</tr>
</thead>
</table>
| **Abnormal kidney and/or liver function** | 1 point for impaired kidney or liver function  
2 points for both |
| **Stroke** | 1 point for previous history of stroke, especially deep brain (lacunar) stroke |
| **Bleeding** | 1 point for previous history of bleeding, anemia, or predisposition to bleeding |
| **Labile international normalized ratio (INR)** | 1 point for unstable or high INRs or <60% of time in therapeutic range |
| **Elderly** | 1 point for age 65 or older |
| **Drugs and/or alcohol** | 1 point for taking antiplatelets agents  
1 point for consuming 8 or more alcoholic drinks per week (or 2 points for both) |

The ATRIA (Anticoagulation and Risk Factors in Atrial Fibrillation) bleeding risk score determines major bleeding risk for patients on warfarin. It is composed of anemia (hemoglobin <13 g/dL in men and <12 g/dL in women), severe renal disease (glomerular filtration rate <30 mL/min or dialysis dependent), age ≥75, any prior hemorrhage diagnosis (eg, gastrointestinal bleed, intracranial hemorrhage), or a history of hypertension. Major hemorrhage was defined from clinical databases by retrospective search of International Classification of Diseases, Ninth Revision, codes for extracranial hemorrhages (ie, gastrointestinal, genitourinary, retroperitoneal) and primary and secondary diagnoses of intracranial hemorrhage, including intracerebral, subarachnoid, or subdural hemorrhages, which were confirmed by chart review and restricted to fatal,
requiring transfusion of ≥2 units of packed blood cells, or hemorrhage into a critical anatomic site (e.g., intracranial, retroperitoneal).

The HEMORR\textsuperscript{2}HAGES risk score\textsuperscript{58} was developed from existing classification schemes, classified into a new scheme, and validated in 3791 AF patients in a combined Medicare inpatient administrative dataset from 7 states.\textsuperscript{58} The score assigns 2 points for a prior bleed and 1 point for each variable shown in Table 59-9. Patients are stratified into low, intermediate, and high risk for major bleeding according to scores of 0 to 1, 2 to 3, and ≥4, respectively. In patients prescribed warfarin, HEMORR\textsuperscript{2}HAGES had a greater predictive accuracy than older bleed prediction schemes. Interestingly, the score performed similarly in subjects prescribed aspirin or no antithrombotic therapy.

1 point for previous history of fall risk

Stroke
1 point for previous stroke or brain infarct detected by brain imaging

Abbreviations: ALT, alanine aminotransferase; AST, aspartate aminotransferase.

The use of the ATRIA and HEMORR$_2$HAGES risk scores in clinical practice is currently debated because it has been demonstrated that the HAS-BLED score shows significantly better prediction accuracy than the weighted (and more complex) ATRIA and HEMORR$_2$HAGES scores.

Finding the right balance that minimizes bleeding risk and maintains anti-ischemic efficacy remains a complex and controversial clinical dilemma in these unique patients. The arrival of novel antiplatelet agents and anticoagulants on the scene has led to an exponential increase in the combinations that may be employed by clinicians in real-life situations. At present, 4 novel and approved oral anticoagulant options have been studied in AF populations (dabigatran, rivaroxaban, apixaban, and edoxaban), none of which have been tested in connection with PCI or any of the 4 commonly used oral antiplatelet options (aspirin, clopidogrel, ticagrelor, prasugrel). Just the sheer number of combinations means that the best antiplatelet and oral anticoagulant combination based on data from RCTs will not be known for many years. At present, clinical trials for some of the novel oral anticoagulant options have either been announced or started to enrolled AF patients undergoing PCI, but results will not be available for another couple of years.

CONCLUSION

The outcome measure of bleeding in patients undergoing percutaneous cardiovascular interventions has evolved into a central and permanent end point in RCTs, as an increased number of studies rely on the combined end point of ischemic and bleeding adverse events in order to describe net clinical
benefit of a new antiplatelet or anticoagulant drug. In addition, in clinical practice, increased attention is steered toward the avoidance of bleeding complications, with the goal of balancing antithrombotic regimens to the benefit of patients undergoing PCIs and TAVR, with or without AF.

In an effort to produce comparable data, the number of bleeding criteria applied should be limited, and reporting 1 bleeding criterion of choice as well as 1 standardized set of criteria, such as the definitions by BARC or VARC, should become the standard method for reporting bleeding complications in a randomized or observational context.

INTRODUCTION

Percutaneous coronary intervention (PCI) is one of the most common procedures performed in US and European hospitals. In the United States, 954,000 PCI procedures were performed in 2010, and in over 90% of these procedures, at least 1 coronary stent was implanted. Stent thrombosis (ST) is the most feared complication of coronary stenting and is characterized by rapid accumulation of thrombus within or adjacent to the stent. ST is typically associated with the abrupt onset of an acute coronary syndrome (ACS), manifesting as severe unstable angina, acute myocardial infarction, or sudden cardiac death. ST should be distinguished from progressive in-stent restenosis, resulting in eventual vessel occlusion, typically presenting as progressive exertional angina, but occasionally as ACS.

In this chapter, we will review the classification of ST, the pathophysiology and predictors of ST, its consequences and treatment, and ongoing efforts to prevent this rare but major complication of percutaneous coronary revascularization. Data will be presented separately for bare metal stents (BMS; in aggregate for all types) and for first-generation (G1) and second-generation (G2) drug-eluting stents (DES). The G1-DES data refer specifically to paclitaxel-eluting stents (PES; Boston Scientific, Natick, MA) and sirolimus-eluting stents (SES; Cordis, Miami, FL), whereas G2-DES data reflect the experience accumulated predominantly with everolimus-eluting
stents (EES; Abbott Vascular, Santa Clara, CA; or Boston Scientific), zotarolimus-eluting stents (Endeavor [E-ZES] and Resolute [R-ZES]; Medtronic, Santa Rosa, CA). All these DESs have durable polymers (Table 60-1). A special section is devoted to DESs with bioabsorbable polymers or polymer-free DESs and to bioresorbable vascular scaffolds toward the end of this review.

CLASSIFICATION OF STENT THROMBOSIS

ST has been defined by the Academic Research Consortium (ARC) with respect to both its timing and certainty of its occurrence, in order to standardize interpretation of clinical trials and registries (Table 60-2). The ARC classification only considers events that occur after PCI is completed (after the patient has left the catheterization suite). More recently, an additional category of ST has been proposed—that which occurs after the stent has been implanted but before the PCI is completed, known as intraprocedural stent thrombosis (IPST). IPST is defined as the new appearance or worsening of preexisting thrombus within or adjacent to the recently implanted stent, with or without associated clinical symptoms. Diagnosis of IPST requires frame-by-frame angiographic analysis, usually in an angiographic core laboratory. The frequency of IPST is increased in patients undergoing stent implantation for ST-segment elevation myocardial
infarction (STEMI), those with high white blood cell count, and patients receiving treatment for thrombotic or bifurcation lesions and with bivalirudin monotherapy (vs heparin plus glycoprotein IIb/IIIa inhibitors).\textsuperscript{4} IPST is an independent predictor of subsequent mortality, reinfarction, and out-of-lab ARC ST. IPST heralds a much worse outcome at both 30 days and 1 year, even when normal epicardial blood flow is achieved at the end of the procedure.\textsuperscript{4,5}

\textbf{Table 60-2 Classification of Stent Thrombosis (Academic Research Consortium)}
Before the introduction of DES in 2003, acute (<24 hours) and subacute (1-30 days) ST was noted in 0.9% of more than 6000 patients treated with BMS, with approximately 50% of the events occurring within the first day of stent implantation.
implantation. The most important parameters associated with early ST were residual dissection, longer stent(s), and smaller minimal in-stent luminal diameter. Thus, most early ST was caused by inadequate deployment, which could be improved by more liberal use of intravascular ultrasound to avoid stent underexpansion and uncovered edge dissections or residual disease. The introduction of G1-DES did not reduce the incidence of early ST, especially if antiplatelet therapy is interrupted within the first 30 days. Similarly, the risk of early ST with G2-DES was reported to be 0.5%, compared with 0.7% for both BMS and G1-DES ($P = .074$), in a large German registry of PCI.

In contrast, incidence of late (1-12 months) and very late (>1 year) ST differs significantly among the different stent types. G1-DES are associated with a significantly higher risk of very late definite ST than either of the other types of stents (BMS or G2-DES), and it appears that this excess risk persists over many years after stent implantation. Among more than 18,000 patients treated in the German Registry, placement of G1-DES increased the risk of ST between years 1 and 3 nearly 5-fold compared with BMS or G2-DES. In fact, the risk of very late ST with G2-DES may be similar to BMS, although more studies are required in this regard to be certain of these observations.

**PATHOPHYSIOLOGY OF STENT THROMBOSIS**

Acute and subacute ST differ significantly from late and very late ST with respect to pathophysiologic mechanisms. For the former, a number of factors contribute, including technical issues such as stent underexpansion, untreated disease at the edges, and residual uncovered dissections; patient- and lesion-related characteristics, such as presentation with ACS, small vessel size, long lesion length, and plaque characteristics such as presence of thrombus; and the inherent thrombogenicity of the implanted stent, determined by its architecture and presence or absence of polymer and antiproliferative drugs. All these variables further interact with the potency and continuity of dual antiplatelet therapy (DAPT), whose premature discontinuation appears to be the most powerful predictor of early ST.

Late and very late ST is characterized by a number of pathologic processes...
and conditions: delayed arterial healing and endothelial coverage after DES; hypersensitivity reactions to the polymer (particularly relevant to SES); vessel toxicity with positive remodeling and fibrin deposition behind the struts (particularly relevant to PES); and bifurcation stenting, neoatherosclerosis, and strut fracture (which affects both BMS and DES). Neoatherosclerosis is a recently described phenomenon that underlies both restenosis and ST (Fig. 60-1). Neoatherosclerosis may be incited by the persistent inflammatory stimulus provided by the permanent presence of the drug-eluting polymer. In vivo studies of patients with ST using optical coherence tomography (OCT) highlighted the role of lipid-laden intima with (explaining clinical presentation as ACS) or without rupture, suggestive of neoatherosclerosis, as the underlying cause. In a series of 15 patients with ST, OCT identified an obstructive thrombus in all subjects, marked stent underexpansion (60% of predicted area), and neoatherosclerosis in one-fourth of cases. In contrast to early ST, interruption of DAPT plays a less important role in late ST (although it may be important if there is an additional trigger to increase platelet reactivity, such as trauma or the need for unplanned surgery). At least for G1-DES, the risk of late and very late ST appears to remain constant over 4 to 5 years from stent implantation, at a rate of 0.3% to 0.6% per year.

**FIGURE 60-1** Neoatherosclerosis and stent thrombosis. A. Cross-sectional histology
of bare metal stent (BMS) implanted in the coronary artery for 7 years antemortem (Movat, ×20). B. High-power image of the box in A (×100). A large necrotic core (NC) containing cholesterol crystals is identified within the neointima. The fibrous cap overlying the NC is infiltrated by numerous foamy macrophages and is markedly thinned (yellow arrowheads point to thinnest portion), which resembles vulnerable plaque encountered in native coronary arteries. The asterisks represent metal struts. C. Cross-sectional histology of paclitaxel-eluting stent (PES) implanted in the coronary artery for 4 years antemortem (Movat, ×40). D. High-power image of the box in C (×200). A relatively small NC containing cholesterol crystals is formed around metal struts (asterisk). The fibrous cap is infiltrated by numerous foamy macrophages and is markedly thinned (yellow arrowheads point to thinnest portion). (Histology images A—D reprinted from Park SJ, Kang SJ, Virmani R, Nakano M, Ueda Y. In-stent neoatherosclerosis: a final common pathway of late stent failure. J Am Coll Cardiol. 2012;59:2051-2057, Copyright © 2012, with permission from American College of Cardiology Foundation.)

G2-DESs, particularly EES with durable fluorinated polymer, appear to be less susceptible to late and very late ST. In a pathologic analysis of patients (after excluding those with stent duration of implantation >3 years), morphometric assessment was available in 73 SES, 85 PES, and 46 EES stents, half of which were implanted for off-label indications.19,20 Remarkably, the incidence of uncovered struts in each of these groups was 18.0%, 18.7%, and 2.6%, respectively (P <.0005), despite a similar average implant duration of approximately 9 months in the 3 groups. The 3 groups also had similar rates of restenosis underlying ST (12%-17%). Neoatherosclerosis was observed in 35%, 19%, and 29% of patients in the SES, PES, and EES groups, respectively (P = .91), while hypersensitivity reactions were seen exclusively with SES. The overall inflammation score was significantly lower for EES (0.26 vs 1.00 for each of G1-DES; P <.0005). It is important to emphasize that these data were obtained from autopsies, but only one-third of the deaths were stent related, whereas one-third were a result of noncardiac causes and the remainder were cardiac deaths unrelated to ST. Thus, only one-third of these patients fulfilled the criteria for definite ST according to the ARC definition (see Table 60-2).

PREDICTORS OF STENT THROMBOSIS

Multiple observational series and randomized clinical trials have analyzed the
independent predictors of ARC ST for BMS and DES, with models including demographic and baseline characteristics, procedural variables, and medication regimen and adherence.\textsuperscript{8,12,21-25} Almost invariably, early discontinuation of DAPT—defined as <4 weeks for BMS and <3 to 6 months for G1-DES—was associated with a 5- to 90-fold increase in hazard of ST (Table 60-3). Other important predictors emerging in some of these analyses were chronic kidney disease, diabetes mellitus, bifurcation stenting, stent length, and intracoronary irradiation provided for BMS in-stent restenosis.

Abbreviation: MI, myocardial infarction.

A more recent analysis of nearly 19,000 patients stented between 1998 and 2011 demonstrated that, using BMS as reference, G1-DES, diabetes mellitus, current smoking, prior myocardial infarction (MI), presentation with STEMI, complex lesion morphology, and increasing residual stenosis were independently associate with higher rates of definite ST up to 3 years from procedure. More than 50% of all events occurred within the first month.\textsuperscript{10}

Following the first report of 4 cases of late and very late ST occurring after G1-DES,\textsuperscript{26} Stone et al\textsuperscript{27} performed a meta-analysis of 9 randomized clinical trials comparing SES with BMS (n = 1748 patients, 4 trials) or PES with BMS (n = 3513, 5 trials). The rates of protocol-defined ST up to 4 years were 1.2\% versus 0.6\% for SES and BMS, respectively ($P = .20$), and 1.3\% versus 0.9\% for PES and BMS, respectively ($P = .30$). The study highlighted the excess of ST events occurring beyond 1 year from PCI in the DES-treated
patients, corresponding to approximately 1 additional event for approximately 500 patient-years. The majority of patients were not on DAPT at the time of the event. Notably, the incidence of death or MI was similar in DES and BMS patients. In this regard, the beneficial effects of DES in terms of preventing restenosis (which, when severe, may lead to MI) may offset the rare but serious consequences of ST.28

In a consecutive series of nearly 6000 patients treated between 2007 and 2010 and followed for 2 years, definite or probable ST occurred in 1.9%. Three-quarters of the events occurred within 30 days, and only 16% occurred beyond 1 year. Cardiogenic shock, STEMI presentation, lack of DAPT, diabetes mellitus, and stent length and diameter were independent predictors of ST.29

Recent data suggest that G2-DES, particularly EES, have lower rates of ST than G1-DES. In an analysis of 4 randomized trials of EES and PES (n = 6789), ST occurred by 2 years in 0.7% of EES patients and 2.3% of PES patients (P = .0001). The reduction in ST events with EES was apparent in all intervals—early, late, and very late. DAPT discontinuation beyond 6 months was associated with increased risk of ST in PES patients only.30 Supporting these data are the results from the XIENCE V USA postapproval registry of 8061 patients. The incidence of definite or probable ARC ST was 0.8% at 1 year, and the independent predictors for its occurrence were discontinuation of DAPT before 30 days (hazard ratio [HR], 8.63; 95% confidence interval [CI], 2.69-27.73; P = .0003), chronic kidney disease, and total stent length.31 Black race may also be related to higher risk of ST, independent of medication compliance.32

**PLATELET INHIBITION AND STENT THROMBOSIS**

The most comprehensive analysis to date of the relationship between high on-treatment platelet reactivity (HPR) and ST is derived from the Assessment of Dual Antiplatelet Therapy With Drug-Eluting Stents (ADAPT-DES) study. Patients (n = 8583) with uncomplicated DES implantation had platelet function testing at an average of 20 hours after PCI using the VerifyNow device (Accriva, San Diego, CA). Half of the patients had ACS, and one-
third had 3-vessel coronary artery disease (CAD) or left main trunk involvement. An average of 1.8 lesions per patient were treated using 1.7 stents. Nearly two-thirds of the stents used were EES, whereas 30% were G1-DES. At 1 year, the compliance was 84% with DAPT (aspirin and clopidogrel) and 95% with aspirin. Forty-two percent of patients had platelet reactivity units (PRU) >208, consistent with HPR on clopidogrel. Definite or probable ST occurred in 0.84% of patients by 1 year and in 1.07% of patients by 2 years. There was a significant excess of definite or probable ST in those with PRU >208, (HR, 1.98; 95% CI, 1.30-3.01; P < .0001; Fig. 60-2). Eighty percent of the events were definite ST; very late ST accounted for only a fourth of all events. HPR was predictive for 2-year definite or probable ST (HR, 2.08; 95% CI, 1.22-3.17; P = .008) and even more so for definite ST (HR, 2.84; 95% CI, 1.48-5.48; P = .002), but was not an independent predictor of mortality at 1 or 2 years, reflecting possibly the interplay between higher bleeding risk and lower ischemic risk associated with more effective platelet inhibition.

At the clinical level, the PARIS Registry evaluated in detail the compliance of patients to DAPT as well the reasons and timing of its discontinuation. Among 5033 patients enrolled in 5 countries after successful DES or BMS implantation for any clinical indication, the rate of discontinuation of DAPT was 2.6% at 30 days, 11.8% at 6 months, and 19.9% at 1 year. As expected, the rate of physician-recommended discontinuation was different at each time point: 0.3%, 7.6%, and 12.3%, respectively. At 1 year, the rate of death was 2.2%, spontaneous MI 1.9%, ST 1.9%, and revascularization 4.5%. There was no significant difference in protocol-defined ST between patients on and off DAPT (1.9% vs 2.7%, \( P = .14 \)), but the incidence of MI was higher in those off DAPT (4.8% vs 1.4%, \( P < .001 \)). After adjusting for baseline characteristics, patients off DAPT were more likely to experience death (\( P = .002 \)), MI (\( P < .001 \)), and ST (\( P = .009 \)), particularly in the first 7 days after PCI, and only when discontinuation was the result of disruption (interruption due to noncompliance or bleeding), rather than physician-recommended interruption.\(^{34}\) A recent evaluation of DAPT disruption in the R-ZES program found that discontinuation beyond 1 month after PCI is associated with a very low risk of ST.\(^{35}\)

**DURATION OF DUAL ANTIPLATELET THERAPY AFTER STENTING**

The duration of DAPT after stenting is dictated both by clinical presentation and by stent type. European and American professional guidelines concur that ACS patients should receive DAPT for up to 1 year regardless of whether PCI was performed or DES was implanted.\(^{36,37}\) In contrast, for patients undergoing stent implantation for non-ACS indications, the duration of DAPT prescription varies with stent type. Consensus has evolved that BMS does not require more than 1 month of DAPT.\(^{38}\) For DES, considerable uncertainty remains. Concerns of increased ST rates with G1-DES led to the recommendation (not founded on randomized trials) that at least 1 year of DAPT should be used. Furthermore, the ongoing hazard of very late ST with G1-DES has prompted the evaluation of longer DAPT therapy, even up to 36 months from PCI.

Several randomized trials have been performed to determine whether
patients might benefit from DAPT usage after DES for longer than 1 year. The Optimal Duration of Clopidogrel Therapy With DES to Reduce Late Coronary Arterial Thrombotic Events (DES LATE) trial enrolled 5045 patients free of any complications 12 months after DES implantation and randomized them to aspirin alone or to DAPT for at least an additional year. Two-thirds of the patients received G1-DES, and the same proportion had ACS. The primary end point was a composite of cardiac death, myocardial infarction, or stroke 24 months after randomization. There was no difference in the incidence of the primary end point between the 2 groups (2.4% vs 2.6%, respectively; \( P = .75 \)). Definite ST occurred in 0.5% and 0.3%, respectively (\( P = .34 \)), whereas Thrombolysis In Myocardial Infarction (TIMI) major bleeding was noted in 1.1% and 1.4%, respectively (\( P = .20 \); Fig. 60-3).39

**FIGURE 60-3** Major adverse coronary events according to duration of dual antiplatelet therapy (aspirin alone = red; dual therapy = blue) in 5045 event-free patients 12 months after drug-eluting stent implantation. FU, follow-up; HR, hazard
These results confirmed a previous report from the same group. The Prolonging Dual Antiplatelet Treatment After Grading Stent-Induced Intimal Hyperplasia Study (PRODIGY) randomized 2013 patients to 1 of 4 stents (EES, PES, ZES, or BMS) and to short (6 months) or long (24 months) DAPT. Aspirin was continued indefinitely in all patients. After excluding failed PCI and early complications, 1970 patients were randomized to the 2 DAPT regimens. Three-fourths of patients had PCI for ACS. The primary end point (all cause death, MI, or stroke) occurred in 10.0% and 10.1% of patients in the short and long DAPT groups, respectively ($P = .98$), and there was no interaction between the rate of events and clinical presentation or stent used (BMS vs DES). ST was not different between the groups ($P = .80$; Fig. 60-4). Type 2 or greater Bleeding Academic Research Consortium classification (BARC) bleeding was less common in the short DAPT group (3.5% vs 7.4%; $P = .0002$), with all the difference occurring, as expected, beyond 6 months from randomization. In a more detailed analysis of the event rates according to stent type, the investigators found that E-ZES patients had significantly better outcomes with shorter DAPT ($P_{INT} = .004$).

Similar results were reported from another meta-analysis of more than 8000 patients followed for nearly 1.5 years and comparing DAPT for 16 versus 6 months. The Dual Antiplatelet Therapy Study (DAPT) compared 12 to 30 months of DAPT after BMS or DES and was powered to detect differences in rare events such as ST. Among 9961 patients treated with DES, adherent to DAPT, and free of major ischemic or bleeding complications after 12 months of DAPT, an additional 18 months of DAPT resulted in a significant reduction in definite or probable ST (0.4% vs 1.4% for aspirin monotherapy, \( P < .0001 \); almost all due to fewer instances of definite ST). Importantly, there was also a substantial reduction in MI (2.1% vs 4.1%, \( P < .0001 \)), but no effect on cardiac death (0.9% vs 1.0%, \( P = .98 \)). Both stent-related and non–stent-related MI were lowered by approximately 50% with prolonged DAPT, at the cost of an increased rate of moderate or severe bleeding (2.5% vs 1.6%, \( P = .001 \)).

In contrast to considering longer DAPT, the advent of G2-DES and the frequent need to discontinue DAPT earlier because of intervening surgery or bleeding have spurred studies evaluating DAPT duration shorter than 1 year, even as low as 1 month. The Efficacy of Xience/Promus Versus Cypher to Reduce Late Loss After Stenting (EXCELLENT) trial randomized 1443 patients to EES or SES (3:1) and 6 or 12 months of DAPT (1:1). The incidence of target vessel failure (TVF, defined as cardiac death, target vessel MI, or target vessel revascularization) was 4.8% and 4.3% for the 6- and 12-month DAPT regimens, respectively (\( P = .001 \) for noninferiority). Interestingly, ST occurred in 0.9% of the short DAPT group and in 0.1% of the long DAPT group (\( P = .10 \)). The Real Safety and Efficacy of a 3-Month Dual Antiplatelet Therapy Following E-ZES Implantation (RESET) trial compared 3 months of DAPT in patients receiving E-ZES to 12 months of DAPT in patients receiving other DES. Among 2117 patients followed for 1 year, the incidence of TVF was 4.7% in each group (\( P = .84 \); \( P < .001 \) for noninferiority). Definite ST occurred in 0.2% and 0.3%, respectively (\( P = .65 \)). The OPTIMIZE trial randomized 3119 patients receiving E-ZES for
stable CAD or low-risk ACS to 3 or 12 months of DAPT. All-cause death, MI, stroke, or major bleeding occurred in 6.0% and 5.8% of patients, respectively ($P = .84$; $P = .002$ for noninferiority). There was also no significant difference in outcome in a landmark analysis at 3 months $P = .91$). ARC definite or probable ST occurred in 0.6% and 0.7% of patients, respectively ($P = .64$), until 3 months, and in 0.3% and 0.1%, respectively ($P = .18$), beyond 3 months (Fig. 60-5).^47

![ARC Def./Prob. stent thrombosis](image)

None of these trials have been adequately powered to definitively
determine the optimal duration of DAPT after DES, particularly as the risk-to-benefit ratio of DAPT duration may be stent specific. Nonetheless, data are accumulating that there is little to be gained from extending DAPT beyond 1 year, and in fact, this practice may result in excess major bleeding. Conversely, data are emerging that 3 to 6 months of DAPT may be safe for several G2-DES, although more data are required before firm recommendations can be made to routinely stop DAPT early.

An interesting observation emerged from the review of these 11 trials and the 12 meta-analyses that have been performed to summarize them. For definite or probable ST, there was no interaction between the length of DAPT and stent type ($P = .76$ for SES vs PES vs ZES vs EES), suggesting that longer DAPT is equally beneficial for all stents in preventing ST. In contrast, major adverse cardiac events were predominantly reduced by prolonged DAPT in G2-DES, with little or no effect for ZES and EES ($P = .048$).

For now, a rational proposal would be to continue DAPT for 1 year after DES in patients with ACS and for 3 to 6 months (or possibly 12 months in the absence of side effects) after G2-DES in patients in whom the stent was implanted for stable coronary artery disease. The US Food and Drug Administration (FDA) recently completed a review of all the 11 trials published since Fall 2015 on this topic (n = 33,051 patients) and concluded that shorter DAPT duration is associated with increased risk of ST (odds ratio [OR], 1.63; 95% CI, 1.00-2.66, random effect model, $I^2 = 39\%$) and MI (OR, 1.37; 95% CI, 1.08-1.72; $I^2 = 31\%$), without a significant effect on all-cause mortality.

**COMPARISON OF SPECIFIC STENT TYPES**

Because ST is infrequent, reliable estimation of ST rates and comparison between stents in individual trials are difficult. To overcome this limitation, network meta-analyses have been performed that enable indirect comparison of studies with common comparator groups. Palmerini et al $^{49}$ culled information from 49 randomized clinical trials describing the incidence of definite ST in 50,844 patients followed for up to 2 years. At 30 days and 1 year, fluoropolymer-based EES (both cobalt-chromium [CoCr] and platinum-
chromium [PtCr]) had significantly lower rates of ST than BMS, SES, PES, E-ZES, and R-ZES (Fig. 60-6). At 2 years, only comparisons of EES with BMS and PES were possible and showed continued marked reductions in ST with EES (OR, 0.35 [95% CI, 0.17-0.69] and OR, 0.34 [95% CI, 0.19-0.62], respectively). Direct and indirect estimates provided similar results in favor of CoCr-EES versus BMS, strongly suggesting that the potential hazard for ST associated with EES is reduced not just compared to other DES, but to BMS as well. These data confirmed the experimental observations regarding the passivation and thromboresistance of vascular surfaces afforded by surfaces coated by durable fluoropolymer, as they exist on the CoCr-EES. A smaller meta-analysis of 13 trials comparing EES with SES, PES, or R-ZES in over 17,000 patients followed for nearly 2 years again showed that EES reduced ST by 45% (relative risk [RR], 0.55; 95% CI, 0.38-0.78; \( P = .001 \)). These results were independent of duration of DAPT, duration of follow-up, or the comparator stent. The largest meta-analysis so far, not restricted to ARC definition of ST, in 76 trials with 117,762 patient-years of follow-up found that EES reduced ST compared with BMS by nearly 50% (RR, 0.51; 95% CI, 0.35-0.73; \( P < .001 \); Fig. 60-7).

TREATMENT AND CONSEQUENCES
OF STENT THROMBOSIS

In general, ST results in ACS with or without ST-segment elevation and presents as an acute MI. As with de novo plaque rupture, the preferred therapeutic paradigm is an early invasive strategy with balloon angioplasty and/or stenting, often preceded by thrombus aspiration. Intravascular ultrasound is strongly recommended to exclude stent underexpansion and/or untreated edge disease or dissections. It is obviously important to determine the timing of the event relative to index PCI and the adherence to DAPT on presentation. In the first decade of stenting, ST was associated with considerable mortality and morbidity. In a recent comprehensive analysis from the National Cardiovascular Data Registry (NCDR), ST was noted in 1.8% (n = 7315) of all patients undergoing PCI for ACS. The timing of ST was early in 20%, late in 20%, and very late in 60% of patients. As in other series, the in-hospital mortality in patients with early ST was much higher than in the other groups (7.9% vs 3.8% vs 3.6%, respectively; P < .001) a finding that persisted after multivariable adjustment. It is notable that BMS was involved in one-third of the patients with early and late ST, but in only one-sixth of patients with very late ST. The mortality did not differ in patients with DES or BMS ST, but the treatment received did, particularly for early ST. Patients with ST due to DES were much more likely to receive another DES (37%) than those with BMS (8.6%), probably reflecting the initial reluctance to implant a DES. Balloon angioplasty alone was used in 30% to 50% of all patients, while thrombus aspiration was performed in only 50%. It remains unclear why early ST may be associated with higher mortality. It is possible that early ST is associated with greater thrombus burden in the presence of poorly inhibited platelets, which contributes to inadequate myocardial reperfusion. Similar data were generated from the large HORIZONS AMI trial.

STENT THROMBOSIS AFTER STEMI

Among all patients undergoing PCI and stenting, those with STEMI usually harbor the largest thrombus burden. Intuitively, placing a metallic object in such an environment, even after thrombus aspiration (which is rarely
complete\textsuperscript{56}, is expected to lead to a higher rate of ST. Indeed, ACS in general has been found to be an independent predictor of ST.\textsuperscript{10} The randomized Evaluation of the Xience-V Stent in Acute Myocardial Infarction (EXAMINATION) trial evaluated the efficacy and safety of BMS versus EES in 1498 STEMI patients. At 2 years, the composite of all-cause death, MI, and any revascularization was 17.3\% versus 14.4\%, respectively ($P = .11$). Definite ST occurred in 2.1\% of BMS-treated patients compared to 0.8\% of EES-treated patients ($P = .03$), consistent with the results of the network meta-analysis discussed earlier.\textsuperscript{57} Two meta-analyses of STEMI datasets confirm these observations.\textsuperscript{58,59} In the larger meta-analysis including 28 trials and 34,068 patient-years of follow-up, SES, PES, and EES reduced the need for revascularization compared with BMS and had equivalent rates of death or recurrent MI. Moreover, EES was associated with a statistically significant reduction in the rate of ST, including very late ST when compared with SES ($RR$, 0.38; 95\% CI, 0.21-0.74), PES ($RR$, 0.39; 95\% CI, 0.21-0.73), and even BMS ($RR$, 0.42; 95\% CI, 0.23-0.76). In a recent network meta-analysis of 21 trials (15 of which compared G1-DES with BMS, 4 of which compared G1-DES with G2-DES, and 2 of which compared G2-DES with BMS) including 12,866 patients, G2-DES were associated with a significantly lower incidence of definite ST at 30 days compared with BMS ($OR$, 0.36; 95\% CI, 0.15-0.81) and at 1 year ($OR$, 0.49; 95\% CI, 0.30-0.79). The reduction in ST was accompanied by a significantly lower rate of MI and TVR but not mortality (Fig. 60-8).\textsuperscript{60}

These data, in aggregate, suggest that DES (and in particular EES) may be appropriate in most patients with STEMI, in the absence of a clear need for early discontinuation of DAPT or anticipated noncompliance with medical therapy.

NEW APPROACHES FOR PREVENTION OF STENT THROMBOSIS

Because of the inherent thrombogenicity and inflammatory potential of a permanent implant consisting of metal and polymer, 2 concepts have evolved to resolve the persistent risk of very late ST, observed particularly with G1-DES. The first approach attempts to eliminate the negative effect of a durable
polymer, by using bioabsorbable polymers or creating polymer-free stents with direct drug coating. Bioabsorbable polymers have been developed to resorb after having eluted the antiproliferative agent. Most of the clinical experience stems from studies of the bioabsorbable polymer (BP)-based biolimus-eluting stent (BES). The polymer is polylactic acid applied solely to the abluminal stent surface by a fully automated process. Over a 6- to 9-month period, the polymer is converted into carbon dioxide and water. In a noninferiority trial comparing SES with BES in 1707 patients with stable CAD or ACS (55% of all patients), the primary end point of cardiac death, MI, or TVR at 9 months was 10.5% versus 9.2%, respectively (PNI = .03). Definite ST occurred in 2.0% and 1.9% of patients, respectively.61

A similar approach to BES was tested in the EVOLVE II trial comparing the platinum-chromium EES stent with the SYNERGY stent (Boston Scientific), an EES-eluting stent with bioresorbable PLGA [poly(lactic-co-glycolic acid)] polymer applied only to the abluminal aspect of the vessel. Target lesion failure at 1 year was well within the noninferiority margins at 1 year (6.5% vs 6.7%, respectively). Definite or probable ST was noted in 0.6% and 0.4%, respectively (P = .50).62

In the LEADERS-FREE trial, 2466 patients at high risk for bleeding because of advanced age or need for oral anticoagulation therapy were randomized to a polymer-free biolimus-coated stent or a BMS with DAPT for 1 month only. There was no difference between the groups in incidence of definite or probable ST at 1 year (2.0% vs 2.2%, respectively; P = .70).63 In the ISAR-TEST 3 study, SES was compared with a BP-SES and with a polymer-free (PF) SES. The primary end point of in-stent late loss at 6 to 8 months was significantly higher in the PF-SES arm compared with the other two arms, failing noninferiority criteria. Death or MI was similar at 1 year in the 3 groups (P = .70), whereas the incidence of definite ST was 0%, 0.5%, and 1.0%, respectively (P = .72). Obviously, the study (n = 605) was not powered for any of the clinical events.64

Extending the network meta-analysis described earlier to include studies with BES, Palmerini et al65 concluded that BES is superior to PES and to BMS with respect to cardiac death or MI. BES is equivalent to SES, EES, and ZES with respect to cardiac death or MI, whereas EES is superior to BES with respect to definite ST (OR, 0.41 [95% CI, 0.21-0.77] at 1 year and OR, 0.52 [95% CI, 0.29-0.98]) at longest term follow-up available.65
The second approach to mitigating the consequences of a permanent implant, including the need for long-term DAPT, is that of a fully bioresorbable scaffold that resorbs after eluting the antirestenotic drug, leaving behind a well-healed coronary segment without a permanent implant. The restoration of normal coronary physiology in the stented segment is particularly important because adequate endothelial function may prevent further progression of atherosclerosis. The lack of a permanent implant also obviates concerns of late strut fracture or malapposition and may reduce the development of neoatherosclerosis. Six such devices have reached the stage of clinical trials (Table 60-4), although many more are in various stages of preclinical development. The polylactic acid ABSORB scaffold (Abbott Vascular) was first tested in a small first-in-man trial of 30 patients. At 2 years, the rate of ST was 0% and late loss was 0.48 ± 0.28 mm (compared with 0.33 ± 0.37 mm with CoCr-EES in the SPIRIT II study). There was significant change in lumen diameter at 2 years in response to acetylcholine stimulation in the stented segment, as well as proximal and distal to it, suggesting recovered endothelial function. A structural modification of the scaffold (version 1.1, tested in 101 patients in cohort B) led to reduced late loss (0.27 ± 0.20 mm at 2 years), comparable to that observed with EES. The ABSORB II study randomized (2:1) 501 patients to bioabsorbable vascular stent (BVS) or EES. At 2 years, target lesion failure occurred in 4.8% and 3.0% of patients, respectively (P = .35). Definite or probable ST occurred in 1.5% and 0%, respectively (P = .17). The ABSORB III study was recently presented at the 2015 TransCatheter Therapeutics Meeting. Among 2008 patients randomized 2:1 to BVS versus EES, the primary end point of target lesion failure was recorded at 1 year in 7.8% and 6.1% of patients, respectively, satisfying the prespecified criteria for noninferiority (P = .007). All components of the primary end point were numerically lower in the EES group, whereas angina at 1 year was nearly identical in both groups (18%). Definite or probable ST occurred in 1.54% and 0.74% of patients, respectively (P = .13). Long-term follow-up from these studies is required to determine whether ST rates are at all lower with the bioresorbable scaffold compared to the best-in-class metallic DES. The ABSORB BVS was also tested in the most thrombogenic milieu possible—patients with acute STEMI. In the TROFI II trial, 191 patients were randomized to BVS or EES. The primary end point—healing score by optic coherence tomography—was lower in the ABSORB arm than in the EES arm (1.74 vs 2.80, respectively; P
for noninferiority <.001), and definite ST occurred in 1.1% and 0%, respectively ($P = .70$).

Bioresorbable scaffolds have also been manufactured from magnesium and iron. The paclitaxel-eluting bioresorbable magnesium DREAMS scaffold (Biotronik, Berlin, Germany) was tested in the first-in-man BIOSOLVE I trial. Among 46 patients followed for 1 year, 3 had TVF, and there was no STs. There was improved endothelial function in patients treated with this stent as well. However, the late lumen loss 6 months after the DREAMS stent was 0.68 ± 0.57 mm, higher than with G2-DES. This stent has been reconfigured to elute sirolimus (to further reduce late loss) and is again undergoing human testing.

The next challenges for bioresorbable scaffolds are to determine optimal DAPT duration and confirm the results of ABSORB III and TROFI II in other datasets. An intriguing possibility exists that these bioresorbable scaffolds can be used to “seal” existing coronary lesions that are not yet hemodynamically significant and prevent progression of atherosclerosis and plaque rupture.

**CONCLUSION**
Stents in general and DES in particular have revolutionized PCI. ST is a rare event but continues to be of great importance because of its often devastating consequences. Early ST is typically related to procedural deficiencies or unplanned discontinuation of DAPT. Most studies showed similar rates of early and late ST with DES and BMS, as long as DAPT was not discontinued early. Very late ST, however, was more common with G1-DES than BMS, but appears to have been nearly eliminated with G2-DES, particularly those with a durable fluorinated polymer. Current data do not support the superiority of BP-based DES or polymer-free metallic DES as an alternative to G2-DES, although more data are needed, especially with novel, innovative designs. Completely bioresorbable scaffolds offer the promise of healing the endothelium in the stented area, restoring endothelial function, and potentially, preventing progression of atherosclerosis. Ongoing trials will determine whether these theoretical advantages translate into a reduced risk of very late ST.

**MULTIPLE CHOICE QUESTIONS**

1. After percutaneous coronary intervention (PCI) with a drug-eluting stent (DES), what is the incidence of acute and subacute stent thrombosis?
   A. Similar to incidence after bare metal stent (BMS)
   B. Higher than incidence after BMS
C. Lower than incidence after BMS  
D. Higher for first-generation DES than for BMS but lower for second-generation DES than for BMS

2. Contributors to late and very late DES thrombosis include which of the following?  
   A. Delayed healing and incomplete endothelialization of stent struts  
   B. Chronic inflammation related to polymer-releasing drug  
   C. Neoatherosclerosis  
   D. All of the above

3. In ADAPT-DES, high platelet reactivity after PCI, defined as platelet reactivity units (PRU) >208:  
   A. Was an independent predictor of mortality at 2 years  
   B. Was an independent predictor of definite ST at 2 years  
   C. Was an independent predictor of death or ST at 2 years  
   D. None of the above

4. In the Dual Antiplatelet Therapy (DAPT) study, powered for ST as an individual end point, prolonged DAPT as compared to aspirin monotherapy led to all of the following changes except:  
   A. Reduced incidence of definite or probable ST by more than 50%  
   B. Reduced cardiac mortality by more than 50%  
   C. Increased moderate and severe bleeding by more than 50%  
   D. Reduced incidence of myocardial infarction by more than 50%

5. ABSORB III is the largest completed trial thus far of bioresorbable vascular scaffolds (BVS) compared with the “best-in-class” metallic everolimus-eluting stent (EES). This trial demonstrated that:  
   A. BVS have a significantly lower rate of target lesion failure at 1 year than EES and a similar rate of residual angina as EES  
   B. BVS have a significantly higher rate of target lesion failure at 1 year than EES and a similar rate of residual angina as EES  
   C. BVS have similar rate of target lesion failure and residual angina at 1 year as EES, fulfilling the criteria for noninferiority  
   D. None of the above
ANSWERS

1. A
Early stent thrombosis (ST) is predominantly dictated by procedural considerations (proper deployment and expansion and lack of residual dissection) and adherence to dual antiplatelet therapy and much less by stent type. With proper technique, all devices have a 0.5% to 0.7% rate of early ST.

2. D
Late and very late ST is a complex process involving the interaction between a diseased, nonhealing endothelium (because of the antiproliferative drug), chronic inflammation from the polymer delivering the drug, and even ensuing stent strut fracture. More recently, neoatherosclerosis was added to the list of contributors. It describes a process of accelerated atherosclerosis occurring in the stented segment and leading to plaque rupture similar to that observed in spontaneous myocardial infarction.

3. B
ST, definite in particular, is the quintessential platelet-derived adverse event. Thus, it is logical that insufficient platelet inhibition, as measured by high residual platelet reactivity (HPR), will be associated with and predictive of ST. The association of HPR with death is complicated by the higher risk of bleeding in patients without HPR, which may counteract the effect of lack of ST on mortality.

4. B
In the DAPT study, prolonged DAPT beyond 12 months lowered the incidence of ST (almost exclusively definite ST) by 70% from 1.4% to 0.4% and reduced the rate of spontaneous myocardial infarction by 50% from 4.1% to 2.1%. Importantly, 50% of the myocardial infarction events were not related to previously stented lesions, fulfilling the description of secondary prevention for patients with coronary artery disease. These important effects were countered by a significant increase in clinically relevant bleeding events, resulting in a neutral effect on cardiac mortality.
The ABSORB III trial, not yet published in a peer-review journal, was the pivotal trial for US Food and Drug Administration approval of BVS in the United States. Numerically, all components of the primary end point, target lesion failure at 1 year, were higher with BVS than EES, but well within the prespecified margins of noninferiority. Rate of residual angina was nearly identical in the 2 groups.
Coronary Artery Perforation

James R. Margolis

In the stent era, coronary artery perforation (CAP) is the most serious complication and a leading cause of death from percutaneous coronary intervention (PCI). Although preventable to a great extent, perforations are inevitable in any high-volume center. Prompt recognition and treatment can make the difference between benign and fatal outcomes. The incidence of CAP varies with the complexity of disease under treatment and with the aggressiveness of individual operators. An operator who never experiences a perforation is probably underdilating lesions and underdeploying stents. The reported incidence varies from 0.2% to 0.6%.\(^1\)\(^-\)\(^5\) It is much higher when atheroablative devices are used.\(^5\) In a meta-analysis of nearly 200,000 PCIs, the pooled incidence was 0.43%.\(^4\) Although there is no good series reporting the effect of stenting on the incidence of perforation, routine stenting most likely increases the perforation rate.

CLASSIFICATION

The classification of Ellis and colleagues\(^1\) is generally accepted. In this classification, a grade I perforation is an extraluminal crater without extravasation (this might also be termed a pseudoaneurysm); a type II perforation is a pericardial or myocardial blush without contrast jet extravasation; and a type III perforation is an extravasation through a 1-mm or larger perforation. This classification correlates with prognosis. A fourth
category is designated cavity spilling, in which the perforation empties into an anatomic cavity: right ventricle, left ventricle, coronary sinus, and so on (Fig. 61-1).
Contrast in RV
Perforation site

Contrast in RV outflow track
Site of perforation

Small leak

Tiny leak

Occlusion site
Original perforation site
Small perforations can usually be solved by prolonged balloon inflations combined with reversal of anticoagulation. Large perforations require more sophisticated treatment. Perforations in vein grafts frequently resolve with simple measures. This is because scarring around vein grafts may be enough to limit extravasation.

Perforations in proximal arteries require treatments that will both resolve the perforation and preserve antegrade flow. Blocking antegrade flow can sometimes solve more distal perforations. The most practical way to treat perforation in previously occluded arteries is to reocclude the artery. Perforations involving bifurcations are much more difficult to solve, because it may be necessary to stop bleeding in 2 branches while preserving flow to both branches. Occluding flow is the best way to solve perforations of small branches.

Perforations caused by balloons are relatively easy to solve, whereas those caused by stents are generally more severe and more difficult to treat. Devices are 2-edged swords in that debulking prior to stenting may prevent perforations, but the devices themselves can cause very severe and sometimes untreatable perforations.5

Guide wire perforations are more frequent, especially when hydrophilic wires are used in complex cases. In the usual scenario, the guide wire migrates distally in a tiny branch and eventually perforates the distal tip of the branch. This complication may not be recognized until after the guide wire has been withdrawn. Although the leaks are generally small, they can lead to cardiac tamponade. In one reported series, 20% of perforations causing cardiac tamponade were the result of guide wire perforations.6 This is especially a problem in the presence of glycoprotein IIb/IIIa inhibition. Because of relatively small and sometimes unrecognized leaks, guide wire perforation can lead to late cardiac tamponade.
Perforations are a significant problem in patients with chronic total occlusions. Guide wire perforations in this setting are seldom a serious problem, unless the perforation is unrecognized and balloon inflation is made over the perforating guide wire. In cases of chronic total occlusion, a guide wire may enter a tiny branch running parallel to the main vessel. If a balloon is inadvertently inflated within this vessel, serious perforation can ensue. Either of the aforementioned circumstances may result in cardiac tamponade and death. This is particularly distressing when the intervention is entirely elective.

**HIGH-RISK SITUATIONS**

Certain anatomic and morphologic conditions predispose to perforation. Recognition of these circumstances and appropriate adjustments in treatment strategies can prevent problems that would otherwise occur.

**Native Arteries**

Certain locations in the native coronary arteries represent a higher than standard risk for perforation.

**Lesions on Bends**

In general, lesions on bends present high risks for dissection with balloons and extreme risks for perforation with atherectomy devices. The curving nature of the right and left circumflex arteries may explain the higher incidence of perforation in these vessels.\(^4\)\(^5\) Excimer laser has the highest perforation risk when used on sharp bends. Excimer laser ablates only in a forward direction. Similar to the headlights on an automobile, laser light points straight when the road turns. Thus, excimer laser invariably causes perforation when used on a sharp bend. Rotablator (Boston Scientific, Marlborough, MA) has some ability to follow bends, but wire bias tends to drive the Rotablator burr toward the outer curvature, thus predisposing to perforation. When using Rotablator on sharp curves, the rule is to undersize the burr by at least 1 and preferably 2 sizes. Directional atherectomy and cutting balloon are less likely to perforate lesions on bends, but the undersize
rule is still operative when these devices are used in the curved portions of arteries.

**Bifurcation Lesions**

Bifurcations are troublesome to treat no matter what the strategy. Because plaque in this location frequently involves both the main artery and the ostium of the branch vessel, debulking strategies are often employed. The problem is that debulking devices may perforate the carina of the bifurcation, thus producing a very large hole that requires emergent treatment. Treatment of this problem with a covered stent invariably sacrifices the side branch and may not solve the problem. The perforation may involve both branches; therefore, collateral filling of the side branch can lead to continuing leak. Worse, once the stent graft covers the side branch ostium, access to the side branch is no longer possible.

The best way to deal with this problem is to avoid it. Theoretically, the bifurcation could be reconstructed with 2 “kissing” covered stents, but this is technically difficult because of the bulky nature of the stent grafts. In the face of a large perforation at the left anterior descending (LAD)/diagonal bifurcation, it may be best to occlude both branches with kissing balloons and send the patient to surgery.

**Lesions in Branches and Distal Vessels**

Because of their tapering nature, branches and distal vessels may be prone to rupture during stenting. Stents of appropriate size for proximal branches may be too large distally. This is particularly a problem in the distal LAD, where diffuse negative remodeling may be present. Figure 61-1 is an example of a long, drug-eluting stent in the LAD with a perforation occurring at the distal one-third of the stent. With the advent of drug-eluting stents, it is more common to stent more distally and to use longer stents. The best way to approach these tapering vessels is to carefully interrogate them with intravascular ultrasound (IVUS) before and after stenting. Stents should be sized appropriately for the distal vessel, and then postdilated proximally with short balloons of larger sizes.
Acute Margin Lesions

Lesions of the right coronary artery (RCA) at the acute margin represent a significant risk for perforation, especially with devices. The problem with this area is that the artery bends more acutely than is generally appreciated in the left anterior oblique projection. Compounding the problem is the bifurcation with the anterior ventricular branch and the propensity for severe stenoses to involve this bifurcation. When devices are used to treat this area, there is a tendency for the device to migrate in the direction of the anterior ventricular branch and thus perforate the artery at the inferior aspect of the bifurcation. This results in extremely large perforations that can become catastrophic if not treated within seconds.

Calcified Vessels

Calcified arteries are noncompliant. When stretched to extreme degrees, they tend to tear, especially at junctures where heavily calcified areas meet relatively normal ones. This is a particular problem when stents are placed in these vessels without proper preparation with Rotablator or cutting balloon. When the stents are deployed, they cannot be expanded fully. High-pressure balloons are then used, and the resulting uneven expansion of noncalcified areas leads to perforation or rupture. The mechanisms are similar to those described under vein grafts and eccentric lesions (vida infra).

Vein Grafts

Vein graft perforations generally occur when a resistant lesion suddenly responds to high-pressure balloon inflation. Pathologically, these are tears or ruptures as opposed to discrete holes. These resistant lesions may be the result of old fibrosis, sometimes outside the wall of the vein graft. The vein graft itself is relatively thin walled. Once resistance of the fibrous tissue is overwhelmed, the graft itself ruptures. Clinically, this is seen as an imprint that persists on an inflated balloon despite high pressure. If the imprint suddenly resolves as, for example, after a single bar increase in pressure, the operator should be concerned that rupture has occurred. In this instance, it is prudent to inject around the deflated balloon before removing it. If perforation has occurred, the balloon can be reinflated at low pressure while
anticoagulation is reversed and preparations are made for stent grafting. Because vein grafts are normally embedded in scar tissue and there is no pericardium, vein graft perforations usually act differently from those in native vessels. Following perforation of a vein graft, extravasation is generally limited by the dense surrounding cicatrix. This is especially true of vein grafts to the lateral left ventricle and posterior surfaces of the heart. These perforations can usually be treated with reversal of anticoagulation and observation. There are exceptions to this rule, especially in the proximal and mid-portions of grafts to the LAD and RCA. Vein graft perforations tend to be large. When they do bleed freely, blood loss is extreme, and early and effective treatment is mandatory. The first treatment must always be to cover the perforation with an inflated balloon.

**Eccentric Lesions**

Plaque eccentricity is the single most important morphologic feature that portends a propensity to perforation. Thick atheroma on one side and thin, frequently normal, arterial walls on the other characterize eccentric plaques. Balloon inflation and stenting tend to preferentially stretch the thin normal wall while barely affecting the noncompliant plaque. This is especially true when the plaque is diffusely fibrotic or heavily calcified. This is one condition in which preparation of the vessel with cutting balloon or a debulking device prior to stenting may actually reduce the risk of perforation. Routine use of IVUS prior to stenting will identify extreme eccentricity that may not be evident on the angiogram. Sumitsuji and colleagues in the Japanese Intervention and Ultrasound Study group have identified 3 ultrasound patterns that may predict perforation: (1) severe eccentric calcified plaque with weak segment on the opposite side; (2) severe eccentric fibrous plaque with weak segment on the opposite side; and (3) severe superficial calcium with weak segment in the opposite side.

**Guide Wire Perforations**

Guide wire perforations are a product of technologic advance (Fig. 61-2). They occur most frequently with hydrophilic wires. The extreme lubricity of these wires allows them to migrate without being noticed distally into and out of the tips of small branches. During difficult cases, involving multiple
balloon exchanges, it is not unusual to find the tip of a hydrophilic wire several centimeters into the pericardial space. Usually, this does not result in a clinical problem. Occasionally, it can result in a minor or major leak into the pericardium that is difficult or impossible to resolve.
FIGURE 61-2 Guide wire perforation treated with thrombin injected through a microcatheter. (A) Guide wire in distal portion of small branch. (B) Faint contrast stain during first post–percutaneous coronary intervention injection. (C) Subsequent injection shows grade II perforation. (D) Balloon inflated at low pressure temporarily stops the leak. (E) After balloon inflation, the perforation is not fully sealed. (F) Grade II leak resumes within a few minutes after balloon inflation. (G) After thrombin administration, the perforation is sealed without interrupting flow to other branches.

The best way to prevent guide wire perforations is to avoid hydrophilic
wires whenever possible, but guide wire perforations can also occur with conventional wires, especially ones with stiffer tips. The guide wire perforation in Figure 61-2 was caused by a conventional wire with intermediate tip stiffness. Unfortunately, hydrophilic wires are most useful in the most difficult cases. In such cases, it is good practice to exchange the hydrophilic wire for a conventional wire at the earliest opportunity. When using hydrophilic wires, it is important to be constantly aware of distal tip position and to guard against distal migration. Problems with guide wire perforation are accentuated in the presence of glycoprotein IIb/IIIa inhibitors. Most guide wire perforations can be easily solved with reversal of anticoagulation. When IIb/IIIa inhibitors are used, anticoagulation reversal is prolonged.²

**Aortic Perforations**

In a single case, I had the experience of a pinhole leak in the aortic root resulting from stenting of the RCA ostium. This occurred in an elderly patient with a calcified aorta. The aortic location of the leak was immediately above the RCA ostium and could not be distinguished angiographically from a proximal RCA perforation. This problem was only identified at surgery after stent grafting of the proximal RCA and its ostium failed to correct the problem. It was possible to suture the small aortic hole without cardiopulmonary bypass and without grafting the coronary artery.

**ROLE OF ANTICOAGULATION**

Effective management of perforations is greatly dependent on the ability to reverse anticoagulation. Different anticoagulants have different levels of reversibility and differing times required to reverse their effects. All anticoagulants can be reversed with large amounts of fresh frozen plasma and platelets. Unfortunately, the time required to obtain these agents from the blood bank and subsequently administer them is at best 1 hour and usually much longer. Although it has been my general practice to fully reverse anticoagulation in the presence of any perforation ≥ grade 2, there is evidence that partial reversal of anticoagulation is safe.²
**Heparin**

Heparin is the anticoagulant most commonly used for PCI. In the case of perforation, it is the anticoagulant that can be most quickly and completely reversed (using protamine). Although protamine reversal should be instantaneous, in reality, it takes almost 30 minutes to achieve a normal activated clotting time (ACT) in the setting of perforation. Because protamine titrations are not generally available in the catheterization laboratory, it is necessary to perform a de facto titration by guessing at the initial protamine dose and giving additional protamine after serial ACT measurements. There is a minimum delay of 10 to 15 minutes between doses. If too much protamine is given initially, the protamine itself acts as an anticoagulant, and the operator does not know what to do in the face of a persistently elevated ACT. There is also the problem of reabsorption of heparin from adipose tissue and release of protein-bound heparin. Thus, the theoretically instantaneous reversal of heparin does not take place under real-world conditions. The heparin problem is further complicated by the concomitant use of glycoprotein IIb/IIIa inhibitors. It is extremely difficult to reverse anticoagulation in the presence of these agents.²,⁸

**Direct Thrombin Inhibition**

Direct thrombin inhibition with bivalirudin in lieu of heparin has become increasingly popular. The advantages of bivalirudin are predictable pharmacokinetics and the ability to avoid concomitant administration of a glycoprotein IIb/IIIa inhibitor. The half-life of bivalirudin is 25 minutes. After 2 half-lives (50 minutes), anticoagulation is essentially finished. Although there is no readily available antagonist to bivalirudin, its effect is dissipated in less time than it takes to obtain and infuse fresh frozen plasma. Because bivalirudin blocks thrombin-induced platelet aggregation, it is unnecessary to give concomitant glycoprotein IIb/IIIa inhibitors, even in the presence of unstable angina.⁷ This is a major advantage of bivalirudin, if perforation occurs.

**Thienopyridines**

Theoretically, the presence of thienopyridines should make it difficult to stop
bleeding after coronary perforation. There is no specific information on this subject either in the literature or in my personal experience. My colleagues and I give thienopyridines during or immediately after stent procedures; pretreatment is the exception. However, an increasing number of patients undergoing PCI are receiving chronic thienopyridine therapy. In these patients, platelet transfusion would be the only way to completely reverse anticoagulation. Newer antiplatelet agents, specifically prasugrel and ticagrelor, have a more rapid onset of action compared to clopidogrel. Theoretically, this could be problematic in the presence of CAP, but there are no reports of problems with these agents in the presence of CAP.

**Glycoprotein IIb/IIIa Inhibitors**

Glycoprotein IIb/IIIa inhibitors present the greatest problem when attempting to reverse anticoagulation after coronary perforation. Despite relatively short half-lives and low blood levels, the effects of these agents generally persist. Although there is no series that documents a poorer prognosis in patients with perforation who have been treated with IIb/IIIa inhibitors, it is generally accepted that that these agents complicate the treatment of perforation. There are only 3 possible solutions: (1) avoid use of IIb/IIIa inhibitors whenever possible; (2) avoid coronary perforation when IIb/IIIa inhibitors must be used; or (3) transfuse platelets when perforation occurs in the presence of IIb/IIIa inhibition. In my opinion, glycoprotein IIb/IIIa inhibition is only indicated in the presence of thrombus (ie, acute coronary syndromes). High-risk situations for perforation occur mostly in chronic settings in which IIb/IIIa inhibition has little rationale. When an operator approaches situations that are high risk for perforation, this risk must be carefully evaluated before administration of these agents.

**ROLE OF DEVICES**

Although devices make it possible to successfully treat otherwise untreatable lesions, the perforation rate with devices is more than double the rate with balloons alone. Devices have been discussed elsewhere in this chapter, especially in relation to lesions on bends, eccentric lesions, and bifurcation lesions. Here, each of the devices is discussed on an individual basis. In
general, when used incorrectly, devices can be a source of massive perforation. When used correctly, they can actually prevent perforation by changing the compliance of diseased arteries and allowing ballooning and stenting at lower pressures.

**Balloons and Stents**

Balloons and stents are responsible for more perforations than all other devices combined. The major causes of perforations with balloons and stents are oversizing and stenting of highly eccentric lesions. In the series by Sumitsuji, the stent-artery ratio was 1.25 or more in 67% of perforations, and 72% of perforations occurred when eccentric lesions were treated. Guidance using IVUS or optical coherence tomography (OCT) is invaluable in accurately sizing vessels and assessing eccentricity.

**Rotablator**

Although Rotablator use has decreased over the past 15 years, this device is invaluable in the presence of heavy calcification. Perforation secondary to Rotablator occurs mostly with larger burr sizes and when treating lesions on sharp bends. In recent years, I have avoided large burr sizes, because complete debulking is no longer my primary goal. Rather, I am trying to merely change lesion and vessel compliance to permit full stent deployment. This goal can usually be accomplished using burr sizes of 1.5 mm or less—never more than 1.75 mm. With lesions on sharp bends, I invariably start with a 1.25 burr, and check compliance with a balloon before going to larger burr sizes. Compliance is evaluated by the ability to fully inflate a 2.5-mm or 3.0-mm balloon. When a larger stent is contemplated, compliance is verified with a larger balloon. If full balloon inflation is possible, then it should also be possible to fully deploy a stent. If an imprint remains on the balloon, even at high pressure, then further rotational ablation is necessary. I never exceed a burr size of 1.5 mm for lesions on sharp bends.

**Excimer Laser**

Much of the preceding commentary on Rotablator use is also true for excimer laser. The goal is not massive debulking, but rather compliance changes that
will permit full stent deployment. Such compliance changes can often be accomplished with very small laser catheters used at higher-than-conventional energies. Excimer laser is absolutely contraindicated for lesions on sharp bends.

**Directional Coronary Atherectomy**

The safety of directional coronary atherectomy (DCA) is highly dependent on operator skill and experience. This method can be extremely useful in preparing arteries for stenting but extremely dangerous when used overaggressively. Perforations secondary to DCA tend to be massive and possibly untreatable. Again, when the final goal is full stent deployment, aggressive debulking is unnecessary. To avoid perforations from DCA, IVUS guidance is essential. Directional atherectomy catheters are no longer available in the United States and are available only by special order elsewhere.

**Cutting Balloon and Angioscore**

Cutting balloon is a hybrid between an angioplasty balloon and an atherectomy device. In terms of perforation, it tends to act more like a balloon in that oversizing is the most important cause of perforation. Similar to the debulking devices, the present role of cutting balloon is to change the arterial wall compliance to allow proper stenting. When used properly in this regard, cutting balloon can change lesions from undilatable to easily dilatable and easily stentable. In my practice, cutting balloon has greatly reduced the need for Rotablator. To avoid perforation from cutting balloon, I tend to slightly undersize the balloon but use relatively high pressures (ie, pressures high enough to fully expand the balloon).

Angioscore is mechanistically similar to cutting balloon, but easier to use and theoretically safer on sharp bends. Like cutting balloon and other atherectomy devices, the goal should be compliance changes allowing full stent expansion. Perforation is best avoided by using high pressure but with undersized balloons.

**Problem With Devices on Bends and at Bifurcations**
As previously noted, cutting and ablating devices must be used with extreme caution when treating lesions on bends and when treating bifurcation lesions. For bifurcation lesions, these devices are especially dangerous when used in the direction of side branches, especially when side branches arise at steep angles.

**ROLE OF STENTING**

In 2015, stents were used in nearly 100% of PCI procedures. It is not surprising that they are involved in a high percentage of perforations. Some of these perforations are caused by balloon angioplasty or another device used prior to stenting. When this occurs, deployment of a conventional stent is absolutely contraindicated. Stent deployment almost invariably worsens the problem and rarely solves it. The stent serves only to enlarge the perforation, thus converting a potentially manageable problem into a disaster. Covered stents, of course, are the exceptions to this rule and are the most useful tools for managing large perforations. Recent reports of perforation closure using an MGuard stent (2 reports) and Magic Wallstent (1 report) represent exceptions to this rule.

The conundrum of stenting and perforation is that one strives to achieve as large a lumen as possible within the stent, but the larger the stent-artery ratio, the higher is the likelihood of perforation. IVUS guidance and proper preparation of arteries prior to stenting are the best ways to prevent perforation. One should aim for stent-artery ratios of 1:1. If IVUS suggests poorly compliant plaque (eg, diffuse fibrosis with negative remodeling, heavy calcification) or significant eccentricity or both, primary stenting should be avoided. In these cases, the arteries need further preparation prior to stenting. This can be done with cutting balloon, Angioscore, undersized balloons at very high pressures, or cutting or ablating devices. If high pressures for stent deployment are anticipated, a slightly undersized stent should be chosen. This stent can be postdilated with a larger balloon once the initial result has been assessed by IVUS.

**PREVENTION**
Although perforations are relatively uncommon, their sequelae are so devastating that all measures must be taken to prevent them. Most perforations are preventable. Operators must be constantly cognizant of high-risk situations and properly prepare arteries prior to stenting. If an artery cannot be properly prepared, stents should not be used. Oversizing must be avoided. In high-risk situations, devices, balloons, and sometimes stents should be slightly undersized. Routine use of IVUS or OCT is integral to each of these disciplines. Guide wire perforations are best prevented by using hydrophilic wires only when necessary, exchanging these wires for conventional wires whenever possible, and being constantly aware of the potential for guide wire perforation in long, complex cases.

Caveats for prevention of CAP include the following:

1. If inexperienced or low-volume operator:
   a. Avoid treating lesions at high risk for perforation: lesions on bends, eccentric lesions, calcified lesions, bifurcation lesions, branch lesions, distal lesions, lesions requiring devices, acute margin lesions, vein grafts
   b. Avoid devices
2. If experienced and high-volume operator:
   a. Do not do complex cases at same time as diagnostic procedure
   b. Spend extra time before case reviewing films with specific interest in preventing CAP
   c. Use IVUS or OCT routinely before, during, and after treatment
   d. With eccentric lesions, settle for less than optimal result, and do not strive for a circular lumen
   e. When using hydrophilic wires, constantly check for distal migration
   f. Undersize all devices except stent; the goal is to change compliance enough to allow full expansion of coronary stent

Following these guideline, an experienced operator can probably reduce perforation rate to <0.2%, but never to zero.

**MANAGEMENT**
Coronary perforation is an emergency. The window of opportunity for effective treatment can be quite short, frequently less than 1 minute. Treatment delay can mean the difference between life and death. Mortality in type III perforations (large perforations with a jet of contrast) is 20%. This is 10 times the mortality associated with grade I and II perforations. Mortality associated with grade III perforations remains high despite the introduction of covered stents. When pericardial tamponade occurs, mortality increases. Appropriate action in the first minute can prevent the occurrence of tamponade. Every catheterization laboratory should have the following basic materials available to treat perforation.

- Angioplasty balloons
- Pericardiocentesis tray
- Covered stents
- ACT machine

If these materials are not immediately available, the window of opportunity may be lost.

The single most important piece of equipment for the emergency management of perforation is the simple angioplasty balloon. Balloons are the first line of defense, because they are used to temporarily seal the hole while other more definitive measures are prepared. Even in patients who become abruptly hypotensive following perforation, sealing the hole will frequently stabilize blood pressure without concomitant pericardiocentesis or fluid administration. Because the opportunity to stabilize the patient with this approach may last only 30 to 60 seconds, any delay in searching for a balloon outside the catheterization laboratory may result in devastating consequences. Any balloon of any size is satisfactory, and an unprepared balloon is as effective as one that is carefully prepped.

Pericardiocentesis may be necessary to stabilize blood pressure and preserve cardiac output. Materials for pericardiocentesis must be immediately available.

Covered stents are the definitive treatment for CAP. They have revolutionized the treatment of this condition. Covered stents of various sizes and lengths must be immediately available. Stents that are too short may not cover the hole. Stents that are too long may cover important side branches.

Reversal of anticoagulation is a mainstay of treatment. Sometimes this is
the only necessary treatment. Satisfactory reversal of anticoagulation is best
determined by return of ACT to normal.

Prerequisites for the intermediate treatment of CAP include the following:

• A second interventional cardiologist
• Surgical standby
• Echocardiography
• Platelets
• Coils

If the patient becomes hemodynamically unstable or pericardiocentesis
must be performed, a second experienced physician is invaluable. The second
physician also can serve as a sounding board for ideas regarding definitive
care. Sometimes it is necessary to invent solutions to individual perforation
problems. In such cases, the interchange of ideas between 2 experienced
interventional cardiologists may produce a solution that neither could have
devised alone.

Surgical standby has become less and less important during PCI. Some
coronary perforations cannot be solved in the catheterization laboratory.
Sometimes it is better to stabilize the patient with balloon sealing of the
perforation, with or without pericardiocentesis, and then take the patient to
surgery. This is a decision best made by interplay between the interventional
cardiologist and surgeon.

Patients should not be taken to surgery while still actively bleeding into
the pericardium. The transfer time and time to open the chest and gain control
of bleeding exceeds 30 minutes under the best of circumstances. Concomitant
blood loss combined with pericardial tamponade may lead to irreversible
cardiac and end-organ damage.

Surgical mortality is high in these very sick patients—18% in one large
series. Patients frequently have bleeding into the myocardium, which poses a
major surgical problem. All medical efforts to solve the problem should be
exhausted before sending a patient to surgery. Specific exceptions to this
caveat include certain bifurcation lesions, in which covered stenting will
sacrifice 1 or more large side branches, and perforations that involve the
aorta.

The echocardiogram is invaluable in determining the hemodynamic effect
of a perforation and whether or not it has been solved. Small or no pericardial effusion suggests that it will be possible to solve the problem in the catheterization laboratory without pericardiocentesis. Large effusions require pericardiocentesis, continuous pericardial drainage, and a possible trip to the operating room.

In the presence of glycoprotein IIb/IIIa inhibitors or thienopyridines, or both, platelet transfusion may be required to reverse anticoagulation. Because there is an inherent delay in obtaining and infusing platelets, the decision to transfuse platelets must be made early in the treatment course. The urgency of the situation must be properly communicated to the blood bank. Most perforations can be managed without platelet infusion.

Vascular coils may be useful in occluding small branches that have perforated. This is especially true in the case of guide wire perforations. The availability of coils and operator experience with their use can save an otherwise difficult situation. Many interventional cardiologists have no experience with coils. The assistance of an interventional radiologist or neuroradiologist may be required. It is worthwhile to establish a liaison with such individuals in anticipation of needing their help in an emergency.

**TREATMENT ALGORITHM**

**Stay Cool and Never Lose Guide Wire Position**

There are 2 absolute caveats in the management of CAP: stay cool and never lose guide wire position. These 2 caveats are grouped together, because if the operator panics when a perforation is first noticed, he or she may by reflex remove the guide wire. Alternatively, if a small perforation is noted, there is a natural tendency to rationalize it away with such thoughts as “it is only a small branch” or “it will stop spontaneously when the anticoagulation goes away.” In such cases, the guide wire may be removed only to find that the perforation is a much greater problem than originally thought.

A large perforation is a true emergency. However, once bleeding has been controlled (with a balloon), there is usually time to proceed in an orderly manner. If guide wire position is lost, it may be impossible to control bleeding. Recrossing with a guide wire may not be possible. In this setting, the guide wire tends to exit through the perforation.
Recognize Perforation Immediately

It should be the habit of an interventional cardiologist to be vigilant about looking for perforation after device use, balloon dilatation, and stenting. Small perforations recognized early are easy to treat. Even small perforations left untreated can lead to cardiac tamponade and death. When additional balloon dilatation, stenting, or both are performed in the presence of unrecognized small perforations, the perforations invariably enlarge and lead to major bleeding.

First Action: Block the Perforation

As one learns in any elementary first-aid course, it is imperative to control bleeding before undertaking any other treatment. With coronary perforation, inflating a balloon at low pressure across the entrance to the perforation controls bleeding. The essence of this treatment is time. Any balloon—even an unprepped balloon—is suitable. Balloon size is unimportant; the balloon need only be large enough to block the flow of blood. The fastest way to get a balloon in place is to readvance the last balloon used. For this reason, it is a good habit to make a post-PCI injection while the balloon is still in the guiding catheter.

With large perforations, time is so important that a delay of only 30 seconds may create a downward spiral, leading to death. Following major perforation, blood pressure can fall 100 mm Hg in 30 seconds. This is due to a combination of blood loss, pericardial tamponade, and a vagal-mediated reflex (Bezold-Jarisch) from sudden distention of the pericardium. Treatment of this severe hypotension consists of stopping the bleeding and then performing pericardiocentesis. Pericardiocentesis will not be effective if the bleeding is not controlled. In the 30 seconds necessary to open a pericardiocentesis tray, it should be possible to cross the mouth of the perforation and inflate a balloon at low pressure. On occasion, merely controlling the bleeding will allow the pericardium to accommodate the blood; blood pressure will increase spontaneously, and pericardiocentesis can be avoided.

Once bleeding is controlled, pericardiocentesis, if necessary, can be performed in an orderly manner with proper positioning of the patient and sterile preparation of the chest. Prior to pericardiocentesis, blood pressure
should be maintained with intravenous fluids and vasopressors. These 2 measures are usually effective in maintaining a satisfactory blood pressure for 15 to 30 minutes, as long as bleeding is controlled. During this time, first efforts to reverse anticoagulation must be initiated.

**Second Action: Stop and, If Possible, Reverse Anticoagulation**

Although reversal of anticoagulation is fully dependent on the type of anticoagulation in use, the combination of fresh frozen plasma and platelets can be expected to fully reverse virtually any anticoagulant regimen. Procuring and infusing sufficient quantities of these blood products to control bleeding takes more than 1 hour. Therefore, if it appears that blood products will be required, they must be requisitioned at the outset.

**Heparin**

Protamine is a specific antagonist for heparin. It should be available in all catheterization laboratories where PCI is performed. Immediate administration of protamine is always appropriate when perforation occurs in heparinized patients. The usual initial dose of protamine is 10 to 20 mg, depending on how much heparin has been given and on the ACT level. We tend to err on the low side, because protamine itself is anticoagulant, and too much protamine will be counterproductive. Additional protamine is given if the ACT is not normalized with the first dose. Titrating protamine administration in this manner usually results in complete reversal of anticoagulation in 30 minutes.

**Direct Thrombin Inhibition**

Reversal of bivalirudin is less complex. Although fresh frozen plasma is the only way to directly reverse bivalirudin, this is rarely necessary. The short and predictable half-life (25 minutes) of this medication means that merely turning off the infusion will reverse anticoagulation. Normal coagulation should ensue within 2 half-lives (50 minutes). Figure 61-1 shows a large (type III) perforation from the LAD to the right ventricle. This perforation sealed within 30 minutes after discontinuation of bivalirudin anticoagulation. At 25 minutes, the perforation was essentially sealed and the artery was patent. The operator chose to leave a balloon inflated an additional 5 minutes,
during which the mid-LAD occluded within a stent. It is a difficult decision whether to remove the balloon in the presence of a small residual leak and a patent vessel or to proceed with further balloon inflation until the perforation is completely closed. In the former case, there is risk of the perforation reopening, possibly after the patient has left the catheterization laboratory. In the latter case, there is risk of occluding the stented vessel.

**Glycoprotein IIb/IIIa Receptor Inhibitors**

These agents are the most problematic when perforation occurs. Reversal of heparin anticoagulation with protamine will normalize the ACT in patients treated with IIb/IIIa inhibitors, but the antiplatelet effect persists. The only effective way to reverse these agents is with platelet transfusion. Theoretically, platelet transfusion is more effective against abciximab than against eptifibatide or tirofiban, but in practice, all 3 agents should be effectively reversed by platelets. Although there is a simple assay to measure platelet function in the catheterization laboratory, it is not available in most labs. From a practical standpoint, it takes 1 to 2 hours to obtain and transfuse platelets.

Glycoprotein IIb/IIIa receptor inhibitors are most troublesome with small perforations, especially guide wire perforations, which can be solved with low-pressure balloon inflations and reversal of anticoagulation. In the presence of IIb/IIIa inhibition, these small perforations can ooze for hours. Occasionally, they will appear to seal while the patient is in the laboratory and then start to bleed again when the patient is returned to the ward. This can lead to slowly developing pericardial tamponade that manifests surreptitiously in the middle of the night.

Despite these reservations, a practical approach to perforation in the presence of glycoprotein IIb/IIIa inhibitors is to reverse concomitant anticoagulation (heparin or bivalirudin), perform prolonged balloon inflation, and observe the results. In most cases, the problem will resolve without further ado. Because of the long lag time in procuring platelets, these should be ordered as soon as the problem is recognized. If the perforation has been solved before platelets become available, so much the better.

**Third Action: Solve the Problem**

The problem is how to stop the bleeding while retaining antegrade flow. In
small perforations and guide wire perforations, the problem is frequently solved by reversal of anticoagulation and concomitant prolonged low-pressure balloon inflation.

**Covered Stents (Stent Grafts)**

When simple measures fail, covered stents are by far the most effective treatment. In the appropriate setting, deployment of a covered stent across the perforation is a simple, quick, and elegant solution. Bleeding stops immediately, even in a fully anticoagulated patient. The problem with stent grafts is that they are much more difficult to use than ordinary stents.

Because of their bulk and stiffness, they require 7-Fr guiding catheters, and they may not negotiate tortuous or diffusely diseased vessels. They cannot be used to treat small vessels or branches. In large perforations, there may not be time to do the various maneuvers required to deploy these stents.

Side branches represent a major problem for covered stents. If the stent covers the ostium of a side branch, the branch will be sacrificed. If the side branch is small, it can be sacrificed. If the side branch is large, surgery should be considered as an alternative to stent grafting.

Before attempting to deploy a stent graft, it is best to reverse anticoagulation and to minimize bleeding to the greatest extent possible. Graftmaster stent grafts require 7-Fr or larger guiding catheters. If it is necessary to switch from a 6-Fr to 7-Fr catheter, this must be done carefully and, if possible, in an unhurried manner. The exchange is made over a 300-cm 0.014-inch guide wire, preferably a stiff wire such as the Ironman or Platinum Plus. Exchange for one of these wires is best accomplished through an over-the-wire balloon catheter or transit-type catheter. Although it may be possible to place the new wire as a “buddy” wire, this is not always easy to do in the presence of perforation. There is a tendency for the wire to migrate through the perforation or into a subintimal space that leads to the perforation. This is especially likely with the stiff wires that must be introduced. An alternative is to leave a partially occlusive balloon to block the perforation while passing the new wire alongside. The most important caveat is never to lose distal guide wire position. There is a strong likelihood that it will not be possible to recross for previously stated reasons. If this is the case, a fatal outcome may ensue. If an operator is unsure whether he or she has the skills to change the guiding catheter and sheath without losing guide wire position, it may be best to send the patient to surgery with a
balloon inflated across the perforation.

Alternatively, a 7-Fr guiding catheter can be introduced via the contralateral femoral artery while an inflated balloon remains across the perforation.

With the new guiding catheter and a stiff wire in place, it should be possible to deploy the stent graft without undue difficulty. If significant bleeding has occurred during the guiding catheter exchange, it may be prudent to reintroduce a balloon, tamponade the perforation, and make sure that the patient is hemodynamically stable. If there are signs of cardiac tamponade, it may be possible temporarily to stabilize the hemodynamics with intravenous fluid and pressors. Pericardiocentesis may be necessary at this point. It is better to perform pericardiocentesis during relative calm than to have to do so as an emergency while struggling to deploy a stent graft.

Stent grafts must be deployed at high pressure. These are extremely stiff devices that require a minimum of 14 to 16 atm for proper deployment. To avoid endoleak, the stent graft must be long enough to cover the perforation with 4-mm margins on each side. If a shorter margin is necessary to avoid covering a side branch, the operator needs to weigh the importance of losing the side branch versus the possibility of not sealing the perforation.

Once the stent graft is deployed, bleeding should cease immediately. If bleeding does not stop, the graft is too small or underdeployed, it is too short to cover the perforation with adequate margins, or there is a second perforation. Bleeding should again be controlled with a low-pressure balloon while each of these possibilities is considered by careful review of the angiograms. IVUS may be helpful. Even if bleeding is controlled with the covered stent, IVUS should be used to verify full stent deployment. More often than not it will be discovered that the stent graft is underdeployed. Stent grafts available in the United States are “stent sandwiches”—2 stainless steel stents with a layer of fabric between. As a result, the outer diameter of these devices is 0.5 mm greater than the inner diameter. Thus, the stent may appear fully deployed on angiogram when it is in fact grossly underdeployed. IVUS will reveal this discrepancy and guide appropriate postdilation. When one has solved a perforation with stent grafting, there is a tendency to finish the case without further ado. This is a mistake. An underdeployed stent graft has a significant probability (5.7%) of subacute thrombosis.¹¹

The only coronary stent graft available in the United States is the Graftmaster by Abbott (Abbott Park, IL), and this is only available under a
human device exemption protocol that requires institutional review board approval. This device, which was developed 20 years ago, is cumbersome to use, difficult to deploy, and has a high rate of subacute thrombosis and an in-stent restenosis rate >30%. For economic reasons, there is no incentive for industry to develop a better product.

Two production stents have been used successfully to treat Ellis grade II perforations—Magic Wallstent from Boston Scientific and MGuard stent from InspireMD Boston, MA. The Wallstent is a self-expanding stent with tight wire mesh design reported in a single case report to successfully close a grade II LAD perforation. MGuard is a conventional balloon-expandable stent covered with an ultrathin mesh sleeve with pore size <200 μm, whose primary use is to minimize distal embolization when stenting thrombus-laden arteries. In 2 separate case reports, this stent was used successfully to close grade II perforations. Both stents have logistic advantages over Graftmaster in that they are 6 Fr compatible and are considerably more flexible. MGuard has CE mark since 2007, but is not yet available in the United States. Evidence for effectiveness of these 2 stents in the treatment of CAP is only anecdotal.

Exotic Solutions
In some situations, stent grafting will not be possible; these include diffusely diseased arteries, small vessels, and distal branches (including guide wire perforations). In these instances, it is necessary to create solutions that fit the actual circumstances. The focus should be on controlling bleeding as opposed to preserving antegrade flow. In most of these situations, the amount of myocardium at risk is relatively small. The general approach to this problem is to permanently block antegrade flow. Although collateral blood flow may allow continuing leakage through the perforation, this is generally small and self-limiting. When perforations are caused by stents, blocking antegrade flow may be difficult or impossible.

The most effective way to block antegrade flow is through coil embolization. Although this technique is not particularly difficult, it should not be tried for the first time in an emergency situation. If the coils are not deployed precisely, they can occlude the wrong vessel(s). It is worthwhile to learn the technique from an interventional radiologist or neuroradiologist and to know where to obtain coils if they are needed.

An alternative to coils is the intentional underdeployment of a coronary
stent. This can be expected to induce thrombosis when anticoagulation has been reversed. Although I have successfully used this approach, coils represent a more elegant and more secure approach.

**Thrombin Injection**

Injection of Gelfoam\textsuperscript{16} or thrombin through a microcatheter can be used to close distal perforations, especially those caused by guidewires. Figure 61-2 shows a distal branch perforation that was closed with thrombin injection. It was possible to close the perforation while preserving flow in all other branches. This would have been difficult to do with coils.

**Surgery Should Be the Last Resort**

Most perforations can be solved with the methods described. If these methods fail, then surgery is the only other option. The cardiac surgeon should be notified as soon as a perforation is recognized and should participate in the decision-making process. Although surgery is best deferred until other measures have been exhausted, one should not wait until a patient is in extremis before sending him or her to the operating room. If the previously described approach to treatment is followed, it should be possible to maintain the patient in stable condition. Once the decision is made to go to surgery, preparations must be made to ensure that the patient remains stable during the transfer process and during the time necessary to induce anesthesia and open the chest.

Bleeding must be controlled with an inflated balloon across the perforation. If pericardial tamponade is present, the pericardial cavity must be drained before the patient leaves the catheterization laboratory. Although attention to these matters may create ongoing ischemia, maintenance of hemodynamic stability is of primary importance.

When surgery is required, it is important for the surgeon to limit the operation to what is absolutely necessary. The primary goal is to control bleeding from the perforation. It may or may not be necessary to bypass the artery in which the perforation has occurred. Frequently, the perforation occurs as part of a successful opening of the artery in question, and the artery can be expected to stay open once bleeding is controlled. There is little rationale for doing a “complete” operation involving bypassing of multiple vessels and/or valve replacement. Patients who go to the operating room as a
result of CAP are already high risk and have been through a lot before reaching the operating room. They cannot tolerate a long and complex surgical procedure.

This concept is a difficult one to transmit to a cardiac surgeon, who has been trained to do “complete” procedures. It helps if there is a close working relationship between cardiologist and surgeon. It has been my practice to accompany the patient to the operating room and to remain there at least until the perforation is identified and the bleeding controlled. This is a time when surgeon and cardiologist can intelligently discuss what must be done immediately and what can wait for another day.

**SUMMARY**

Perforation as a result of PCI is uncommon but not rare. Any operator who performs several hundred interventions a year can expect at least 1 perforation. The best way to prevent perforations is to recognize situations of increased risk and take appropriate precautions. When a perforation does occur, it is mandatory to promptly recognize it, avoid manipulations that make it worse (eg, stenting), and start treatment immediately.

The cornerstones of treatment are maintaining guide wire position and control of bleeding with a low-pressure balloon across the perforation. Prompt control of bleeding can prevent life-threatening complications such as pericardial tamponade. Reversal of anticoagulation is mandatory. Deployment of a covered stent across the perforation is the ultimate solution, but this is seldom easy to do and not always possible.

Surgery in this setting carries a high mortality. Most perforations can be solved without surgery. It is important always to be prepared to treat perforations without delay. This requires appropriate knowledge and skill as well as the immediate availability of the necessary equipment.

MULTIPLE CHOICE QUESTIONS

1. Lesions at high risk for perforation include which of the following?
   A. Lesions on bends
   B. Bifurcation lesions
   C. Lesions in branches and distal vessels
   D. Calcified lesions
   E. Eccentric lesions
   F. All of the above
   G. None of the above

2. Guide wire perforation is most likely to occur with which of the following?
   A. Stiff wires
   B. Hydrophilic wires

3. Factors relating to prevention of perforation include which of the following?
   A. Avoidance of high-risk lesions
   B. Careful review of diagnostic angiograms prior to starting case
   C. Undersizing devices
D. Use of intravascular ultrasound and optical coherence tomography before, during, and at end of procedure
E. All of the above
F. None of the above

4. Management of perforation may include which of the following?
   A. Maintenance of guide wire position
   B. Tamponade of leak by inflating balloon across perforation
   C. Covered stent
   D. Pericardiocentesis
   E. All of the above
   F. None of the above

5. In management of a perforation, what is the single most important caveat?
   A. Reverse anticoagulation
   B. Tamponade perforation by inflating balloon across lesion
   C. Use covered stent (stent graft)
   D. Maintain guide wire position
   E. Pericardiocentesis

Embolization and No-Reflow During Percutaneous Coronary Intervention

Ted Feldman
Timothy A. Sanborn
Carl L. Tommaso

INTRODUCTION

Embolization and coronary no-reflow are rare but important complications during percutaneous coronary intervention (PCI). Recognition and treatment are important in that they may reduce or prevent myocardial necrosis and serious subsequent complications. Additionally, nonclinical events may occur as a result of this phenomenon, and prevention where possible becomes important. Macroembolization usually is due to macro-particles and/or blood clots that may occur during intervention of patients with acute coronary syndromes. No-reflow may occur due to the embolization of micro-particulate matter as debris from coronary lesions, activation of platelets, and/or release of vasoactive substances that may modulate distal vasculature. No-reflow is defined as the reduction of coronary flow in the absence of a proximal occlusive lesion with resultant myocardial ischemia. In PCI of native coronary vessels in absence of acute coronary syndromes, no-reflow may be due to microvascular spasm and/or platelet microemboli. When PCI is performed in thrombotic lesions, such as in acute coronary syndromes, no-reflow may be due to distal embolization of thrombus. During saphenous vein graft intervention and rotational atherectomy, it is most often related to
embolization of degenerated plaque elements including thrombotic and atherosclerotic debris. Any or all of these mechanisms can occur simultaneously.

A number of strategies have been available as adjuncts to reduce embolization, but many have been shown to be ineffective and are no longer available. Many are mentioned here for an historical perspective.

**EXPERIMENTAL STUDIES**

The problem of embolization of plaque material during percutaneous catheter angioplasty and stenting has been recognized since the early development of balloon angioplasty. Shortly after the introduction of balloon angioplasty in an experimental model of angioplasty, effluent debris was collected and analyzed by histologic and polarized light microscopic examinations for gross debris and cholesterol.¹ This study is often widely cited as showing no evidence for significant embolization during balloon angioplasty. Microscopically visible atherosclerotic debris was present in 12% of procedures, and thin-layer chromatography showed evidence of cholesterol embolization in 25%. These findings of atherosclerotic debris in between 12% and 25% of treated vessels is completely in line with clinical studies that followed in patients over the next 2 decades.

Both particle size and amount of the embolic material are important. Small amounts of 15-μm particles have been shown to cause patchy ischemia, while increased numbers of particles can cause decrease in flow. When particles are larger, in the 100 to 300 μm range, a relatively few particles can reduce flow.

**EMBOLIZATION IN CLINICAL STUDIES**

Clinical studies have found evidence for embolization associated with PCI procedures. In the stent era, embolization has been detected in about 20% of simple native vessel stent implantation procedures based on the occurrence of creatine phosphokinase-MB (CPK-MB) enzyme release only. For example, in the STARS trial, patients with type A lesions who had completely
uncomplicated, successful stenting with a single stent were evaluated. In this group, the incidence of CPK-MB release was 20%.\textsuperscript{2} In the STARS registry, which included patients who had dissections, had suboptimal stent results, or required additional stents, the incidence of CPK-MB release was close to 30%.\textsuperscript{3} Similarly, in the STRATAS rotational atherectomy trial, almost 30% of patients had CPK-MB release.\textsuperscript{4} The majority of these enzyme elevations are not associated with clinical events.

Clinically apparent embolization occurs more frequently in saphenous vein graft (SVG) interventions. In-hospital major events occur in almost 15% of these interventions.\textsuperscript{5,6} In contrast to the enzyme elevations seen with PCI in native vessels, these are clinical events including chest pain, electrocardiographic changes, and/or marker elevation. Thus, suspected embolization occurs in 15% to 20% of PCI cases overall.

One of the more severe manifestations of embolization is the no-reflow phenomenon. This was originally identified in experimental models of myocardial infarction.\textsuperscript{7} It is the failure of restoration of myocardial flow despite removal of the epicardial coronary obstruction. This is an infrequent event during PCI, complicating between 0.5% and 3% of procedures. It is most typically associated with reperfusion after acute coronary syndromes, particularly acute ST-segment elevation myocardial infarctions and in SVG interventions. It also occurs as a result of rotational atherectomy. It can also occur, more rarely, in native vessels.

The clinical sequelae of the no-reflow phenomenon can be both acutely and chronically severe. Patients have, in the most profound situations, hemodynamic collapse or a severe ischemic syndrome, depending on the size of the affected vessel territory. Both prevention and treatment have been challenging during the development of catheter intervention.\textsuperscript{8}

**CLINICAL RELEVANCE**

The short-term and long-term consequences of particulate embolization during PCI have been studied extensively. Acute complications include the no-reflow phenomenon, which is slow or no flow in treated vessels, causing prolonged chest pain, and can produce myocardial cell necrosis.

In the Primary Angioplasty and Myocardial Infarction (PAMI) trial, no-
reflow occurred during primary coronary intervention for ST-segment elevation acute infarction in 1.3% of over 1000 patients. Compared with patients who did not have no-reflow during PCI, those with the no-reflow phenomenon had a significantly higher hospital and 6-month mortality. Hospital mortality was 2% without versus 13% with no-reflow ($P = .04$), and at 6 months, it was 3% without versus 31% with no-reflow ($P = .0001$); this illustrates the striking clinical importance of this phenomenon. In another study, data were prospectively collected from over 4200 consecutive patients undergoing PCI to identify those with no-reflow. No-reflow was identified in 3.2% of patients. Patients with no-reflow were more likely to have acute myocardial infarction, unstable angina, and cardiogenic shock or have undergone SVG intervention. No-reflow in this group was also highly predictive of postprocedural myocardial infarction (17.7% vs 3.5% in patients without no-reflow). No-reflow was similarly a strong predictor of in-hospital mortality. Administration of calcium-blocking drugs or nitroprusside was not associated with improved in-hospital outcomes in these patients, although antegrade flow rates improved in patients treated with nitroprusside in this group. Mortality was 7.4% with versus 2% without no-reflow ($P < .001$; odds ratio [OR], 3.6). Late consequences of these events have been characterized in numerous studies, suggesting a relationship between in-hospital CPK elevations, reflective of embolization, and increased late mortality as long as 3 years after the index interventional procedure.

**PARTICULATE ANALYSIS**

A variety of mechanisms for the clinical effects of embolization during PCI have been elucidated (Table 62-1). Most simply, mechanical disruption of the plaque results in fragmentation of plaque elements. A variety of plaque elements can be identified, including plaque fragments, cholesterol crystals, foam cells, and amorphous debris.

• Capillary plugging by red blood cells and activated neutrophils
• Neutrophil-mediated endothelial cell dysfunction/vasoconstriction
• Intracellular and interstitial edema
• Intramural hematoma
• Loss of capillary integrity due to completed myocardial infarction

In a study of the aspirated particles from 23 SVG procedures retrieved using an extraction system, a mean particle size of 168 μm was noted. The range was large, from a minimal of 6 to a maximum of 815 μm in the minor access, and 7 to 3427 μm in the major access of these particles. Particles were composed of cholesterol clefts, lipid-rich macrophages, fragments of fibrous cap, necrotic lesion core, and fibrin.

Many of the causes of embolization of microscopic debris into the small vessels of the distal microcirculation are well described. This is evidenced by studies of rotational ablation. Debris of varying sizes of particulate has variable effects on microcirculatory plugging. Rotational atherectomy creates particulate debris with a mean particle size of less than 6 μm. These smaller particles pass through the capillary circulation in the same manner as red blood cells. Larger particulate, which comprises about 20% of the rotational atherectomy debris, can be trapped in the microcirculation and contributes to slow flow and CPK elevations.

Hori et al studied the effective particle size and number in a coronary arterial microsphere embolization perfused canine model. Small numbers of 15-μm particle emboli caused patchy myocardial ischemia and a paradoxical regional increase in blood flow from the effect of reactive increased flow to nonaffected adjacent areas. Increasing numbers of emboli caused impaired flow reserve and decreased resting flow. Larger particles (100-300 μm) caused a dramatic reduction in the number of emboli needed to cause decreased resting flow.

**ROLE OF THROMBUS**
Angiographic thrombus is a powerful predictor of PCI complications. In the clinical setting of acute coronary syndromes, macroembolization of clot is well known. Gross distal embolization can be observed even when no thrombus is identified. Many interventionalists have had the experience of watching a fragment of clot, or thrombus, visibly embolize downstream during injections in the middle of PCI procedures.

**VASCULAR REACTIVITY**

Liberation of vasoactive humoral substances such as serotonin has also been implicated in the genesis of slow flow and no-reflow. Serotonin levels have been measured in the distal coronary artery in patients after angioplasty or stenting. Balloon angioplasty caused an increase in coronary sinus serotonin from basal values of 3 ng/mL to almost 30 ng/mL after balloon angioplasty and from 3.5 ng/mL to 114 ng/mL after stenting. This increase in liberation of serotonin was dramatically blunted by the administration of the serotonin antagonist ketanserin. Coronary cross-sectional area distal to the site of dilatation significantly decreased after angioplasty and stenting from 4.33 to 3.3 mm$^2$ after balloon angioplasty, and from 4.27 down to 2.86 mm$^2$ after stenting, consistent with distal vessel modulation. Pretreatment with ketanserin diminished this decrease in distal coronary luminal area.

One candidate protein that may cause coronary no-reflow is tissue factor. This is abundant in atherosclerotic plaque. In 1 study, coronary blood was drawn from 6 patients undergoing coronary intervention with a distal protection device, and the particulate material that was recovered showed tissue factor activity. To examine the role of tissue factor in no-reflow, blood was drawn via a catheter from coronary vessels in 13 patients during no-reflow and after restoration of flow. Mean tissue factor antigen levels were elevated during no-reflow compared with levels after flow restoration (194 vs 73 pg/mL, $P = .02$). Tissue factor induced no-reflow in a porcine model after selective intracoronary injection of atherosclerotic material or purified tissue factor. These data suggest that tissue factor is released from dissected coronary plaque and is 1 of the factors causing the no-reflow phenomenon.

Indirect evidence for the role of vasoactive mediators is seen in the attenuation of rotational ablation flow effects by the use of a vasoactive "cocktail."
The problem of embolization during PCI became particularly apparent during SVG intervention. Both the volume of SVG atheroma and its friable nature make it prone to embolization during intervention (Fig. 62-1).
FIGURE 62-1 Histologic section from a degenerated saphenous vein graft. The thickened wall of the vessel is easily seen. The volume of plaque material is large, and its friable nature can be seen easily.

As many as half of patients with saphenous vein bypass graft (SVBG) have angiographic evidence of atherosclerosis 5 years after surgery. A large
proportion of grafts are severely diseased by 7 to 10 years after surgery. In most PCI trials, the mean age for SVGs undergoing PCI is between 8 and 9 years after the original bypass surgery. In addition to the problems presented by the nature of the graft atheroma itself, patients are obviously a decade older than when their initial bypass surgery was done and represent a group with high frequency of congestive heart failure, prior myocardial infarction, depressed left ventricular function, and other comorbid conditions.

During PCI for SVGs, distal embolization is common. Patients who suffer distal embolization during these procedures have significantly poorer outcomes than patients who do not. The proportion of patients with major adverse in-hospital events after embolization approaches three-quarters, whereas patients without clinical evidence of embolization during their intervention have major adverse event rates in the hospital of less than 20%.\textsuperscript{21}

**PLAQUE REMOVAL DEVICES**

Early attempts to improve the outcome of intervention in SVGs included the use of plaque removal or debulking using directional coronary atherectomy (DCA). In the CAVEAT-2 study (Coronary Angioplasty Versus Excision Atherectomy Trial), patients were randomized to receive DCA versus plain balloon angioplasty (percutaneous transluminal coronary angioplasty [PTCA]). Although angiographic success rate was improved with DCA (from 79% with PTCA to 89.2% with DCA) and 6-month restenosis rates were similar (45.6% for DCA and 50.5% for PTCA), distal embolization occurred more frequently with DCA than PTCA (13.4% vs 5.1%; \(P = .012\)). The risk of thrombus embolization was much higher when visible thrombus was recognized (39% vs 14%). The 1-year outcomes were worse in patients who developed distal embolization. Figure 62-2 shows a simple thrombus aspiration catheter.
Other devices, such as the transluminal extraction catheter (TEC), were developed for plaque and thrombus removal.\cite{22,23} No-reflow was seen in 19% of patients with thrombus and 5% of patients without thrombus. Late complete vessel occlusion was seen in over one-third of patients with thrombus. The excimer laser has also been evaluated as a method of plaque
removal. In an initial series of 495 patients, embolization occurred in only 3.3% of patients and Q-wave infarction in only 2.4% of patients. However, in some laser studies, thrombus-containing lesions were associated with increased rates of embolization and poor clinical outcomes.

Rheolytic thrombectomy, a technique that uses high-velocity saline jets directed retrograde into the open mouth of a Bernoulli device, draws thrombus into the catheter tip for maceration and evacuation. In the Vegas II trial, rheolytic thrombectomy in native coronary vessels and SVGs containing thrombus was compared to urokinase infusion. Over half the patients treated had vein graft as opposed to native vessel thrombus-containing lesions. Rheolytic thrombectomy resulted in a significant decrease in major events at 30 days. Little subsequent study has been conducted of the efficacy of this form of thrombectomy therapy for the treatment of degenerated SVG lesions that are predominantly atherosclerotic rather than thrombotic.24

Another atherectomy (X-Sizer; EV3, Plymouth, MN) device using a cutting device with suction has been evaluated. No difference in acute events or outcomes at 1 year were noted.25,26

A recent meta-analysis of over 9000 patients in 16 trials found that ablative devices failed to reduce complications associated with embolization. Periprocedural myocardial infarctions occurred in 4.4% of patients tested with devices versus 2.5% without (OR, 1.83; 95% confidence interval [CI], 1.43-2.34).27

PREVENTION OF DISTAL EMBOLIZATION IN SAPHENOUS GRAFTS

Covered Stents

The use of conventional bare metal stents had improved the results of catheter therapy for obstructive SVGs but did not demonstrate any reductions in restenosis rate. In addition, the potential for liberation of particulate degree with embolization seems increased by the use of stenting compared to conventional plain balloon angioplasty. One of the first concepts tested to
diminish the potential for embolization using stenting was evaluation of membrane-covered metal stents compared with bare metal stents (Fig. 62-3). A polytetrafluoroethylene (PTFE) membrane–covered balloon-expandable stent was compared with conventional stents in a randomized trial. The concept that the PTFE membrane might trap graft atheroma behind the stent and prevent its liberation was assessed. Over 200 patients were randomly assigned to receive either a conventional metal stent or a membrane-covered stent. Neither restenosis nor acute procedural events were diminished by the use of a membrane-covered stent.

**FIGURE 62-3** Angiographic frames from a saphenous vein graft percutaneous coronary intervention (PCI) in which a polytetrafluoroethylene (PTFE) covered stent was used. A. There is a proximal graft lesion, noted by the circle. The inset shows the covered stent being deployed in the lesion. High pressure is required to fully expand the combination of graft membrane and stent material. In this case, 18 atmospheres was necessary for adequate stent expansion. B. The silhouette of the fully expanded stent in the proximal vessel.

**Distal Occlusive Devices**

Embolic protection devices were developed to prevent the consequences of embolization during SVG PCI. Embolic protection devices fall into 3 categories: distal occlusion, filter, and proximal occlusion devices.
The first device to undergo extensive clinical testing was the PercuSurge GuardWire (Medtronic, Minneapolis, MN).\textsuperscript{32} This device has a distal occlusion balloon mounted on a 0.14-inch angioplasty wire. The balloon is inflated in the distal SVG, intervention is performed, aspiration of the blood column is performed, and then finally, the balloon is deflated. This necessitates total cessation of flow to the target perfusion bed of the SVG. Some patients do not tolerate the ischemia. The system allows recovery of any liberated plaque material by aspiration before balloon deflation and restoration of forward flow in the treated vessel (Figs. 62-4 to 62-7).

**FIGURE 62-4** Focal saphenous vein graft lesion. A. Prior to intervention, a simple graft lesion is seen in the mid-vessel. B. After stenting, an excellent angiographic appearance is noted. This patient was treated with the PercuSurge distal balloon occlusion embolization protection.
Aspirated debris from the simple graft lesion in Figure 62-4. This highlights that even a relatively focal, saphenous graft lesion may liberate a great deal of embolic material. The filter here shows multiple particulate elements of highly variable sizes and composition.
FIGURE 62-6  A. Thrombotic, complex graft lesion with large thrombus and atherosclerotic burden. The patient was treated with the PercuSurge distal balloon occlusion embolization protection. B. Poststent result. Figure 62-7 shows the debris aspirated from this graft during intervention.
FIGURE 62-7 Debris aspirated from the saphenous vein graft shown in Figure 62-6. In contrast to the aspirate in Figure 62-5 from a simple lesion, the aspirate here shows macroscopic elements of thrombus and plaque, in addition to multiple particles of smaller, variable size.

In the Saphenous Vein Graft Angioplasty Free of Emboli Randomized (SAFER) trial, patients were randomized to treatment with distal embolization protection versus PTCA without embolic protection prior to stent placement. There was a 42% relative reduction in major adverse cardiac events with use of distal protection, which was driven principally by reductions in myocardial infarction (8.6% vs 14.7%; $P = .008$) and no-reflow phenomenon (3% vs 9%; $P = .02$). The overall composite end point in this subgroup occurred in 10.7% of protection device patients compared with 19.4% of control patients ($P = .008$). The mean total occlusion time for completion of the procedure was 6.5 minutes.

It was concluded that the use of a distal protection total occlusion device during stenting for stenotic SVG disease was associated with a highly significant reduction in major events compared with stenting using a conventional angioplasty guide wire without embolic protection. This represented the first important inroad into preventing the consequences of distal embolization during PCI. The substate of graft intervention represents an ideal model for the development of these devices, since there are no proximal side branches for embolic material to run off into during PCI.

Filters

A second class of embolization protection device is filter based. These devices use a wire micropore filter material in the distal target vessel (Figs. 62-8 and 62-9). A clear advantage of this category of devices is that perfusion is maintained in the distal circulation during the performance of stenting in the vast majority of patients.
FIGURE 62-8 Embolic filter devices. Upper left shows the Guidant Accunet Filter. The upper portion of the upper left figure shows the open filter, and the lower portion of the figure shows the filter constrained in a delivery sheath. (Image used with permission from Guidant, Inc.) Upper right shows the Cordis ANGIOGUARD RX Guidewire System. The lower left shows the FilterWire EZ, which is open in the upper portion of the panel and in the retrieval sheath in the lower portion of the panel. (Image provided courtesy of Boston Scientific. Copyright © 2017 Boston Scientific Corporation or its affiliates. All rights reserved.) Lower right is the Abbott Emboshield filter in the open and constrained configurations. (Image used with permission from Abbott Vascular Devices, Redwood City, CA.) At the time of writing the Accunet, Angioguard and Abbott devices are investigational.
The first device in the filter category to complete a large randomized trial is the FilterWire (Boston Scientific, Natick, MA). In a randomized study of the FilterWire versus GuardWire, device success was 95% with FilterWire compared to 97% with GuardWire. Measures of epicardial flow and angiographic complications were similar between the 2 groups. The primary end point, which was a composite of death, myocardial infarction, or target vessel revascularization at 30 days, occurred in 9.9% of FilterWire patients and 11.6% of GuardWire patients. This represents a clear noninferiority result comparing the 2 devices. It was concluded that distal protection with the FilterWire might be safely used as an adjunctive PCI of diseased SVGs, and compared with distal protection using the GuardWire occlusion and aspiration system, the FilterWire resulted in similar rates of major adverse
cardiac events at 30 days (Fig. 62-10).

![Comparison of clinical event rates in 3 trials with embolization protection devices. MACE, major adverse cardiovascular event.](image)

**FIGURE 62-10** Comparison of the clinical event rates in 3 trials with embolization protection devices. MACE, major adverse cardiovascular event.

In the SAFER and FIRE trials, patients represented typical SVG intervention patients, who are older and have more comorbidity than patients undergoing native vessel PCI.

A review of the National Cardiovascular Data Registry (NCDR) database and Medicare claims data using propensity matching in patients 65 years and older undergoing SVBG intervention examined patients who had a distal protection device versus those who did not. This review revealed a slightly higher incidence of procedural complications in those with a distal protection device, including no-reflow (3.9% vs 2.8%; \( P < .001 \)), vessel dissection (1.3% vs 1.1%; \( P = .05 \)), perforation (0.7% vs 0.4%; \( P = .001 \)), and periprocedural myocardial infarction (2.8% vs 1.8%; \( P < .001 \)). By 3 years, death, myocardial infarction, and repeat revascularization occurred in 25%, 15%, and 30% of patients, respectively.\(^{33}\)

However, another report from the NCDR indicated that embolic protection device use was independently associated with a lower incidence of no-reflow (OR, 0.68; \( P = .032 \)), but not in-hospital mortality (1.0% vs 0.9%; \( P = \) not significant).\(^{34}\)

Despite the great enhancements provided by embolic protection devices, there are limitations to these approaches as well. The major limitation of the
balloon occlusion distal embolization protection system is total occlusion of
the vessel during stent implantation. Additionally, aspiration of the
particulate in the fluid column proximal to the inflated balloon is not
completely efficient, since events still occur in patients treated with this
modality. The balloon and wire system is less steerable than a conventional
angioplasty device. Some embolization may occur when the device is passed
across the lesion, although the balloon occlusion device has a lower profile
than the filter devices. The filter devices require a delivery sleeve to be
placed across the filter, increasing their profile. Iterations in device design
have made both of these classes of device easier to use with each successive
generation.

The filter devices may completely fill with debris, transforming them
effectively into occlusion devices. Trying to recapture the filter once it is
completely full may be problematic, since particulate embolic material might
be suspended in the blood column proximal to the filter. Thus, when a filter
device completely occludes and flow ceases in the target vessel, aspiration of
the blood column below the filter with an aspiration catheter may be
appropriate.

**Proximal Occlusive Devices**

Proximal occlusion devices represent another category of embolization
protection devices. An occlusive balloon is inflated in the vessel origin to
interrupt flow and create a static blood column distally (Fig. 62-11). During
intervention, any particulate will remain in the blood column in the vessel.
PCI can be performed through the balloon and the debris aspirated. This has
the advantage of causing stasis of blood flow proximal to the origin of side
branches. Thus, particulate released during the intervention will not run off
into the capillary bed, which allows the application of this system in both
SVG lesions and also in native vessels. Both SVG and native vessels (35% of
cases) were treated. The overall major adverse clinical event rate was 5.7%
in this nonrandomized group. Embolic material was obtained in the aspirate
from all of the patients enrolled.
FIGURE 62-11 The Proxis proximal occlusion device. Via the guide catheter, a proximal native coronary soft occlusion balloon is deployed. This creates a static blood column including in both the epicardial vessel and also in the side branches of the distal vessel. Through the occlusion balloon system, conventional stents may be placed. After treatment of the vessel, the blood column can be aspirated through the occlusion catheter. This device is investigational and not intended for clinical use at this point. (Image used with permission from Velocimed, Inc., Minneapolis, MN.)
PREVENTION OF DISTAL EMBOLIZATION IN NATIVE VESSELS: ACUTE MYOCARDIAL INFARCTION

Signs of microvascular hypoperfusion occur commonly after successful PCI for acute myocardial infarction. The large thrombus burden associated with these procedures causes embolization to be a common occurrence. Deterioration of flow after initially successful balloon angioplasty, worsened by stent implantation, has been commonly observed. Stent expansion with mechanical abrasion of the lesion by the stent struts, or the so-called “cheese grater effect,” is probably partially responsible. An evaluation of ST-segment elevation myocardial infarction (STEMI) patients using intravascular ultrasound (IVUS) and optical coherence tomography (OCT) noted that OCT-derived lipid and IVUS-derived plaque burden were the best discriminators for myocardial no reflow.\textsuperscript{35}

An early trial that evaluated the use of the FilterWire during primary PCI for acute myocardial infarction\textsuperscript{36} demonstrated improved flow as measured by frame counts, blush score, creatine kinase release, and time to resolution of electrocardiogram (ECG) changes. However, subsequently, a large randomized trial failed to show any differences between balloon occlusion embolization protection and conventional PCI and stenting.

Among patients with STEMI, the use of a distal protection balloon occlusion system was not associated with improvement in the primary end points of ST resolution or infarct size. Despite the capture of visible debris in almost three-quarters of patients, no improvements in myocardial profusion were observed compared to conventional therapy with balloon angioplasty and bare metal stenting.

ASPIRATION THROMBECTOMY

Aspiration thrombectomy (AT) catheters have been employed over the last 10 years. The catheter is a dual lumen catheter with a rapid-exchange port enabling passage over a guide wire that has been passed into the vessel and across the clot. The other lumen is larger and extends the length of the
catheter. A syringe is attached to the proximal end, and suction is applied manually while the catheter is passed back and forth through the clotted area to aspirate the clot (see Fig. 62-2).

Clot aspiration using AT is very successful; however, patient outcomes initially demonstrated improved outcomes, but subsequent randomized trials revealed no difference from balloon angioplasty and stenting. TAPAS (Thrombus Aspiration during Percutaneous Coronary Intervention in Acute Myocardial Infarction Study), an early trial assessing AT, demonstrated that, at 1 year, there were reductions in all-cause mortality (4.7% vs 7.6%; \( P = .04 \)) and cardiovascular mortality (3.6% vs 6.7%; \( P = .02 \)).\(^{37}\) This was consistent with other smaller trials.\(^{38}\) Based on these data, AT received wide acceptance.

However, subsequent trials did not support these results. The INFUSE-AMI (Infuse–Acute Myocardial Infarction) trial failed to replicate the findings of the TAPAS trial in a small group of patients, with no differences observed in infarct size with AT at 30 days.\(^{39}\) TASTE (Thrombus Aspiration in ST-Elevation Myocardial Infarction in Scandinavia) was a large, multicenter, registry-based randomized clinical trial. This trial found no differences in clinical outcomes assessed at 1 year between AT versus conventional PCI, including all-cause mortality (5.3% vs 5.6%; \( P = .57 \)) or stent thrombosis (0.7% vs 0.9%; \( P = .51 \)).\(^{40}\)

Another randomized trial, TOTAL (Trial of Routine Aspiration Thrombectomy With PCI Versus PCI Alone in Patients With STEMI), was a large and more definitive trial. No clinical outcome differences were observed at 6 months between patients who received or did not receive AT. These results included the primary outcome of major adverse cardiovascular events (6.9% vs 7.0%; \( P = .86 \)), cardiovascular death (3.1% vs 3.5%; \( P = .34 \)), or stent thrombosis (1.5% vs 1.7%; \( P = .42 \)); stroke rates were higher in patients receiving AT (0.7% vs 0.3%; \( P = .02 \)).\(^{41}\) As a result, AT has not been recommended as routine adjunctive therapy in STEMI.

The potential use of AT in patients presenting with STEMI late with “old” thrombus (>12 hours), in obvious thrombotic occlusions of SVBG, or in situations where there has been obvious distal thrombotic emboli has not been studied to date.
NO-REFLOW: SUPPORTIVE MEASURES

Treatment of no-reflow includes basic supportive measures for the patient, including fluid resuscitation, attention to oxygenation and airway management, and blood pressure maintenance with pressors or inotropes (Table 62-2). Maintenance of blood pressure is especially important, since distal perfusion pressure is necessary for recovery from no-reflow and also for the delivery of pharmacologic therapy to the distal vascular bed. When no-reflow occurs in the right coronary artery or inferior distribution, atropine therapy may be necessary to treat the reflex hypotension and bradycardia that may occur. Intra-aortic balloon pump therapy for blood pressure support is another mainstay of therapy in refractory cases. 42,43

Table 62-2 Initial Evaluation and Treatment of No-Reflow

- Exclude dissection, thrombus, spasm at lesion site (intravascular ultrasound, distal contrast injections, and/or translesion pressure gradient may be useful)
- Achieve adequate activated clotting time (250-300 s with unfractionated heparin if a glycoprotein IIb/IIIa inhibitor has been given, >300 s if one has not been given, and 325-375 s with direct thrombin inhibitors)
- Ensure sufficient oxygenation and airway management
- Treat vagal reactions (intravenous atropine and fluids)
- Maintain adequate perfusion pressure with intravenous fluids, vasopressors, inotropes, and intra-aortic balloon pump, if necessary
- Administer intracoronary nitroglycerin (100-200 μg up to 4 doses) to exclude epicardial spasm
- Consider administering a glycoprotein IIb/IIIa receptor inhibitor
- Administer pharmacologic agents through an infusion catheter or the central lumen of the balloon catheter to assure drug delivery to the distal bed

The basis of most therapy for no-reflow is intracoronary pharmacotherapy.\textsuperscript{44} This will often rapidly restore improved flow and reestablish a more stable condition. A wide array of pharmacologic agents has been used for this therapy. None have shown clear superiority in a trial setting. Most of the practice involved with pharmacotherapy for no-reflow is based on operator experience and anecdote.

No-reflow is likely to be multifactorial in most cases.\textsuperscript{45} It is often difficult to distinguish whether large thrombotic occlusion of the distal vessel, dissection, guide catheter damping, or no-reflow is the etiology of diminished distal runoff. In many cases, it is necessary to treat all of these possible etiologies. Balloon inflations in and distal to the lesion to evaluate the potential for dissection and distal large thrombus formation are frequently necessary. Occasionally, additionally stenting in the inlet or outlet of stented lesions is important to eliminate edge dissections as an etiology of diminished blood flow. Mechanical aspiration may be of value if clot or obvious mechanical obstruction is noted. Intracoronary therapy delivery through the guide catheter, over-the-wire balloon catheter, specialized infusion catheters, or aspiration catheter can be employed.

**PHARMACOLOGIC THERAPY**

Drug treatment has been used as pretreatment to reduce the likelihood of no-reflow and as treatment when it occurs. The success of pharmacologic therapy in reversing no-reflow is probably 2-fold. It may reverse the small vessel vasoconstriction due to release of vasoactive substances from the lesions and, by doing so, allow increased debris passage through the myocardial bed.

Pretreatment with intracoronary verapamil, adenosine, or nitroprusside is a common strategy prior to PCI of SVGs, but there is little evidence to support this practice. Sdringola et al\textsuperscript{46} reported that prophylaxis with multiple doses of adenosine was ineffective in preventing no-reflow. More recently, liraglutide, a glucagon-like peptide-1, has been demonstrated to reduce no-reflow in STEMI patients from 15% to 5%.\textsuperscript{47}

Pharmacologic agents are administered into the affected vascular bed
through a distal catheter. When drugs are given through a guiding catheter, they will preferentially flow to areas that have preserved runoff. For example, with distal circumflex, slow flow injections into a left system guide catheter will result in the injected agent going to the contralateral vessel and never reaching the target vascular bed. Thus, an infusion catheter or an over-the-wire balloon catheter must be delivered distal to the target lesion into the distal vasculature, and injections must be given through this catheter.

Intracoronary nitroglycerin has been the traditional first-line agent for this therapy. The experience with no-reflow responding to nitroglycerin has been poor, and it is not realistic to recommend this as a first-line therapy. A number of other agents have shown more promise (Table 62-3).

Table 62-3 Intracoronary Drug Therapy for No-Reflow

I. First-Line Management
   • Adenosine (10-20 μg bolus)
   • Verapamil (100-200 μg boluses or 100 μg/min up to 1000 μg total dose with temporary pacer on standby)
   • Nitroprusside (50-200 bolus, up to 1000 μg total dose)

II. Evidence Less Strong
   • Rapid, moderately forceful injection of saline or blood (to “unplug” microvasculature)
   • Diltiazem (0.5-2.5 mg over 1 min up to 5 mg)
   • Papaverine (10-20 μg)
   • Nicardipine (200 μg)
   • Nicorandil (2 μg)
   • Epinephrine (50-200 μg)

III. Never shown to be effective
   • Intracoronary nitroglycerin
   • Coronary artery bypass graft
   • Stent placement at site of original stenosis, if widely patent
   • Thrombolytics (eg, urokinase, tissue plasminogen activator)
Agents that have shown positive results in at least small reported series include adenosine, verapamil, nicardipine, and nitroprusside. The anecdotal experience for these agents has been generally positive. The published evidence for the clinical utility of any of these drugs is remarkably small.

Intracoronary calcium blockers are best described. It has been shown that intracoronary verapamil in doses between 50 and 900 μg improved Thrombolysis in Myocardial Infarction (TIMI) flow grade in almost 90% of cases.

Abbo reported a success rate of two-thirds with intracoronary verapamil, especially in cases related to rotational ablation. Kaplan compared intragraft verapamil with nitroglycerin and found improvement in all patients who received verapamil, whereas those who received nitroglycerin had no improvements. Other publications have shown similar results with calcium blocker therapy. The total number of reported cases remains relatively small.

Adenosine has similarly been evaluated in a small number of patients with positive results. In one series of vein graft intervention, adenosine was successful in the majority of cases. Multiple doses and higher doses of adenosine have been found to be more effective than low doses. In an animal model, bolus plus 2-hour constant infusion was superior to bolus injection alone.

One small experience demonstrating the efficacy of nitroprusside exists. Our own experience with this agent has been extremely positive, even in cases refractory to intracoronary calcium blocker administration.

Forceful injection of saline or blood has been described as a method for hydraulically dislodging platelet aggregates or microthrombi from the distal vascular bed. Multiple high-velocity drug doses may be effective as well.

Intravenous and intracoronary platelet glycoprotein IIB/IIIA inhibitors have been described as successful in some cases, but the results seem to be variable. A review of the effects of glycoprotein IIB/IIIA agents in over 4000 patients in the EPIC and EPILOG trials failed to show any benefit from the use of these agents in SVG intervention. Placebo-treated patients had a
16.3% incidence of complications versus 18.6% with abciximab.

A variety of other agents have been described, including a number of other calcium channel blocking drugs. Intracoronary epinephrine has been described as effective in this setting as well and has the appeal that it will not cause blood pressure to decline when it is already a problem. Skelding identified 29 patients in whom intracoronary epinephrine was administered for refractory no-reflow. Administration of a mean dose of 139 ± 189 μg resulted in establishment of TIMI grade 3 flow in 69% of patients. Mean TIMI flow increased from 1 to 2.7 (P = .0001). Heart rate increased on average from 72 to 86 bpm, but no cases of rhythm disturbance were noted. Nicardipine has been studied in animal models and has been effective in our experience. Nicorandil has been used with some success intravenously, as has papaverine.

Intracoronary thrombolytic agents are ineffective, even when thrombotic embolization is grossly visible. Mechanical disruption of these thromboemboli is probably more effective than thrombolytic drugs.

SUMMARY

No-reflow has been a feared complication of PCI since the inception of balloon angioplasty. No-reflow occurs in 0.5% to 3% of cases and is particularly common in intervention for acute myocardial infarction, SVG disease, rotational atherectomy, and less frequently native coronary artery interventions. Recent advances have made the prevention of no-reflow a reality. Embolic protection devices for use in SVG intervention have become routine. Pharmacotherapy for no-reflow has similarly improved. Previously, nitroglycerine was the mainstay of intracoronary therapy after no-reflow occurred, despite its ineffectuality. More recently, therapy with calcium-blocking agents, nitroprusside, adenosine, and possibly epinephrine has proven effective in improving epicardial coronary flow in the no-reflow phenomenon. It remains to be demonstrated whether the acute improvements in epicardial flow correlate with improved late outcomes from no-reflow. It is clear that preventive measures, including embolization protection devices, should be used in high-risk settings for the no-reflow phenomenon. SVG intervention has been proven to be safer with embolization protection, and these devices should be used in conjunction with virtually all SVG
interventions. The application of embolization protection devices to other settings, such as acute myocardial infarction, requires further study.

The use of AT in STEMI was very promising; however, randomized clinical trials demonstrating no advantage and perhaps increased incidence of cerebrovascular accident have dampened enthusiasm for this technique.

Emergency Surgery Following Percutaneous Coronary Intervention

Michael A. Kutcher

HISTORICAL PERSPECTIVES

As a result of significant technologic improvements over the past 30 years, percutaneous coronary intervention (PCI) has become an increasingly safe and effective procedure. Along with this maturation, the indications for emergency cardiac surgery for failed PCI have been reduced. Nevertheless, some type of surgical backup strategy continues to be a standard of practice for the optimal performance of PCI. To understand this evolution, it is appropriate to start this chapter with an historical perspective.

On September 16, 1977, Andreas Gruentzig performed the first percutaneous transluminal coronary angioplasty (PTCA) in Zurich, Switzerland. Elaborate precautions were taken in the event that emergency coronary bypass surgery was necessary to rescue an unstable patient following a failed PTCA attempt. These provisions included a roller pump coronary perfusion device, an open ready operating room, and the physical presence of a cardiac surgeon and an anesthesiologist in the catheterization laboratory room. Fortunately, the procedure was successful, and the rest is history. Ironically, the birth of angioplasty would not have been possible without the support and interaction of cardiovascular surgeons with cardiologists. Gruentzig freely credited Ake Senning and Marko Turina, his cardiovascular surgeons in Zurich, with allowing him to develop the PTCA.
technique.

Of Gruentzig’s first 50 patients, 7 (14%) needed emergency bypass operations, but surgery was accomplished with no major mortality or morbidity. In June 1979, a PTCA workshop was convened in Bethesda, Maryland, sponsored by the National Institutes of Health National Heart, Lung, and Blood Institute (NIH-NHLBI), at which the initial clinical experience in the technique was discussed. Out of this pivotal meeting, the founding fathers of PTCA took the unprecedented step to commit a fledging procedure and themselves to a comprehensive multicenter registry that would fairly assess safety and efficacy. As a result, the NIH-NHLBI PTCA Registry was formed, setting the standards for the rigorous analysis of PCI that continues to this day in various registries, institutional databases, and multicenter randomized trials. It is with this tradition of open granularity that the evolution of PCI and the role of emergency surgery can be best assessed.

DEFINITIONS

Different degrees and complexity of coronary artery bypass graft (CABG) surgery may be necessary following a failed PCI. The most appropriate definitions of urgency are provided by the National Cardiovascular Data Registry (NCDR) CathPCI Registry version 4.4 data elements.

- **Elective:** The patient’s cardiac function has been stable in the days prior to the operation. Cardiac surgery could be deferred without risk of compromised cardiac outcome.
- **Urgent:** Procedure required during same hospitalization in order to minimize chance of further clinical deterioration. Examples include, but are not limited to, worsening sudden chest pain, congestive heart failure, acute myocardial infarction, anatomy, intra-aortic balloon pump (IABP), unstable angina with intravenous nitroglycerin, or rest angina.
- **Emergency:** Patients requiring emergency operation will have ongoing refractory (difficulty, complicated, and unmanageable) unrelenting cardiac compromise, with or without hemodynamic instability, and be not responsive to any form of therapy except cardiac surgery. An emergency operation is one in which there should be no delay in providing operative intervention. The patient’s clinical status includes any of the following:
a. Ischemic dysfunction (any of the following):
   1. Ongoing ischemia including rest angina despite maximal medical therapy (medical or IABP)
   2. Acute evolving myocardial infarction with 24 hours before surgery
   3. Pulmonary edema requiring intubation

b. Mechanical dysfunction (either of the following):
   1. Shock with circulatory support
   2. Shock without circulatory support

• **Salvage:** The patient is undergoing cardiopulmonary resuscitation (CPR) in route to the operating room or prior to anesthesia induction.

This chapter will focus on the above-listed definitions of “emergency” and “salvage” surgery for failed PCI. Complications and emergency surgery for failed structural heart interventions, including transcatheter aortic valve replacement (TAVR), will be covered by the chapters on these various procedures in this textbook.

The coronary indications for emergency CABG surgery for failed PCI include left main dissection, abrupt occlusion, extensive coronary dissection, perforation, cardiac tamponade, retained equipment fragments, and inability to stabilize the affected vessel.

Urgent systemic problems to be corrected may include hypoxia, hypotension, acute pulmonary edema, ongoing cardiopulmonary resuscitation, cardiogenic shock, and uncontrolled bleeding.

Noncoronary indications may also necessitate emergency cardiac and vascular surgery. These include aortic dissection and severe peripheral vascular access complications.

**LOGISTICS**

Clarification of the actual logistics and role of the surgeon and the operating room facilities is necessary to avoid confusing terms. Appropriate terminology to differentiate the degree of surgical commitment reflects 2 levels of support:

• *Surgical standby* indicates a strict arrangement with an open operating
room and a surgical team immediately available.

- **Surgical backup** indicates that the cardiac surgery suites are available and emergency surgery cases may be added on to the schedule on a first-case basis.

Logistical arrangements for surgical standby or backup during PCI consist of:

- **On-site**: Surgical facilities are physically present in the medical center facility where PCI is performed.
- **Off-site**: Surgical facilities are present in an institution physically separated by a significant distance from the facility where PCI is performed. Timely plans and transportation arrangements are mandatory in the event that a patient requires emergency cardiac surgery for failed PCI.

### INCIDENCE, MORTALITY, AND MORBIDITY OF EMERGENCY CARDIAC SURGERY FOR FAILED PCI

From the 14% emergency surgery rate in Gruentzig’s first PTCA cohort 40 years ago, there have been major evolutionary reductions in the incidence of emergency surgery. The NIH-NHLBI PTCA Registry reported an emergency surgery rate of 5.8% in the years 1979 to 1981 followed by a lower rate of 3.4% in 1985 to 1986, primarily due to technical improvements and better operator experience. With the emergence of intracoronary stents, the incidence dropped even further in the early 2000s to reported rates of 0.14% by the Cleveland Clinic and 0.3% by the Mayo Clinic. Regardless of the low incidence of emergency surgery in these 2 studies, the mortality rate with emergency surgery continued to be high, ranging from 10% to 15%. A recent contemporary review from the NCDR reported emergency surgery rates of 0.18% in nonprimary PCI and 0.93% in primary PCI ST-segment elevation myocardial infarction (STEMI) patients.

In summary, experience from the various PCI registries and literature
indicates that although the incidence of emergency surgery over the years has decreased to acceptably low levels, when it does occur, the consequences of mortality and morbidity continue to remain high.

**FACTORS THAT HAVE REDUCED THE INCIDENCE OF EMERGENCY CARDIAC SURGERY FOR FAILED PCI**

The best approach to reducing the mortality and morbidity of emergency cardiac surgery for failed PCI would be to avoid the need for emergency surgery altogether. Significant technologic improvements have occurred over the past 30 years to make PCI safer and more effective.

There has been a reduction in the French (Fr) size of guiding catheters from 8-, 9-, and 10-Fr to 7-, 6-, and even 5-Fr catheters. The guiding catheters have become much softer, decreasing the likelihood of dissection and complications at the coronary takeoff. Steerable wires have been reduced in diameter size from 0.18-inch to the current standard 0.14-inch diameter. Various soft steering wire tips are available that reduce the chance of perforation or dissection of the coronary intima. Balloon and stent delivery shaft profiles have been significantly lowered over the years from 1.4-Fr to less than 0.5-Fr diameter in a deflated state. The growth of radial artery access for PCI has resulted in the reduction of complications and bleeding.

Along with advances in catheters, there has been a significant improvement in radiologic imaging techniques. Initially biplane fluoroscopy and angiography were thought to be the most effective ways of translating a 1-dimensional plane or imaging to at least 2 dimensions and extrapolating this to 3 dimensions. However, digital fluoroscopic and cine technology is now the standard of practice. This technology has markedly improved the capabilities for more precisely visualizing the coronary artery tree and various coronary angioplasty devices.

Adjunctive pharmacotherapies such as direct thrombin inhibitors, platelet glycoprotein IIb/IIIa receptor agents, and P2Y\textsubscript{12} agents have reduced the thrombotic complications of coronary intervention and the need for emergency surgery.
In the 1990s, the enthusiasm to lower the restenosis rate by using atheroablative devices such as directional coronary atherectomy, rotational atherectomy, transluminal extraction atherectomy, and excimer laser coronary angioplasty was tempered by a higher perforation rate and incidence of emergency surgery. Once experience with the devices became more extensive, the emergency surgery rate was somewhat reduced. However, a meta-analysis of multiple device trials confirmed the clinical impression that when atheroablative devices are compared with standard PTCA, there is no reduction in the restenosis rate and an increase in major adverse cardiac events (5.1% vs 3.3%). As a result, the widespread use of atherectomy devices has fallen out of favor and should be reserved only for very select cases.

The introduction of intracoronary stenting in the mid-1990s and eventual refinements in stent technology and pharmacology in the late 1990s resulted in a reduction in the incidence of emergency surgery by providing a more reliable solution to elastic recoil and coronary dissection. An analysis of the Society for Cardiovascular Angiography and Interventions Registry trends in 16,811 consecutive PCI procedures during this later era documented a 0.3% incidence of emergency surgery when stents were used compared with a 0.7% incidence ($P = .002$) with balloon angioplasty.

The development of polytetrafluoroethylene (PTFE)-covered stents has provided a better option to seal coronary artery perforations. A European series demonstrated that when perforation occurred as a complication of PCI, use of a PTFE stent reduced the incidence of emergency surgery from 88% to 18%. In addition, even if patients went on to surgery, the PTFE stent served as a valuable supportive device and resulted in a reduction of mortality and morbidity.

The wealth of experience and data in various PCI registries has now permitted risk-adjustment scores, which indicate that hemodynamic instability, disease severity, demographics, and comorbid conditions may predict adverse outcomes. The strongest predictors of emergency surgery are cardiogenic shock, acute myocardial infarction (MI), emergency PCI, multivessel disease, and type C lesions.

**STRATEGIES TO REDUCE**
MORTALITY AND MORBIDITY WHEN EMERGENCY CARDIAC SURGERY FOR FAILED PCI OCCURS

When all attempts at a percutaneous solution have failed and emergency surgery is necessary, supporting the patient in the catheterization laboratory prior to transfer to the operating suite is crucial to reduce the already evolving higher chance of mortality and morbidity.

Coronary perfusion catheters that allow balloon inflation while still permitting coronary flow via perforated portals in the catheter shaft were an early PCI era mainstay prior to the development of intracoronary stents. Autoperfusion catheters are no longer made, but standard balloon dilatation catheters may be used to maintain at least partial coronary flow by alternating inflation and deflation sequences. This temporary strategy may stabilize dissected coronary flow or to stanch a perforation prior to emergency surgery in circumstances where a stent cannot be deployed. As mentioned earlier, PTFE-coated stents also may have a role in stabilizing a coronary perforation prior to going to the operating room.

In the case of coronary perforation, attention should be paid to hematologic and hemodynamic instability. There should be a hematologic strategy to stop heparin, consider reversal with protamine, discontinue glycoprotein IIb/IIIa receptor blockers, plan for platelet transfusion, or all of the preceding. This must be done in coordination with the cardiac surgeons as heparin will be needed for CABG surgery. When cardiac tamponade is present, percutaneous pericardiocentesis is helpful in reducing this hemodynamic impediment prior to surgery.

The IABP has been a mainstay to support patients with cardiovascular hemodynamic compromise who require emergency surgery. However, newer percutaneous mechanical circulatory support devices such as the nonpulsatile axial flow Archimedes screw pump (Impella; Abiomed, Danvers, MA) and extracorporeal bypass with membrane oxygenator (ECMO) may be used for catastrophic hemodynamic collapse if there is a delay to transfer to the operating room.

The cardiac surgeon, anesthesiologist, and operating room should be
alerted at the first sign that a patient may need emergency surgery. It is better to err on the side of mobilizing a room and the cardiac surgery team even though the event may eventually be controlled and surgery averted. Appropriate anesthesia backup and control of the airway are paramount in providing support of the compromised patient. Advances in surgical technique over the past 20 years have been instrumental in reducing complications following emergency surgery. Having a more stable patient as a result of the preceding support initiatives may also allow arterial conduits, such as the left internal mammary graft vessel, to be used in the emergency setting.

Lastly, with the development of hybrid catheters and operating room laboratories, extremely high-risk PCI patients may be pre-emptively managed in these suites with close surgical standby if PCI fails and emergency surgery is necessary.\textsuperscript{25}

Figure 63-1 is a flow diagram of strategy options that should be considered or initiated in the catheterization laboratory to support the patient who requires emergency surgery for failed PCI.

**FIGURE 63-1** Failed percutaneous coronary intervention (PCI) emergency surgery strategy. ECMO, extracorporeal membrane oxygenator; IABC, intra-aortic balloon counterpulsation; OR, operating room.
GUIDELINES FOR PCI

The 2011 American College of Cardiology Foundation/American Heart Association/Society for Cardiovascular Angiography and Interventions (ACCF/AHA/SCAI) 2011 guideline\textsuperscript{13} has recommended that a mechanism of quality assurance review be established and ongoing at each institution performing PCI. Operator statistics and institutional data should be reviewed on at least a quarterly basis. Monitoring outcomes by this mechanism assures a mechanism to review cases of mortality, morbidity, or emergency surgery.

The current 2011 guidelines\textsuperscript{13} continue to recommend that PCI be performed by higher volume operators performing 75 or more cases per year (class I) and that these operators have advanced technical skills and knowledge. Subspecialty certification in interventional cardiology is a class IIa recommendation. PCI should be performed at institutions with fully equipped interventional laboratories and experienced support staff with the anticipation of performing more than 400 cases per year with an on-site cardiovascular surgical program (class I). Options for emergency cardiac surgery should be available for instances of failed PCI and instability. The guidelines recommended against low-volume operators (<75 cases per year) performing PCI who work in low-volume institutions (200-400 cases per year) with or without on-site surgical coverage (class III). An institution with less than 200 procedures per year should reconsider whether to continue to offer PCI service, unless it can be clearly documented that it is in an underserved region due to geography.\textsuperscript{13}

In addressing off-site PCI centers, the 2011 guidelines gave a class IIa recommendation for primary PCI for acute STEMI and a class IIb recommendation for elective PCI if there was an appropriate backup plan and proper case selection.\textsuperscript{13} This was a major change from the previous 2005 guidelines, which gave off-site centers a class IIb indication for primary PCI and a class III indication for elective PCI.\textsuperscript{26} The current 2011 guidelines continues to advise against primary or elective PCI at off-site centers without a proven plan for rapid transport to a surgical center or without appropriate hemodynamic support strategies during transfer (class III).

PCI EXPERIENCE AT CENTERS WITH
OFF-SITE SURGICAL BACKUP

Primary PCI for STEMI

A key meta-analysis of 23 randomized trials in acute MI documented that primary PCI for STEMI is superior to thrombolytic therapy, with significant reductions in death (7% vs 9%), nonfatal reinfarction (3% vs 7%), stroke (1% vs 2%), and combined end point (8% vs 14%). These results were particularly possible if a door-to-balloon time of less than 90 minutes could be achieved. Another meta-analysis of 6 major MI trials assessing a strategy of transfer for primary PCI versus immediate thrombolysis reaffirmed a significant reduction in morbidity and a trend in reduction of all-cause mortality in the transfer PCI group. These analyses have reaffirmed the favorable risk-benefit ratio of primary PCI as the treatment of choice over thrombolytic therapy for early STEMI.

The Primary Angioplasty in Myocardial Infarction Trial-2 (PAMI-2) investigators reported that in 982 patients undergoing primary PCI for acute MI, there was a 0.4% incidence of emergency surgery for failed angioplasty. The Atlantic Cardiovascular Patient Outcomes Research Team (C-PORT) documented a 0% emergency surgery rate in 225 primary PCI patients with STEMI who presented to off-site centers. An article by Singh and colleagues from the Mayo Clinic reviewed overall single-center and multicenter experience with primary PCI at off-site centers and concluded that the risk-benefit ratio for mortality, morbidity, and emergency surgery was favorable. These were the historic benchmark studies that established the appropriateness for off-site centers to perform primary PCI for acute STEMI without surgical backup on site.

Elective or Nonprimary PCI

Select Registry Data

As a result of the positive experience of primary PCI for acute MI at off-site centers and with extensive safety and effectiveness data from Europe regarding elective PCI without on-site surgical backup, in the early 2000s,
there was increasing debate in the United States as to whether low-risk, nonemergency, and elective PCI could be extended to off-site centers. This was particularly controversial due to the class III designation given to elective PCI in off-site centers by the 2005 PCI guidelines.\textsuperscript{26}

Over the past 10 years, there have been a number of single-center or combined registry data studies that have assessed the risk-benefit ratio of elective or nonprimary PCI in off-site centers. Among these, there were 2 major registry studies that vigorously assessed the appropriateness of nonprimary PCI in off-site centers.

The pivotal study from the NCDR reported on a large multicenter US database.\textsuperscript{32} Clinical characteristics and in-hospital outcomes were assessed in consecutive PCI cases from January 1, 2004 to March 30, 2006. Of this cohort, 8736 patients who had PCI performed in 60 centers that did not have cardiac surgery on site (off-site) were compared with 299,425 patients at 405 centers that did have cardiac surgery on site (on-site). Off-site facilities performed a median of 134 overall annual PCI procedures, and 72% performed <200 per year, compared with 612 procedures and 6% at <200 per year for on-site facilities ($P < .001$). PCI for STEMI or non-STEMI occurred more frequently at off-site centers than on-site centers (41% vs 29%; $P < .001$). Off-site PCI facilities, relative to on-site facilities, had similar observed rates of success (94% vs 93%), total complications (6.5% vs 6.3%), emergency cardiac surgery (0.3% vs 0.4%), and mortality with emergency surgery (13.6% vs 12.8%). The risk-adjusted odds ratio (OR) for in-hospital mortality of off-site versus on-site centers revealed no difference in overall mortality (OR, 0.90; 95% confidence interval [CI], 0.72-1.14; $P = .388$) or mortality in patients who underwent primary PCI (OR, 0.97; 95% CI, 0.75-1.25; $P = .807$) or nonprimary PCI (OR, 0.86; 95% CI, 0.63-1.16; $P = .319$).

The recently reported retrospective United Kingdom Registry evaluated early and long-term mortality outcomes (median follow-up of 3.4 years) for PCI centers with and without surgical support between the years 2006 and 2012.\textsuperscript{33} A total of 384,013 patients were assessed, of whom 31% (119,096) were treated at off-site surgical centers. Unadjusted mortality rates were lower in patients treated at off-site centers versus on-site centers (2.0% vs 2.2%; $P < .001$). Multivariate adjustment revealed there were no differences in the primary end point of survival between the naive and imputed populations at 30 days (naive population hazard ratio [HR], 0.87; 95% CI, 0.71-1.06; $P = .16$; imputed population HR, 0.99; 95% CI, 0.89-1.09; $P = \ldots$)
This lack of difference carried over to the secondary end points of survival at 1 year (naive population HR, 0.92; 95% CI, 0.79-1.07; \( P = .26 \); imputed population HR, 0.99; 95% CI, 0.92-1.06; \( P = .78 \)) and at 5 years (naive population HR, 0.92; 95% CI, 0.84-1.01; \( P = .10 \); imputed population HR, 0.97; 95% CI, 0.92-1.03; \( P = .29 \)). Of note, there were no differences in mortality in sensitivity analyses performed using a propensity-matched population. The results were consistent regardless of primary or nonprimary PCI indications.

**Key Randomized Clinical Trials**

Regardless of registry and single-center studies, confirmation of the safety and effectiveness of elective PCI at off-site centers can only be definitively confirmed by well-defined randomized studies.

The C-PORT-E trial led by Aversano and colleagues\(^3\) was a large multicenter trial that randomly assigned elective PCI patients to undergo the procedure at either a hospital with or a hospital without on-site cardiac surgery. A total of 18,867 patients were randomly assigned in a 3:1 ratio to undergo PCI at a hospital without on-site cardiac surgery (14,149 patients off-site) or a hospital with on-site cardiac surgery (4718 patients on-site). The primary end point of 6-week mortality rate was 0.9% at off-site hospitals versus 1.0% at on-site hospitals (difference, –0.04 percentage points; 95% CI, –0.31 to 0.23; \( P = .004 \) for noninferiority). The 9-month rates of major adverse cardiac events (the composite of death, Q-wave MI, or target vessel revascularization), which was the coprimary end point, were 12.1% and 11.2% at off-site versus on-site centers, respectively (difference, 0.92 percentage points; 95% CI, 0.04-1.80; \( P = .05 \) for noninferiority). The rate of target vessel revascularization was higher in off-site hospitals (6.5% vs 5.4%; \( P = .01 \)). This was the first major large randomized trial to document that PCI performed at off-site hospitals was noninferior to PCI performed on-site at hospitals for mortality at 6 weeks and major adverse cardiac events at 9 months.

Approximately a year later, the MASS-COMM trial led by Jacobs and colleagues\(^4\) reported on nonemergency PCI patients who were randomized in a 3:1 ratio to have their procedures at an off-site (10 centers) or an on-site (7 centers) facility. A total of 3691 patients were randomized, 2774 to off-site centers and 917 to on-site centers. The primary safety end point of 30-day
major adverse cardiac event rate (composite of death, MI, repeat revascularization, or stroke) was 9.5% in off-site hospitals compared to 9.4% in on-site hospitals (relative risk, 1.00; 95% one-sided upper confidence limit, 1.22; \( P < .001 \) for noninferiority). The coprimary effectiveness end point of major adverse cardiac events at 12 months was 17.3% and 17.8% in off-site and on-site hospitals, respectively (relative risk, 0.98; 95% one-sided upper confidence limit, 1.13; \( P < .001 \) for noninferiority). The rates of death, MI, repeat revascularization, and stroke did not differ significantly between the groups at either time point. The primary end points were analyzed according to the intent-to-treat principle and were tested with the use of multiplicative noninferiority margins of 1.5 (for safety) and 1.3 (for effectiveness). The MASS-COMM study reaffirmed that, in Massachusetts, nonemergency PCI procedures performed at off-site hospitals were noninferior to those performed at on-site hospitals with respect to 30-day and 1-year rates of clinical events.

**Meta-Analyses**

The mortality and morbidity of primary PCI and nonprimary elective PCI at off-site PCI centers versus on-site centers was further affirmed by a number of meta-analysis studies that included robust single-center, multicenter, registry, and randomized studies. The 2 most important of these meta-analyses will be discussed below.

Singh and colleagues\(^{36}\) selected 40 high-quality studies and applied pooled-effect estimates calculated with random-effects models. Analysis of 124,074 patients who underwent primary PCI for STEMI and 914,288 patients who had nonprimary PCI (elective and urgent) demonstrated that procedures at off-site centers were not associated with a higher incidence of in-hospital mortality or emergency bypass surgery.

A more recent meta-analysis by Lee and colleagues\(^{37}\) analyzed 23 high-quality studies and used a mixed-effects model to compare complication rates of 1,101,123 patients after PCI at off-site and on-site centers. They concluded that clinical outcomes and complication rates of PCI in patients treated at off-site centers did not differ from those in patients who had procedures at on-site centers for both primary PCI for STEMI and for nonprimary PCI. They did report temporal trends of improved clinical outcomes for nonprimary PCI in off-site centers since 2007.
SCAI/ACCF/AHA EXPERT CONSENSUS DOCUMENT FOR OFF-SITE PCI

The 2014 update on PCI without on-site surgery backup in the United States was an expert consensus panel convened to update the original 2007 SCAI document on the topic. Of note, many things have changed since 2007, when there were only 28 states with off-site PCI centers performing both primary and elective PCI, 12 states performing only primary PCI, and 10 states where off-site PCI centers were not allowed. In contradistinction, in 2013, there was only 1 state that did not permit off-site PCI, 4 states that permitted only primary PCI, and 45 states that had both primary and elective PCI at off-site centers.

This consensus document is a comprehensive and exhaustive analysis that provides guidelines for the proper performance of PCI centers that do not have surgery on site. A streamlined outline of facility requirements (Table 63-1), personnel requirements (Table 63-2), STEMI treatment recommendations (Table 63-3), and surgical backup and elective case selection (Table 63-4) for off-site PCI centers is provided in this chapter. The reader is advised to refer to the consensus document for more extensive details.

</tbody>
</table>
• Program to track adherence to ACC/AHA-based class I therapy
• Full-service labs for both primary and elective PCI
• Geographic isolation exists if emergency transport time is >30 minutes
• National benchmarking of outcomes
• Quality improvement review of all patients transferred for emergency CABG

Abbreviations: ACC, American College of Cardiology; AHA, American Heart Association; CABG, coronary artery bypass graft; NCDR, National Cardiovascular Data Registry; PCI, percutaneous coronary intervention.

Table 63-2 Personnel Requirements for Off-Site PCI Programs

• Experienced catheterization laboratory nursing and support staff
• Appropriate supportive equipment
• CCU staff experienced in monitoring, temporary pacemaker, and IABP
• Personnel capable of intubation and ventilator management
• Operators ABIM certified in interventional cardiology
• Operators perform over 2-year period
• Primary PCI for operators with ≥50 elective and ≥11 primary PCIs per year
• Institution experience: ≥200 elective and ≥36 primary PCIs per year
• Internal review and quality improvement process for underperformers
• Unwise for newly trained interventional cardiologist to start a new off-site program

Abbreviations: ABIM, American Board of Internal Medicine; CCU, cardiac care unit; IABP, intra-aortic balloon pump; PCI, percutaneous coronary intervention.

Table 63-3 **STEMI Treatment Recommendations for Off-Site PCI Program**

- Community STEMI process at least as strong as mission lifeline
- Primary PCI as standard of practice for STEMI
- Catheterization facility service “24/7”
- Institution experience: ≥36 primary PCIs per year
- Institutional experience: ≥200 total PCIs per year
- Recognized STEMI receiving center and a liaison/coordinator for communication
- Participation in regional endeavors such as ACTION Registry-GWTG
- Monthly quality improvement multidisciplinary meetings to review metrics of STEMI activation, door-to-balloon time, and other important process metrics

Abbreviations: ACTION, Acute Coronary Treatment and Interventions Outcomes Network; GWTG, Get With the Guidelines; PCI, percutaneous coronary intervention; STEMI, ST-segment elevation myocardial infarction.

Table 63-4 **Recommendations for Off-Site Surgical Backup and Elective Case Selection**

**Interactions with Cardiac Surgeons**
- Heart team approach and communication for PCI case selection
- Initial informed consent for PCI includes terminology indicating the risk of no surgery on-site and the process of emergency transfer if necessary
- Transferring physician will obtain consent if emergency surgery needed

**High-Risk Patients**
- Decompensated congestive heart failure
- Cerebrovascular accident <8 weeks
- Advanced malignancy
• Know clotting disorder
• LVEF ≤30%
• Chronic kidney disease
• Ongoing ventricular arrhythmias
• Unprotected significant left main stenosis
• Multivessel disease with high SYNTAX score
• Single-target lesion that jeopardizes extensive myocardium
• PCI to last remaining conduit to the heart

High-Risk Lesions
• Unprotected left main
• Diffuse disease ≥20 mm
• Extremely angulated ≥90-degree segment or excessive tortuosity
• More than moderate calcification
• Inability to protect major side branches
• Degenerative old vein grafts with friable lesions
• Substantial vessel thrombus
• Any features that could interfere with stent deployment
• Anticipated need for rotational atherectomy, cutting balloon or laser

Strategy for Surgical Backup Based on Risk
• High-risk patient + high-risk lesion = no elective PCI at off-site center
• High-risk patient + non–high-risk lesion = elective PCI but tight surgery backup
• Non–high-risk patient + high-risk lesion = no additional precautions, but be alert
• Non–high-risk patient + non–high-risk lesion = best scenario

Abbreviations: LVEF, left ventricular ejection fraction; PCI, percutaneous coronary intervention; SYNTAX, Synergy Between PCI With Taxus Drug-Eluting Stent and Cardiac Surgery.
The question of whether the development of PCI centers without surgical backup on site is an appropriate national strategy continues to be an issue, albeit less contentious due to recent publications regarding safety and efficacy of well-designed off-site PCI centers. It would seem logical for off-site programs to demonstrate effectiveness on a “24/7” basis in primary PCI for acute MI before expanding to elective PCI. An argument that elective PCI at off-site centers is necessary to assure high institutional and staff skill levels in a less acute setting than acute MI and to provide more convenient service for their patient and referral base appears to be valid. However, it would seem unacceptable for an off-site PCI center to limit itself to only a “9 to 5” or “boutique” elective PCI program and to not eventually commit resources for “24/7” coverage for primary PCI in acute MI where there is a documented greater mortality and morbidity benefit.

Many centers that wish to perform PCI without an on-site surgical program tend to be smaller institutions with smaller volume cases. Dehmer and colleagues recently reported in an analysis of a contemporary NCDR data sample that on-site cardiac surgery was not available in 83% of facilities performing fewer than 200 PCIs annually, with these facilities representing 32.6% of the facilities reporting, but performing only 12.4% of the PCIs. However, regardless of whether a program has on-site or off-site surgical facilities, even an experienced angioplasty operator is no better than the quality of the catheterization laboratory facilities, the experience of the catheterization laboratory staff, and the skill level of the cardiac surgery team.

In parallel with the development of more effective coronary interventional techniques, the incidence of emergency surgery for failed PCI has dropped precipitously over the past 30 years. But the incidence will never be zero. Some form of surgical backup strategy will always be necessary. Unfortunately, in the few times when emergency surgery is necessary, the
mortality and morbidity are still quite high. The interventional cardiologist must ensure that all reasonable, appropriate options are in place to achieve the most effective and safe care for PCI patients.

The analysis of data is empowering. Interventional cardiologists must continue to actively participate in personal and institutional quality assurance programs. Institutions should contribute data to registries such as the NCDR CathPCI Registry. In that spirit, the vision of Andreas Gruentzig, who was courageous in collecting and analyzing the data of a fledgling procedure, may be best served. This tradition of rigorous self-assessment will continue to result in improved techniques, reassessment of strategies, and reduced mortality and morbidity. It is hoped that these efforts will result in both an incidence of emergency surgery that is “close to zero” and in significantly reduced consequences to the few patients who do require this support mechanism.

**MULTIPLE CHOICE QUESTIONS**

1. In patients who undergo elective percutaneous coronary intervention (PCI) at hospitals without cardiac surgery on site compared to hospitals that have surgery on site, the incidence of major adverse cardiac events (MACE) is:
   A. Increased
   B. Decreased
   C. Similar
   D. Unknown
   E. Not important

2. In the current contemporary era, what is the best estimate for incidence of death in patients who undergo emergency cardiac surgery for failed PCI?
   A. 1%-3%
   B. 4%-6%
   C. 7%-9%
   D. 10%-15%
   E. 20%-25%

3. All of the following strategies would be appropriate to stabilize a patient with significant acute coronary artery perforation prior to going to emergency cardiac surgery for failed PCI, EXCEPT:
A. Maintain steering wire access if at all possible  
B. Use inflated dilatation balloon to stanch perforation  
C. Implant a bare metal stent to stabilize the vessel  
D. Implant a polytetrafluoroethylene (PTFE)-covered stent  
E. Perform a pericardiocentesis if severe tamponade is present

4. In hospitals that do not have cardiac surgery on site, the strategy for off-site surgical backup based on risk evaluation in elective or nonurgent PCI cases indicates that which of following patients should NOT be treated but should be transferred for PCI at a hospital that has surgery on site?  
   A. Non–high-risk patient + non–high-risk lesion  
   B. Non–high-risk patient + high-risk lesion  
   C. High-risk patient + non–high-risk lesion  
   D. High-risk patient + high-risk lesion  
   E. Indeterminate-risk patient + indeterminate-risk lesion

5. What is the current national contemporary best estimate of the incidence of emergency surgery for failed PCI?  
   A. 0%  
   B. 0.2%-0.4%  
   C. 1%-3%  
   D. 4%-6%  
   E. 12%-14%

ANSWERS

1. C

The issue of safety and efficacy for elective or nonprimary PCI done at centers that do not have surgery on site was a contentious issue in the early 2000s. The equivalence for elective PCI at off-site versus on-site centers has been consistently answered by large registries such the National Cardiovascular Data Registry (NCDR) and the United Kingdom Registry and by meta-analysis. But more importantly, the well-done recent C-PORT-E and MASS-COMM randomized trials have thoroughly resolved that there are no differences in MACE for patients who undergo elective or nonprimary PCI in
centers with or without surgery on site. A key point to make, however, is that all these published studies involved high-quality off-site PCI centers that adhered to accepted high standards of practice.

2. D

Although the incidence of emergency surgery for failed PCI has consistently dropped over the past 30 years, the mortality rate when emergency surgery does occur has not changed significantly and remains high. The rate 10% to 15% rate appears to be an appropriate estimate. This range was based on reported rates in various key published reports, including those by the Cleveland Clinic, Mayo Clinic, and NCDR.

3. C

Acute severe coronary artery perforation is a calamity that requires thoughtful but quick action. It is essential to try to maintain steering wire position as this allows various maneuvers such as inflation of a balloon to stanch the flow or to implant a PTFE-covered (JoMed) stent. Even if the PTFE-covered stent resolves the perforation, it may still be a short-term temporizing strategy as the patient can go on to more stable emergency surgery. Pericardiocentesis may be life-saving if hemodynamically significant tamponade is present. Of all the stabilizing choices, implantation of a noncovered stent, such as a bare metal or drug-eluting stent, is a poor choice because it potentially could make the perforation worse.

4. D

The recent Society for Cardiovascular Angiography and Interventions (SCAI)/American College of Cardiology (ACC)/American Heart Association (AHA) Expert Consensus Document for off-site PCI centers included definitions of what constitutes a high-risk patient and a high-risk lesion.

- High-risk patients: Decompensated congestive heart failure; cerebrovascular accident <8 weeks; advanced malignancy; know clotting disorder; left ventricular ejection fraction ≤30 %; chronic kidney disease; ongoing ventricular arrhythmias; unprotected significant left main stenosis; multivessel disease with high SYNTAX score; single target
lesion that jeopardizes extensive myocardium; and PCI to last remaining conduit to the heart.

- High-risk lesions: Unprotected left main; diffuse disease ≥20 mm; extremely angulated ≥90-degree segment or excessive tortuosity; more than moderate calcification; inability to protect major side branches; degenerative old vein grafts with friable lesions; substantial vessel thrombus; any features that could interfere with stent deployment; and anticipated need for rotational atherectomy, cutting balloon, or laser.

The case of a non–high-risk patient + non–high-risk lesion is the best scenario. In the case of high-risk patient + high-risk lesion, the consensus document strongly recommends that elective PCI should NOT be done at the off-site center. The other scenarios of patient and lesion risk have variable degrees of appropriateness for elective PCI at the off-site center.

5. B

Andreas Gruentzig’s first cohort of percutaneous transluminal coronary angioplasty patients had an emergency surgery rate for failed balloon angioplasty of 14%. Subsequent reiterations of the National Heart, Lung, and Blood Institute registry reported progressively lower rates due to improved technology and the development of intracoronary stents. The best current estimate of 0.2% to 0.4% comes a combination from the Cleveland Clinic (0.14%), Mayo Clinic (0.3%), and NCDR (0.37%).
INTRODUCTION

Sudden cardiac death (SCD) is the leading cause of cardiovascular death and remains an important public health issue. The definition of SCD includes death from natural causes within an hour of a change in cardiovascular status and can occur in patients with or without preexisting cardiovascular disease. Incidence estimates for SCD in the United States vary from 250,000 to 450,000 cases a year, with most estimates in the range of 300,000 to 350,000 per year.\(^1\) Although the worldwide incidence of SCD is difficult to estimate, several studies have shown the rate of SCD is approximately 50 to 100 per 100,000 people.\(^2\) In the United States, SCD accounts for about half of cardiovascular deaths and 15% to 20% of all deaths.\(^2\) In this chapter, we will briefly review the most common etiologies of SCD as well as outline treatment strategies for dealing with patients who present with SCD because these commonly fall under the realm of the interventional cardiologist. A thorough knowledge of emergency resuscitation measures is critical for the interventional cardiologist who is often called to potentially treat patients with SCD, whether this occurs out of or within the hospital (even within the cardiac catheterization laboratory).

Pathophysiology
Diseases of the coronary arteries account for the majority of SCD (Table 64-1). In the Western world, approximately 80% of SCD is caused by coronary artery abnormalities. Coronary artery disease can precipitate SCD by several mechanisms. Acute coronary plaque instability leading to cardiac ischemia or infarction can lead to electrical instability and ventricular fibrillation (VF). Previously infarcted myocardium can precipitate ventricular arrhythmias around areas of scar. Adverse remodeling after a myocardial infarction (MI) can create another substrate for ventricular arrhythmias. Furthermore, stable coronary disease can precipitate SCD. In an autopsy study of 90 cases of SCD attributed to coronary artery disease (CAD), 17 of the 90 cases (19%) had no evidence of prior MI or active coronary plaque. While the majority of patients with SCD from CAD will have VF as their initial cardiac rhythm, VF will degrade to asystole in a short period of time. Therefore, even though the initial rhythm documented by emergency medical systems can be asystole, coronary abnormalities may still be the primary etiology of the arrest.

Table 64-1 Causes of Sudden Cardiac Death
Nonatherosclerotic coronary abnormalities compose a smaller proportion of the etiology of SCD (see Table 64-1). Congenital abnormalities of the coronary arteries are an important cause of SCD. Anomalous coronary arteries are a common cause of SCD in the young, particularly the left
coronary artery arising from the right aortic cusp. SCD is often precipitated by exercise in this patient population. Other rare causes of coronary ischemia or infarction leading to SCD include coronary vasospasm, coronary artery dissection, and coronary artery embolism. Myocardial bridges, while a common (and often benign) finding in up to 70% in autopsy studies, have in some cases been reported to cause SCD, particularly in those with hypertrophic cardiomyopathy.

Nonischemic dilated cardiomyopathies are responsible for 10% to 15% of SCD in the United States. Several reports have shown that 30% to 50% of all deaths in chronic heart failure are secondary to SCD. Ventricular tachycardia (VT) can occur in chronic heart failure during times of stable hemodynamics (scar-mediated ventricular arrhythmias) or during progressive hemodynamic deterioration that may render the myocardium more susceptible to ventricular arrhythmias. Other fatal arrhythmias, including bradyarrhythmias and pulseless electrical activity (PEA), may occur secondary to worsening pump function and decreased cardiac output. Hypertrophic cardiomyopathy is another common cause of SCD, especially in the younger population. Before the advent of modern treatments for patients with valvular diseases, many died from SCD; however, recently the risk has decreased substantially. Virtually all infiltrative and inflammatory myocardial diseases have been shown to cause SCD.

In approximately 5% of SCD cases, there are no identifiable cardiac abnormalities on autopsy; however, in a younger population, this percentage may be higher. Among these, inherited channelopathies and other primary electrophysiologic abnormalities have been implicated in SCD. These include long and short QT syndromes, Wolf-Parkinson-White syndrome, Brugada syndrome, catecholaminergic polymorphic VT, and idiopathic VF. Many of these syndromes are familial, and appropriate family member screening is essential in preventing SCD.

**Risk Factors for SCD**

In the general population without known cardiovascular disease, the risk factors for SCD parallel those of CAD including age, cigarette smoking, hypertension, hyperlipidemia, diabetes, obesity, sedentary lifestyle, and family history of premature CAD. A family history of SCD infers a 1.5-fold
increase in SCD. However, in patients with diagnosed CAD, these risk factors typically no longer hold prognostic significance for SCD. Instead, the left ventricular (LV) ejection fraction seems to be the most powerful predictor of first-episode SCD and is currently used to risk stratify patients for primary prevention implantable cardiac defibrillator (ICD) therapy. Vigorous exercise has been identified as a risk for SCD; however, the overall risk is very low. Patients with prior MI, frequent premature ventricular contractions, and in particular nonsustained VT have a higher risk of SCD.

INITIAL RESUSCITATION MEASURES

The initial role of healthcare providers and the general population is to recognize and diagnose cardiac arrest, followed by the initiation of basic life support (BLS). The initial evaluation needs to be very brief, and the BLS guidelines from the American Heart Association (AHA) recommend that the initial evaluation of an unconscious man should only include checking for breathing. A pulse check is no longer recommended for the general population. After recognition of cardiac arrest, emergency medical systems need to be activated immediately, followed by initiation of cardiopulmonary resuscitation (CPR). High-quality minimally interrupted CPR appears to improve time to return of spontaneous circulation (ROSC) and neurologic recovery in both out-of-hospital and in-hospital cardiac arrest. Pulse checks and rhythm evaluations should only occur during preset intervals (every 2 minutes) and should only delay CPR for a maximum of 10 seconds.

The concept of cardiocerebral resuscitation, where rescue breathing does not interrupt CPR, is based on the finding that high-quality CPR with minimal interruptions improves outcomes in cardiac arrest patients. A meta-analysis of 3 randomized trials comparing compression-only CPR with standard CPR found a statistically significant 22% improvement in survival (Fig. 64-1; risk ratio 1.22; 95% confidence interval [CI], 1.01-1.47). However, a secondary analysis of nonrandomized cohort studies found no benefit for compression-only CPR. It must be noted that this method of CPR is not recommended for children or suspected noncardiac causes of cardiac arrest. While the 2010 AHA guidelines state that compression-only CPR can be used when initial responders are reluctant to perform mouth-to-mouth ventilations, the recommended approach is still to perform 30
compressions followed by 2 rescue breaths. Because the oxygen level in the pulmonary vasculature is likely adequate during the first minutes of cardiac resuscitation, initial rescue breaths are no longer recommended. After the placement of an advanced airway, asynchronous breaths should be performed at a rate of 8 to 10 breaths per minute with no interruption in CPR. Excessive ventilation can be detrimental as animal models have shown that overventilation can lead to reduced success of defibrillation and decreased survival.

**FIGURE 64-1** Meta-analysis of 3 randomized trials comparing survival to hospital discharge between compression-only cardiopulmonary resuscitation (CPR) and routine basic life support. (Reprinted from Hupfl M, Selig HF, Nagele P. Chest-compression-only versus standard cardiopulmonary resuscitation: a meta-analysis. *Lancet*. 2010;376:1552-1557. Copyright © 2010, with permission from Elsevier.)

Automated chest compression devices have been developed as an alternative to manual chest compressions during cardiac arrest (Fig. 64-2). These devices can include circumferential compression around the chest wall or a piston placed at the sternum to perform compressions in the anteroposterior plane. Several of these devices contain both radiolucent as well as radiopaque components, allowing them to be used within the cardiac catheterization laboratory while performing fluoroscopic procedures. Typically, the views required are angulated views (either cranial or caudal with additional left anterior oblique or right anterior oblique angulation). A meta-analysis of randomized trials found that devices using piston-delivered CPR had the same rate of ROSC compared to conventional CPR, whereas devices using load-distributing band CPR did have a better rate of ROSC. A subsequent large randomized trial found no improvement in survival using a piston-based mechanical CPR device over traditional CPR.
Another alternative method of CPR, called active compression-decompression CPR (ACD-CPR) uses a suction device to convert the passive recoil of a compressed chest wall into active expansion, improving venous return (see Fig. 64-2). A Cochrane review of randomized data including approximately 5000 patients found no benefit with ACD-CPR when compared to standard CPR. As such, the guidelines state there is insufficient evidence to support the use of ACD-CPR.

Interposed abdominal compression CPR (IAC-CPR) involves the use of a second rescuer performing mid-abdominal compression during the upstroke of chest compression. A meta-analysis found that in 34 of 38 studies, including animal and mechanical model studies, there was an improvement in ROSC with IAC-CPR compared to regular CPR. There were 4 prospective studies included, and 3 of them found significant improvements in ROSC with the use of IAC-CPR, with 1 of these studies showing improved survival. These 3 studies included in-hospital arrest, while the fourth study that did not find a difference was in out-of-hospital arrests. Given these initial data, the guidelines state that IAC-CPR can be considered by trained practitioners during an in-hospital arrest.

Inspiratory impedance threshold devices (ITDs) allow positive-pressure ventilation but prevent airflow during chest relaxation, thus increasing negative intrathoracic pressures during chest decompression while performing CPR. This increase in negative intrathoracic pressures improves preload and myocardial perfusion. A meta-analysis of randomized trials examining the role of ITD found that the addition of ITD to standard CPR or
device-assisted CPR resulted in improved rates of ROSC and early survival; however, longer term survival was not improved.\textsuperscript{24} Therefore, current guidelines state there is insufficient evidence to support or refute the use of ITD.\textsuperscript{22}

**Defibrillation**

Survival of patients with cardiac arrest relies on high-quality CPR as well as early defibrillation. An initial chest thump, also called a precordial thump, may be attempted to quickly restore electrical stability. The technique involves 1 or 2 blows at the junction of the middle and lower third of the sternum from 8 to 10 inches away. It should not be used for tachycardias without a loss of consciousness. The initial experience of the chest thump was mixed, with some studies showing successful conversion of VT/VF using the technique. However, a subsequent trial found that in 103 patients treated with a precordial thump as the initial strategy, a rhythm change was noted in 17. Only 5 of the cases had ROSC, whereas 10 others had a deterioration in the cardiac rhythm.\textsuperscript{25} Given these conflicting data, the precordial thump is not considered an alternative to conventional treatments such as expedited defibrillation.

Many researchers have adopted the 3-phase model for resuscitation after cardiac arrest.\textsuperscript{26} The initial phase, or electric phase, occurs during the first 4 to 5 minutes after arrest, and immediate defibrillation is essential in the survival of these patients. The second phase, the hemodynamic phase, usually consists of minutes 4 to 10 after cardiac arrest. During this phase, some have theorized that it might be better to improve oxygen delivery with high-quality CPR followed by defibrillation. While this theory is supported in animal models,\textsuperscript{26} randomized trials employing a strategy of 2 to 3 minutes of CPR prior to defibrillation have yielded inconsistent results. One trial of 200 cardiac arrest patients found an improvement in survival in a CPR-first strategy when the response time of the ambulance was greater than 5 minutes,\textsuperscript{27} whereas 2 other studies found no improvement in survival.\textsuperscript{28,29} Notably, current guidelines state there are insufficient data to support the use of 2 to 3 minutes of CPR prior to defibrillation if immediately available.\textsuperscript{30} The third phase, the metabolic phase, occurs after 10 minutes of cardiac arrest. During this phase, early CPR and defibrillation are less effective, and
outcomes are very poor. In these cases, if ROSC is obtained quickly, postresuscitative treatment is essential in improving outcomes.

While defibrillation is essential for ROSC and early defibrillation improves outcomes, interruptions of high-quality CPR must be kept as minimal as possible. Studies have shown that interruptions of CPR for defibrillation can worsen outcomes. Current guidelines recommend CPR be initiated while the defibrillator is being set up and interruptions kept to a minimal. CPR should stop for a rhythm check, followed by defibrillation if necessary, and immediate resumption of CPR prior to another rhythm check. Only a single shock for VT or VF from either an automated external defibrillator (AED) or monophasic or biphasic defibrillator should be used before resuming CPR. Biphasic defibrillators are preferred because of the ability to perform defibrillation with lower energy levels (200 J compared to 360 J with a monophasic defibrillator).

Given the importance of time to defibrillation as a predictor of outcomes, the use of AEDs provides promise for significantly improving outcomes in victims of SCD. The technology of AEDs has improved, and recent models can weigh as little as 2 to 4 kg and cost under $1000. While initial data regarding the use of public access AEDs were uncertain, larger trials have since shown impressive rates of survival when AEDs are used in airports, airplanes, casinos, and police vehicles. A randomized trial studying placement of AEDs in general community sites demonstrated a significant improvement in survival to hospital discharge when a trained first responder used an AED as opposed to CPR alone (23% with AED use, 14% with CPR alone). These results have led to the increased use of AEDs deployed in high-risk areas. Despite this deployment, public access AEDs are only used in a small proportion of out-of-hospital cardiac arrests, although with increasing awareness, their use should grow.

**Advanced Cardiac Life Support**

After initial resuscitative measures are under way, the next step in management is to obtain stable ROSC and stable hemodynamics. Intravenous (IV) or intraosseous (IO) access should be obtained. If the initial rhythm is VT or VF, CPR should continue in 2-minute cycles with rhythm and pulse checks afterward with subsequent defibrillation for recurrent VT/VF.
Although there is minimal randomized evidence to support its use, epinephrine (1 mg IV/IO) is recommended every 3 to 5 minutes. Several recent observational studies have questioned the utility of epinephrine for out-of-hospital cardiac arrest\textsuperscript{34,35}; however, these studies are by definition confounded by indication (ie, patients receiving epinephrine are inherently sicker than those who do not receive it). Higher dose epinephrine is not recommended because trials have failed to show improvements in survival compared with standard-dose epinephrine.\textsuperscript{36,37} Vasopressin (40 mg IV/IO) can be given in place of a dose of epinephrine.\textsuperscript{38} While a randomized trial showed superiority with this strategy over epinephrine alone,\textsuperscript{39} a subsequent meta-analysis of several randomized trials found no benefit.\textsuperscript{40} Another randomized trial that took place after the meta-analysis found that a combination of vasopressin, epinephrine, and steroids (methylprednisolone 40 mg IV once) improved survival compared to epinephrine and placebo (21% survival with favorable neurologic outcome in the combination group vs 8% in the epinephrine plus placebo group).\textsuperscript{41} The conflicting data regarding the use of vasopressors underscore the importance of high-quality CPR and defibrillation to optimize outcomes for cardiac arrest patients.

Antiarrhythmic therapy can be effective in the treatment of refractory VT/VF. Amiodarone (300 mg initial bolus followed by 150 mg bolus as clinically indicated) is the preferred antiarrhythmic.\textsuperscript{38} The ARREST trial showed an improvement in survival to hospital admission with amiodarone use compared with placebo (44% vs 34%), at the cost of an increase in bradycardia and hypotension requiring treatment.\textsuperscript{42} The ALIVE trial found amiodarone to be superior to lidocaine (1-1.5 mg/kg IV followed by 0.5-0.75 mg/kg every 5-10 minutes).\textsuperscript{43} Magnesium sulfate (2 g IV) can be used to treat torsade de pointes\textsuperscript{44}; however, it is not recommended for routine use in VT/VF.

When the initial rhythm is asystole or PEA, no defibrillation is advised, and high quality CPR should be initiated with rhythm and pulse checks every 2 minutes. In this situation, the most critical role of the physician is to reverse any underlying cause of the arrest. Much like in VT/VF, evidence supporting the use of epinephrine and vasopressin during PEA or asystole is lacking; however, guidelines recommend the use of epinephrine (1 mg IV/IO every 3-5 minutes) with vasopressin (40 mg IV/IO) as an alternative to one of the epinephrine doses.\textsuperscript{38} Atropine is no longer recommended for PEA or
asystole, as recent trials have shown no improvement in outcomes and a potential signal of harm.\textsuperscript{45} While transcutaneous pacing can be temporarily effective in patients with bradycardia, it is usually not effective and therefore not recommended in treating patients with asystole who typically require transvenous pacing.\textsuperscript{46}

**Systems of Care**

Despite many advances in the treatment of heart disease, the outcomes after cardiac arrest remain poor. A changing cardiac arrest population with older age and less VF may offset improvements in bystander CPR rates and shorter times to defibrillation.\textsuperscript{47} The etiology of the cardiac arrest is linked to subsequent survival, with very few patients with asystole surviving to hospital admission or discharge and as few as 11% of patients with PEA surviving to discharge.\textsuperscript{48} On the contrary, reports of survival with VF are better than 25%.\textsuperscript{47}

Initial emergency medical care systems involved training firefighters in the treatment of cardiac arrest patients, including the use of defibrillators. Initial reports from Miami, Florida, and Seattle, Washington, during the 1970s reported initial out-of-hospital cardiac arrest survival rates of 14% and 11%, respectively. Adding emergency medical technicians as trained first responders increased these rates of survival to close to 30% in the late 1980s. More recently, overall survival rates have decreased across the United States, likely due to the addition of emergency medical systems in rural areas and increased population density in urban areas (ie, a greater denominator of patients noted to undergo emergency resuscitation measures).\textsuperscript{49} Significant regional variability exists, with 1 study reporting survival to discharge after all cardiac arrests ranging between 3.0% and 16.3% with survival rates of VF arrests between 0% and 39%.\textsuperscript{50} This large variability underlies the importance of community efforts to optimize the treatment of SCD.

The primary efforts to improve outcomes in cardiac arrest include easy access to emergency medical systems (eg, through calling 9-1-1), training community members to perform bystander CPR, AED placement in public areas, dispatcher-assisted CPR, trained first responder defibrillation, and improvements in advanced cardiac life support (ACLS) from healthcare workers.\textsuperscript{51} These changes have improved outcomes in many emergency...
systems like those in Seattle, Washington, where overall survival rates are nearly double those of the nation. The emergency medical system there has made several changes, including equipping fire fighters with AEDs for rapid response to patients with cardiac arrest. In addition, there is a multilevel review process evaluating the response to cardiac arrests.

Partly based on this paradigm and others like it, the AHA has subsequently released a “chain of survival” designed to help improve outcomes in all communities. This chain includes immediate recognition of cardiac arrest and activation of the emergency response system, early CPR with emphasis on chest compressions, rapid defibrillation, effective ACLS, and an integrated post-cardiac arrest care. In addition, a thorough review process to evaluate the response of emergency medical systems is vital to improving outcomes in out-of-hospital cardiac arrests.

IN-HOSPITAL MANAGEMENT

Upon arrival to the hospital, the initial management for victims of SCD concentrates on stabilization of the patient and determining the cause of the arrest. Prompt electrocardiography is recommended in order to diagnose the postreperfusion rhythm and also to determine whether the primary etiology of SCD is related to acute MI. Depending on the arrest time, the initial electrocardiogram (ECG) may represent severe acidosis with attendant hyperkalemia, and thus serial ECGs are often indicated after reversal of these metabolic abnormalities. Adequate ventilation must be maintained to ensure oxygen saturations greater than 94%, with mild permissible hypercapnia to prevent the physiologic cerebral vasoconstriction in response to hypocapnia. Hemodynamics need to be optimized with mean arterial pressures (MAP) of at least 65 mmHg, preferably even 80 to 100 mmHg, in order to maintain cerebral perfusion and reverse any ischemic consequences of the cardiac arrest. An adequate volume status should be maintained with goal central venous pressure of 8 to 10 mmHg. In addition to hemodynamic support, stabilization of the cardiac rhythm is important, and patients with recurrent VT/VF should be treated with antiarrhythmic therapies (eg, amiodarone) as well as consideration for emergent coronary angiography (see below).

Routine laboratory tests can elucidate reversible causes of cardiac arrest,
including electrolyte abnormalities. Prompt echocardiography can be very useful in order to determine the etiology of cardiac arrest, although global left ventricular dysfunction may be a common finding, particularly for patients with longer times to ROSC. Empiric use of transvenous pacemakers for those with atrioventricular or intraventricular conduction abnormalities have not improved outcomes and are only indicated for severe symptomatic heart block. Empiric use of fibrinolytics in cardiac arrest victims does not appear to improve survival. However, use of fibrinolytics when pulmonary embolism is the presumed cause may be beneficial and is recommended.

**Therapeutic Hypothermia**

The most common cause of death in cardiac arrest survivors is neurologic injury, accounting for approximately two-thirds of all in-hospital mortality. The use of therapeutic hypothermia as a means of preserving neurologic function has been studied in several prospective trials. There is minimal evidence to support the use of therapeutic hypothermia in non-VF arrests; however, the use of therapeutic hypothermia in VF arrests is more controversial. Two randomized trials found the use of mild therapeutic hypothermia for survivors of VF cardiac arrest was associated with improved neurologic outcomes compared to standard intensive unit care. One trial randomized 77 patients and found a 23% improvement in outcomes with hypothermia (49% discharged to home or rehab with hypothermia compared with 26% in standard care), and the other trial randomized 136 patients, finding a similar 16% improvement in neurologic outcomes (55% with good recovery or moderate disability in the hypothermia group compared to 39% with standard treatment). However, a follow-up trial tested the hypothesis that the benefit seen with therapeutic hypothermia might be from avoidance of fevers alone, which have been shown to have detrimental effects on neurologic outcomes following cardiac arrest. This larger trial randomized 950 cardiac arrest survivors (with presumed cardiac etiology) to hypothermia with a goal temperature of either 33°C or 36°C. There was no difference in overall mortality (50% in the 33°C group and 48% in the 36°C group; Fig. 64-3), and neurologic outcomes were similar in the 2 groups. Given these findings, recent guidelines now suggest the use of targeted temperature management with target temperature between 32°C and 36°C.
Further, the exact timing and method of cooling is unclear. The 2 randomized trials started cooling at either <2 or <8 hours\textsuperscript{57,58}; however, subsequent registry data revealed that neither time to cooling nor time to goal temperature was associated with better neurologic outcomes.\textsuperscript{61} In addition, prehospital cold saline infusion is of no benefit over initiation of therapeutic hypothermia in the hospital.\textsuperscript{62,63} The duration of hypothermia was 12 or 24 hours in the 2 randomized trials showing benefit; however, most case series have reported 24 hours of cooling.\textsuperscript{53,57,58} Although guidelines have no clear
recommendation regarding the time to initiate cooling, they do state that cooling should continue for 24 hours with gradual rewarming (0.25°C/h).

Cooling can be accomplished with either external cooling devices or internal catheters with feedback mechanisms. Cooling blankets and application of ice bags can also be used; however, it is more difficult to maintain therapeutic hypothermia with these methods. Cold/iced saline given intravenously is a safe way to initiate hypothermia as well.

Therapeutic hypothermia has several complications that require active management by the intensive care team. Shivering will occur in most patients and needs to be treated with heavy sedation. Hypothermia can induce a mild coagulopathy; however, no clear increase in significant bleeding has been reported with therapeutic hypothermia. If significant bleeding does occur, rewarming is likely indicated. Hypothermia additionally impairs leukocyte function; however, significant infections are unlikely if the time of cooling is under 24 hours. Electrolyte abnormalities are common and need to be monitored closely. Cardiac arrhythmias are common, including severe sinus bradycardia; however, this usually does not require treatment.

**Coronary Angiography and Revascularization**

The cardiac catheterization laboratory plays an important role in the management of SCD patients, as the majority of cardiac arrests are etiologically secondary to CAD. SCD survivors with findings consistent with an ST-segment elevation MI on ECG should undergo emergent angiography and revascularization. Many advocate the use of urgent coronary angiography in all survivors of VT/VF arrests given the large proportion of those patients having significant ischemic heart disease. Registry data have shown improved outcomes in those who undergo successful coronary angioplasty compared to those who have not. Others advocate the use of urgent angiography only in patients with ischemic changes on the ECG or a history of antecedent chest pain prior to the arrest. Regardless of the initial treatment decision, cardiac catheterization should be considered for SCD survivors with continued hemodynamic instability, continued elevation in cardiac biomarkers, segmental wall motion abnormalities on echocardiography, or worsening ischemic changes on the ECG. Coronary angiography is reasonable for all survivors of cardiac arrest to rule out CAD as the primary cause of the arrest, unless a clear noncoronary cause for the SCD exists. Even
in the young population, angiography is reasonable to determine if coronary anomalies exist.

In the acute setting, revascularization should be based on appropriate indications (e.g., it should be strongly considered for those with acute coronary syndromes, ongoing ischemia, or severe CAD thought to be the cause of the arrest). If truly stable CAD is found, revascularization should be reserved for those with indications such as ongoing hemodynamic instability or shock. While there is no clear evidence supporting revascularization in SCD survivors, these patients are at the highest risk and may benefit from a more aggressive revascularization strategy, especially when ischemia is the likely precipitant of the cardiac arrest.

A consensus statement by the American College of Cardiology’s Intervention Council has proposed a treatment algorithm for patients with resuscitated cardiac arrest based not only on the initial ECG, but also on patient and presenting factors that would render individual patients more or less suitable for coronary angiography and therapeutic measures within the cardiac catheterization laboratory (including percutaneous coronary intervention and/or institution of hemodynamic support) (Fig. 64-4).65
A notable (nonclinical) input that often plays into the clinical decision making for taking patients to the cardiac catheterization laboratory for angiography and/or revascularization relates to the implications of public reporting of adverse outcomes following coronary revascularization procedures. Patients with cardiac arrest undergoing revascularization are among those with the worst prognosis, and thus there may be reluctance on the part of the treating physician (and hospital) to perform procedures in high-risk patients who may not survive to hospital discharge independent of the procedure performed. To reduce the impact of this on clinical decision making, some states with public outcomes reporting have employed either systematic exclusions for shock patients or those with anoxic brain injury, while others have tried to incorporate high-risk features into multivariable risk adjustment algorithms. Nonetheless, public reporting has been linked to avoidance of procedures in this high-risk population, and this has been linked to adverse outcomes.\(^{66}\)

**Hemodynamic Support**

Maintaining adequate perfusion pressure is vital during the early period after a cardiac arrest to prevent worsening multiorgan dysfunction and especially prevent further cerebral injury. Vasopressors are often required, especially in the setting of therapeutic hypothermia. There is no clear evidence to support which vasopressor to use after cardiac arrest and specifically in the setting of cardiogenic shock. Dopamine, norepinephrine, vasopressin, and epinephrine can all be used to help maintain adequate MAPs. In the specific setting of cardiogenic shock after cardiac arrest, inotropes including dobutamine and milrinone may be necessary. However, both of these agents cause vasodilation, and dobutamine can cause tachycardia. Revascularization should be performed if cardiogenic shock is present and culprit vessels are identified.\(^{67}\)

If initial attempts at hemodynamic stabilization are not successful, further treatment with cardiopulmonary assist devices may be warranted. While the
use of these devices has primarily been in the setting of cardiogenic shock complicating acute MI, a large proportion of these patients are survivors of SCD. An intra-aortic balloon pump (IABP) may provide stabilization of hemodynamics when initial pharmacologic treatment fails; however, routine use of IABP in cardiogenic shock does not appear to be beneficial. If more profound shock is present (or if hemodynamic instability continues despite the use of IABP), ventricular assist devices (VAD) with greater degrees of support can be considered in appropriate patients. These devices are most efficacious if placed early in the shock cycle (eg, prior to percutaneous coronary intervention). The use of a percutaneous transvalvular VAD (Impella; Abiomed), percutaneous left atrial to femoral artery assist device (TandemHeart; Cardiac Assist), percutaneous cardiopulmonary bypass support with use of an extracorporeal membrane oxygenator (ECMO), or surgical left ventricular or biventricular assist devices can all provide greater amounts of support for SCD patients who have refractory shock. Determining in which patients to employ these advanced therapies is often complicated by the uncertain neurologic status of the postarrest patient, as neurologic recovery can often take a few days. At present, there is no clear evidence supporting the use of these advanced therapies as the primary treatment modality for postarrest patients. However, marked improvements in hemodynamics have been shown when comparing the percutaneous VADs to IABP.

ECMO has also been used during cardiac arrest resuscitation, also known as extracorporeal CPR (ECPR). Implementation of ECMO use during cardiac arrests is complex and requires a highly skilled team due to the large cannula sizes and the maintenance of the ECMO circuit after cannulation. Newer self-contained ECMO systems are available and may reduce the need for active management by perfusionists but still require significant multidisciplinary training as well as system-wide decision making regarding the identification of patients who are the best candidates for this therapy. There are limited data supporting the use of ECPR. One prospective study of in-hospital arrests from a presumed cardiac origin and with CPR lasting over 10 minutes, found a 13% increase in survival with good neurologic function compared to unmatched controls (23.7% in the extracorporeal life support group, 10.6% in the CPR-only group; Fig. 64-5). Other registry data have shown promising results, with reported survival to discharge rates of up to 36% in select
populations. Guidelines state there is insufficient evidence to support more generalized use of ECPR; however, in settings where ECPR is readily available, it may be considered when the arrest time is brief and the condition leading to the cardiac arrest is reversible. 

LONG-TERM MANAGEMENT

If the acute treatment of SCD has been successful, long-term management of these patients focuses on determining the cause of the arrest and preventing
further episodes. If not performed in the acute setting, an echocardiogram should be performed, as several causes of cardiac arrest can be identified including cardiomyopathies (ischemic or idiopathic), valvular disease, hypertrophic cardiomyopathy, and arrhythmogenic right ventricular cardiomyopathy (ARVC). Cardiac magnetic resonance imaging (MRI) can also be useful, especially if an infiltrative myocardial disease is suspected. For patients managed without prompt coronary angiography who have recovery of neurologic function, further ischemic testing (angiography is the preferred modality) should be strongly considered. In addition to appropriate revascularization, medical therapies to improve myocardial ischemia and LV dysfunction should be initiated. Many of the treatments that improve general outcomes in patients with LV dysfunction have been shown to reduce the risk of SCD.

**Implantable Cardiac Defibrillator Therapy**

The use of ICD therapy has been extensively studied in the secondary prophylaxis population, and current guidelines recommend ICD therapy over antiarrhythmic therapy for survivors of VT/VF with no reversible cause identified. The AVID trial randomized 1016 patients with documented VF or unstable VT and a reduced LV ejection fraction to antiarrhythmic therapy or ICD implantation. There was a 10% absolute risk reduction in mortality with ICD use (75% 3-year survival in the ICD group vs 65% in the medication group). The CASH trial randomized 349 survivors of VT/VF arrest to ICD or antiarrhythmic therapy and found a nonsignificant 8% reduction in mortality (36.4% mortality with ICD vs 44.9% with amiodarone or metoprolol). The CIDS trial randomized 659 patients with VT/VF with either syncope or cardiac arrest to ICD or amiodarone and found a nonsignificant reduction in overall mortality. A meta-analysis of these trials found a significant 7% reduction in mortality with the use of ICD compared to medical management (Fig. 64-6).
While ICD therapy is indicated in SCD survivors who have no reversible cause, for those with reversible causes, including polymorphic VT or VF secondary to an acute MI, treatment of the underlying condition may be enough to prevent recurrent events. Nonetheless, even after revascularization, for example, residual risk can remain, and as a result, these patients should be seen by an electrophysiologist and further risk stratified. Patients with a persistent reduction in LV ejection fraction after the acute MI should be treated with guideline-directed ICD therapy. In addition, the presence of spontaneous ventricular premature beats or nonsustained VT on Holter monitoring can signal those at increased risk. In selected patients, performance of a provocative electrophysiology (EP) study can help identify those who are at higher risk of recurrent events.

**Antiarrhythmic Drugs**

ICDs remain the standard of care for survivors of SCD; however, antiarrhythmic therapy is often required during long-term management. The primary reason for the addition of an antiarrhythmic is recurrent VT/VF or other arrhythmias causing appropriate (or inappropriate) ICD shocks. A systemic review of randomized studies comparing antiarrhythmic therapy to

placebo in those with ICDs found that antiarrhythmics significantly reduce the number of shocks with no change in overall mortality.\textsuperscript{84} Amiodarone is the preferred agent, and studies have shown its superiority over other agents.\textsuperscript{85} However, long-term toxicity is a concern, and in certain circumstances, other agents should be considered. β-Blockers should also be used, as data suggest a synergistic effect of β-blockers with other antiarrhythmic therapies.

\textbf{Wearable Cardioverter-Defibrillator}

Clinical trials where ICD implantation occurred in patients with reduced LV ejection fraction soon after an MI failed to show improvements in survival, unlike trials that enrolled patients after a 40-day waiting period.\textsuperscript{86,87} Therefore, current guidelines recommend ICD implantation for persistently reduced LV ejection fraction 40 days after MI. During that waiting period, there remains a residual risk of SCD, especially among patients originally admitted with SCD. The use of a wearable cardioverter-defibrillator has been proposed for protection against SCD during the 40-day waiting period. There are no randomized data to compare the effectiveness of the wearable cardioverter-defibrillator compared with no device. However, postmarketing registry data including 8453 patients with recent MI and a reduced LV ejection fraction (\(\leq 35\%\)) found that 1.6% of patients had an appropriate shock (91% of these were from a ventricular arrhythmia).\textsuperscript{88} Given that patients may have improvements in ejection fraction over time and a lesser need for ICD shocks,\textsuperscript{89} a strategy of using a wearable cardioverter-defibrillator after post-MI revascularization in order to potentially avoid permanent ICD placement merits further study. Another use for the wearable cardioverter-defibrillator includes in those patients who require an ICD but are not candidates for an ICD because of infection, vascular access issues, or patient preference. The use of a wearable cardioverter-defibrillator in this population is effective, with similar survival to those treated with ICDs.\textsuperscript{90}

\textbf{CONCLUSION}

Cardiac arrest can occur from many causes, with VT/VF from CAD being the most common etiology. Treatment of these patients requires immediate
resuscitation with early defibrillation and high-quality CPR. Community programs to reduce emergency response times, increase bystander CPR, and increase availability of AEDs will help improve outcomes for the SCD patient. The goals of hospital care are instituting supportive care in order to preserve organ function (especially cerebral function), identifying the cause of the arrest, and optimizing treatment of this underlying cause. For interventional cardiologists, the catheterization laboratory is essential not only in order to diagnose the precipitant of the SCD but also in further stabilizing the patient: providing hemodynamic support when needed and revascularization in those cases where ischemia or infarction has led to the SCD. Beyond the supportive care instituted for these patients while in the hospital, an eye to long-term management of these patients (with appropriate consideration of ICD or wearable cardioverter-defibrillator therapy) is additionally essential in order to effectively transition survivors of cardiac arrest to the posthospital setting.

**MULTIPLE CHOICE QUESTIONS**

1. Which of the following statements is true regarding the use of therapeutic hypothermia in patients surviving sudden cardiac death?
   A. There is clear evidence to support the use of rapid cooling (ie, within the first 2 hours of cardiac arrest).
   B. The largest randomized trial of therapeutic hypothermia found no benefit of cooling to a goal temperature of 36°C compared to 33°C.
   C. Trials have shown a significant increase in bleeding complications in patients undergoing therapeutic hypothermia.
   D. Current recommendations are that therapeutic hypothermia should be continued for 48 hours followed by gradual rewarming.
   E. All of the above are true.
2. Current recommendations for the initial management of cardiac arrest patients include which of the following?
   A. The use of inspiratory impedance threshold devices if available
   B. High-quality uninterrupted cardiopulmonary resuscitation (CPR) if the initial responders are uncomfortable with mouth-to-mouth resuscitation
   C. After placement of an advanced airway, asynchronous respirations should be provided at a rate of 15 to 20 breaths per minute
   D. Interposed abdominal compression CPR (IAC-CPR) should never be used during the initial management of cardiac arrest patients
   E. There are clear data to support the use of automated chest compression devices instead of conventional CPR

3. Which of the following causes of sudden cardiac death is the leading cause in the United States?
   A. Long QT syndrome
   B. Chronic systolic heart failure
   C. Coronary artery disease
   D. Hypertrophic cardiomyopathy
   E. Congenital heart disease

4. Which of the following is no longer currently recommended during advanced cardiac life support?
   A. Epinephrine every 3 to 5 minutes
   B. Placement of a transvenous pacer for those with asystole
   C. Amiodarone (300 mg bolus) to those with refractory ventricular tachycardia or ventricular fibrillation
   D. Atropine (1 mg) to patients with pulseless electrical activity or asystole
   E. B and D
   F. All of the above are recommended

5. Which of the following should be considered by the interventional cardiologist during the management of cardiac arrest survivors?
   A. Early coronary angiography and revascularization in patients with suspected acute coronary syndrome as the primary cause of the cardiac arrest
B. Complete revascularization in patients with continued hemodynamic or electrical instability
C. Use of percutaneous hemodynamic support devices in patients with severe cardiogenic shock even when the neurologic recovery is unclear
D. Consideration of nonemergent coronary angiography in all patients presenting with cardiac arrest
E. All of the above

Part VI MEDICAL MANAGEMENT OF RISK FACTORS

65 Guideline-Directed Medical Therapy for Patients With Stable Ischemic Heart Disease

66 Appropriateness Use Criteria for Revascularization
INTRODUCTION

Guideline-directed medical therapy (GDMT) is an intrinsic part of management of patients with stable ischemic heart disease (SIHD) whether or not revascularization is performed. GDMT for patients with coronary disease is synonymous with secondary prevention and consists of pharmacologic and lifestyle interventions. This chapter synthesizes the evidence base behind guideline-recommended therapies for secondary prevention. Outside of the use of aspirin, we will not discuss strategies of antiplatelet therapy for post-percutaneous coronary intervention (PCI) patients, which are reviewed elsewhere. Additionally, management of anginal symptoms is outside the scope of this chapter, and angina management in patients with SIHD will be discussed only briefly in the context of other targets for secondary prevention and risk factor modification. We will begin by reviewing the GDMT targets for risk factor modification in the 2012 SIHD guidelines. Following this, we will review the other medical therapies that have been shown to prevent death and myocardial infarction (MI) among patients with SIHD.
RISK FACTOR GOALS

Lipid Management

Elevated concentration of low-density lipoprotein (LDL) cholesterol is a major risk factor for the development and progression of atherosclerosis. Therefore, the principal lipid modification strategy recommended by the National Cholesterol Education Program Adult Treatment Panel III (NCEP-ATP III) and the recent American College of Cardiology (ACC)/American Heart Association (AHA) guideline on the treatment of blood cholesterol is to lower LDL. All patients with coronary disease should be treated with a high-potency statin if tolerated (see below). This does not lessen the importance of nutrition, physical activity, and weight management to reduce the risk of coronary events. Effective dietary strategies to lower LDL cholesterol include replacing dietary saturated fatty acids and trans-fatty acids with unsaturated fatty acids or complex carbohydrates and reducing dietary cholesterol. Specifically, the 2012 SIHD guidelines recommended limiting saturated fat to <7% of total calories; trans-fats to <1% of total; and cholesterol to <200 mg/dL of total. While limiting saturated fat intake to <7% of total calories reduces both LDL cholesterol and high-density lipoprotein (HDL) cholesterol, reducing saturated fat intake lowers LDL more than HDL and has highly beneficial effects on the overall lipid profile and measures of total atherogenic particles, such as non-HDL cholesterol. Currently people in the United States derive between 11% and 15% of total calories from saturated fat. Earlier literature from randomized trials and practice guidelines demonstrated that targeting saturated fat to <7% of total calories lowers LDL by 10% to 15% and reduces risk of ischemic heart disease. In particular, saturated fats with chain lengths of 14 (myristic) and 16 (palmitic) carbons, primarily found in dairy products and red meat, appear most potent in raising serum cholesterol. A meta-analysis by Chowdhury et al reviewed prospective observational studies of dietary fatty acids (32 studies) and fatty acid biomarkers (17 studies) along with randomized controlled trials of fatty acid supplementation (27 studies) and concluded that evidence does not support guidelines that encourage high consumption of polyunsaturated fatty acids and low consumption of saturated fatty acids. This meta-analysis required revisions of errors in the original publication and
generated numerous critical letters to the editor. With the revision, the authors showed the inverse association of intake of long-chain \( \omega-3 \) polyunsaturated fatty acids (PUFAs) with cardiovascular disease (CVD) risk is indeed significant. They were criticized for including the Sydney Diet Heart Study, a randomized controlled trial that replaced saturated fats with an experimental diet that included a trans-fat–based margarine. When that study was excluded, the remaining randomized controlled trials found a benefit from replacing saturated fatty acids with PUFAs. A subsequent systematic review and meta-analysis by Farvid et al\(^7\) summarized the evidence regarding the relation of the predominant dietary PUFA, linoleic acid (LA), with coronary heart disease (CHD) risk. They found that compared with the lowest dietary intake of LA, the highest intake of LA was associated with a 15% (95% confidence interval [CI], 0.78-0.92) and 21% (95% CI, 0.71-0.89) reduction in CHD events and mortality, respectively.\(^7\) They found that replacing 5% of energy from saturated fat with dietary LA was associated with a 9% (95% CI, 0.86-0.96) and 13% (95% CI, 0.82-0.94) lower risk of CHD events and mortality, respectively.\(^7\) Chowdhury et al\(^6\) reported similar findings, with a reduction in CVD risk up to 13% (95% CI, 3%-22%) when comparing the highest to lowest tertiles of intake of PUFA. Notably, the effects of PUFA intake on the secondary prevention of CVD was either not evaluated\(^7\) or evaluated with very few studies\(^6\) in these meta-analyses. Increased trans-fat intake raises serum cholesterol, lowers HDL, and increases CHD events.\(^1,2\) The use of liquid vegetable oils, soft margarine, and trans-fatty acid–free margarine is encouraged instead of using butter, stick margarine, and shortening.\(^2\)

Along with therapeutic lifestyle modification, all patients with SIHD should be prescribed a moderate to high dose of statin therapy (Table 65-1) in the absence of contraindications or documented adverse effects. This is a class I recommendation for management of patients with SIHD.\(^1\) Randomized controlled trials of lipid-lowering therapy have repeatedly demonstrated that lowering LDL cholesterol with statin therapy is associated with a reduced risk of adverse cardiovascular events in patients with established ischemic heart disease (IHD) or with multiple risk factors for future IHD events.\(^1\) Prior guidelines and commentary had focused on specific LDL thresholds to guide therapy, with a cutoff of <100 mg/dL in patients with established coronary artery disease and an LDL cholesterol goal of <70
mg/dL as a therapeutic option in patients at very high risk. However, while a paucity of data exist to confirm the use of specific, numeric targets for LDL, the benefits of moderate- to high-dose statin therapy for secondary prevention of IHD is well established. It is in this context that the 2013 ACC/AHA guidelines on the treatment of blood cholesterol to reduce atherosclerotic cardiovascular risk in adults were published, generating significant controversy. In this guideline, the authors concluded there was insufficient randomized controlled trial evidence to support titrating statin or other medical therapy to achieve a specific LDL or non-HDL target in patients with or without SIHD. Instead of using specific LDL targets as in prior guidelines to guide cholesterol-lowering therapy, this ACC/AHA guideline recommended measuring on-treatment levels of cholesterol only as a tool to gauge adherence with medical therapy. To simplify the identification of patients likely to benefit from statin therapy, the authors identified 4 “statin benefit” groups, the first of which include patients with known SIHD, such as patients after PCI. Per the guidelines, all SIHD patients should receive a high-intensity statin if ≤75 years of age (see Table 65-1) or a moderate-intensity statin if >75 years old. In addition to these major changes, the guideline panel could find no evidence to support the routine use of nonstatin drugs combined with statin therapy to reduce future CHD events. The 2013 ACC/AHA guidelines therefore suggest that the vast majority of SIHD patients undergoing percutaneous revascularization procedures should receive high-intensity statin therapy. If after 4 to 12 weeks of therapy with high-intensity statin there is a less-than-anticipated therapeutic response (anticipated LDL cholesterol reduction of ≥50% or 30%-50% for high- and moderate-intensity statin, respectively), the guidelines recommend assessing adherence to statin and lifestyle modification before additional nonstatin therapies are initiated. If after adherence is documented and the therapeutic response to high- or moderate-intensity statins (see Table 65-1) remains less than anticipated, the addition of nonstatin drug therapy such as bile acid sequestrants can be considered. For patients intolerant of statin therapy, the current ACC/AHA guidelines consider therapy with a bile acid sequestrant, niacin, or both a reasonable therapeutic option (class IIa indication). We refer the interested reader to the ACC/AHA guidelines for detailed recommendations on cholesterol management strategies for patients with familial hypercholesterolemia and
other hypercholesterolemia syndromes.³

### Blood Pressure Management

Hypertension is extremely common among patients with coronary disease and is often less than optimally treated. Lifestyle factors influence blood pressure (BP), and the 2012 SIHD guidelines give a class I indication to counseling all SIHD patients on weight management, increased physical activity, alcohol moderation, sodium reduction, and increased fruit and vegetable consumption. Significant weight loss (average of 10 kg) has been shown to reduce systolic blood pressure (SBP) by 5 to 20 mm Hg.¹⁰ A diet high in fruit, vegetables, and low-fat dairy has also demonstrated improvements in BP,¹¹ as have diets with lower sodium levels.¹² Increased physical activity¹³ and reducing alcohol intake from high to moderate consumption also has beneficial effects on BP.¹⁴

Despite lifestyle modifications, many patients with SIHD require medical therapy for adequate BP control. There is a large body of literature demonstrating that, on average, a reduction in diastolic blood pressure (DBP)
of 5 to 6 mm Hg (10-20 mm Hg SBP) within a population is associated with a 40% reduction in stroke risk and a 20% reduction in risk of IHD.\textsuperscript{15} Despite the abundance of clinical studies, the appropriate BP threshold for initiating medical therapy and specific treatment goals for patients with SIHD remains controversial. The Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure recommends a target of $<140/90$ mm Hg in patients with uncomplicated hypertension and of $<130/80$ mm Hg in patients with diabetes or chronic kidney disease (CKD).\textsuperscript{16} Observations from epidemiologic studies have led some to suggest that a target lower than $<130/80$ mm Hg might be appropriate for patients with SIHD or multiple IHD risk factors.\textsuperscript{17} However, excessive reduction in DBP may compromise coronary perfusion in SIHD patients, leading to a “J-shaped” relationship of increased risk of CVD with DBP $<70$ to 80 mm Hg.\textsuperscript{18} Randomized data from the ACCORD trial also demonstrated no benefit from targeting normal BP ($<120$ mm Hg) versus SBP $<140$ mm Hg on fatal and nonfatal CVD events among patients with type 2 diabetes (T2D).\textsuperscript{19} On the other hand, a lower SBP in ACCORD was associated with a lower risk of stroke, albeit with a higher risk of serious adverse events attributed to antihypertensive medications.\textsuperscript{19} It is in this setting that the Eighth Joint National Committee 2014 Evidence-Based Guideline for the Management of High Blood Pressure in Adults (JNC 8) was released.\textsuperscript{20} While JNC 8 does not specifically address BP control in patients with SIHD, it does recommend treating to BP $<140/90$ mm Hg, a target given a class I recommendation in the 2012 SIHD guidelines.\textsuperscript{1,20}

In patients with uncomplicated hypertension, effective BP lowering is the most important factor in preventing stroke and MI. Clinical trials have failed to demonstrate superiority of any single antihypertensive drug in preventing CVD events.\textsuperscript{1} In many patients with SIHD, the choice of medications to control BP is guided by other compelling clinical indications such as the presence of left ventricular dysfunction, T2D, or CKD (Table 65-2), for which specific medication classes have demonstrated clear evidence of benefit. In recognition of this, the 2012 SIHD guidelines gave a class I recommendation to support the treatment of high BP based on specific patient characteristics and may include angiotensin-converting enzyme inhibitors (ACEi) and/or β-blockers, with the addition of other drugs, such as thiazide diuretics or calcium channel blockers, if needed to achieve a goal BP of
Management of diabetes mellitus continues to pose a quandary with regard to CVD risk. Diabetes is an important risk factor for CVD events and mortality.\textsuperscript{1} Diabetes is also associated with poor outcomes in patients with SIHD, even after adjustment for disease extent and other clinical characteristics.\textsuperscript{21} However, despite multiple randomized trials and observational studies, the efficacy of intensive diabetes therapy in reducing CVD is not well established.\textsuperscript{22} Three seminal trials of intensive glucose control in patients with T2D (ACCORD, VA Diabetes Trial, and ADVANCE) failed to demonstrate an improvement in macrovascular complications or composite outcomes of cardiovascular events and mortality with targeting a hemoglobin A1c (HbA1c) of <7% compared to less stringent control of HbA1c >7%.\textsuperscript{1,23} While intensive glucose control has not demonstrated reductions in macrovascular risk, it has demonstrated notable reductions in morbidity associated with microvascular disease, including retinopathy, nephropathy, and microalbuminuria.\textsuperscript{1,23} Subgroup analyses from the aforementioned trials have also suggested a macrovascular benefit of intensive glycemic control may exist for patients with type 1 diabetes or T2D of short duration and long life expectancy.\textsuperscript{23} Therefore, the 2012 SIHD
guidelines classified an HbA1c target of <7% as reasonable (class IIa) for patients with a shorter duration of diabetes and a longer life expectancy.\textsuperscript{1} Complementing this recommendation, the 2012 SIHD guidelines acknowledge that an HbA1c target of 7% to 9% is reasonable (class IIa recommendation) for older patients, patients with a history of hypoglycemia, and/or patients with microvascular or macrovascular complications.\textsuperscript{1} Regardless of degree of glycemic control, treatment of other modifiable risk factors common in SIHD patients with diabetes, such as hypertension, dyslipidemia, physical inactivity, and smoking, is of paramount importance to reduce cardiovascular risk.\textsuperscript{23,24} If patients and physicians decide to use pharmacologic treatment to improve glycemic control, SIHD guidelines support the use of metformin to reduce diabetic complications, especially for overweight patients.\textsuperscript{1} Available evidence also indicates that rosiglitazone is associated with an excess risk of cardiovascular complications and should not be initiated in patients with SIHD. The US Food and Drug Administration (FDA) has imposed restrictions on the use of this medication, and it has received a class III (harm) indication in the 2012 SIHD guidelines.\textsuperscript{1}

**Physical Inactivity**

The SIHD guidelines recommend 30 to 60 minutes of physical activity 5 to 7 days per week for all patients (class I) and support increasing physical activity, particularly for the most inactive patients.\textsuperscript{1} Virtually all post-PCI patients would benefit from participation in a cardiac rehabilitation program that incorporates supervised exercise into a comprehensive program of secondary CVD prevention.\textsuperscript{1} Despite this benefit, cardiac rehabilitation referral rates remain low, particularly for patients age ≥65 years.\textsuperscript{25} A meta-analysis of 48 randomized controlled trials of exercise interventions of a median of 3 months on duration (95% CI, 0.25-30 months) and with 15 months of follow-up (95% CI, 6-72 months) demonstrated an overall 20% reduction in all-cause mortality; a 26% reduction in total cardiac mortality; and favorable but nonsignificant trends in the occurrence of MI, coronary artery bypass grafting (CABG), and PCI.\textsuperscript{26} The benefits of exercise and cardiac rehabilitation are independent of the actual amount or intensity of exercise and have clear benefits in SIHD patients with and without angina.\textsuperscript{26} The effects of exercise on CVD risk reduction are multifactorial. Exercise
does not lower LDL, but it facilitates weight loss and has other beneficial cardiometabolic effects. Exercise in patients with SIHD is safe, with a rate of major adverse cardiac events (MACE) of approximately 1 in 80,000 patient-hours. Previous SIHD guidelines have recommended that all patients undergo an exercise test before participating in a cardiac rehabilitation program. However, in line with recent recommendations from the World Health Organization, the 2012 SIHD guidelines state that a physical activity history and/or an exercise test is recommended to guide prognosis and exercise prescription.

**Weight Management**

Effective weight management complements many of the secondary prevention targets for patients with SIHD. Regular assessment of patient weight, body mass index (BMI), and/or waist circumference is a class I recommendation in the 2012 SIHD guidelines. Physicians should encourage weight maintenance or reduction through a balance of physical activity and caloric intake to maintain a BMI between 18.5 and 24.9 kg/m$^2$ and a waist circumference <40 inches in men and 35 inches in women. Population studies have repeatedly demonstrated an association between increased BMI and IHD events. Specifically, a large meta-analysis of over 300,000 participants in 21 cohort studies demonstrated that IHD risk increased by 30% and 81% for overweight (BMI 25.0-29.9 kg/m$^2$) and obese (BMI >30 kg/m$^2$) participants, respectively, compared to those of normal weight. This relationship was independent of age, sex, smoking status, and physical activity. After additional adjustment for hypertension and hyperlipidemia, the relationship between BMI and IHD risk was attenuated, but remained statistically significant. These findings suggest that while a portion of the IHD risk of overweight and obesity is conditional on the development of hypertension, hyperlipidemia, and T2D, overweight and obesity also increase risk of IHD through heightened sympathetic tone, hypercoagulability, and inflammation. Interestingly, a similar relationship between BMI and death and CVD events is not consistently observed in cohorts with established IHD. This altered relationship between BMI and IHD risk in patients with established IHD may be due to confounders such as smoking or age or due to the weight loss and lower BMI associated with chronic illness.
clinical trials have examined the effects of weight loss on cardiovascular event rates in patients with SIHD. However, the association of adiposity, overweight, and obesity with other cardiovascular risk factors suggests that weight reduction is indicated in all overweight or obese patients.1

**Smoking Cessation**

The detrimental effects of smoking are clear for patients with IHD. The 2012 SIHD guidelines recommend smoking cessation and avoidance of exposure to tobacco at work and at home (class I).1 The mechanisms of CVD risk from tobacco exposure are well known and include enhanced platelet activity, increased endothelial dysfunction, heightened vasoconstriction, and decreased HDL.1 Although randomized controlled trials have not been performed in patients with SIHD, observational studies strongly suggest that smoking cessation is an important strategy for the secondary prevention of IHD. A meta-analysis of 20 prospective cohort studies in patients with known coronary artery disease (CAD) found a 30% relative risk reduction in mortality for those who quit smoking compared to those with CAD who continued to smoke.29 A similar risk reduction was observed for the occurrence of nonfatal MI.29 The most effective smoking-cessation therapies include both nonpharmacologic and medical interventions. Most of the recommendations to improve quit rates in patients with SIHD are extrapolated from literature in patients without SIHD. Notably, physician advice has a significant effect on smoking quit rates, and the SIHD guidelines recommend physicians inquire about plans for smoking cessation at each visit with patients who continue to smoke. Other useful interventions to improve smoking cessation include self-help programs, behavioral therapy, and possibly exercise interventions.1 Nicotine replacement therapy, sustained-release bupropion, and varenicline all approximately double quit rates. There have been recent concerns of enhanced suicidality and depression in patients prescribed varenicline, which may be an issue for patients with SIHD in whom depression is frequently a comorbid disorder.1 The 2012 SIHD guideline recommends that physicians should use a standardized approach to smoking cessation counseling by using the “6 A’s” framework: Ask, Advise, Assess, Assist, Arrange, and Avoid.1 By applying the 6 A’s framework, physicians can more systematically address principles important to smoking
cessation.

EVIDENCE-BASED PHARMACOLOGIC THERAPIES

Aspirin

Aspirin is the cornerstone of antiplatelet therapy in patients with SIHD. The 2012 SIHD guidelines recommend indefinite aspirin use at 75 to 162 mg in SIHD patients (class I). Aspirin inhibits the cyclooxygenase enzyme and blocks prostaglandin endoperoxide formation, inhibiting platelet aggregation. Major trials and meta-analyses have demonstrated that aspirin use in patients with SIHD leads to a 30% to 50% reduction in vascular events, unstable angina, and revascularization. Importantly, aspirin in a dose of 75 to 162 mg is as effective in secondary prevention as 325 mg and has a lower associated bleeding risk. Aspirin is relatively contraindicated in patients with known allergies to nonsteroidal anti-inflammatory drugs and in patients with the syndrome of rhinitis, asthma, and nasal polyps.

P2Y12 Inhibitors

Clopidogrel, a thienopyridine derivative, is a selective and irreversible inhibitor of the platelet P2Y12 receptor that represents a suitable alternative to aspirin for platelet inhibition for many patients with SIHD. The CAPRIE trial compared clopidogrel 75 mg to aspirin 325 mg in patients with previous stroke, MI, or symptomatic peripheral arterial disease (PAD). There was a small but statistically significant benefit from clopidogrel in the secondary prevention of MI and death in these patients. No additional trials in patients with SIHD comparing aspirin and clopidogrel for the secondary prevention of CVD events have been completed. The 2012 SIHD guidelines recommend the use of clopidogrel for long-term platelet inhibition among patients with SIHD in whom aspirin is contraindicated (class I).

Whether or not patients with SIHD benefit from preventive dual antiplatelet therapy (DAPT) with aspirin and clopidogrel long term is unclear. Evidence from the CURE and CREDO trials indicated that patients with...
recent non–ST-segment elevation myocardial infarction (NSTEMI) or unstable angina benefit from DAPT for 9 to 12 months in terms of reduced risk of death, MI, or stroke, with an increased risk of bleeding, possibly related to aspirin doses >75 mg. In contrast to these positive findings in higher risk patients with recent IHD events, in the CHARISMA trial, DAPT with aspirin and clopidogrel did not reduce the risk of death, MI, or stroke among patients without established IHD but with multiple risk factors. A post hoc analysis of CHARISMA suggests that patients with prior MI, ischemic stroke, or symptomatic PAD might derive greater benefit from DAPT than lower-risk patients, but the role of DAPT in specific high-risk subgroups warrants further study before clear recommendations can be made. With this evidence, the 2012 SIHD guidelines conclude that treatment with aspirin 75 to 162 mg and clopidogrel 75 mg might be reasonable in certain high-risk patients with SIHD. While the newer agents ticagrelor and prasugrel have demonstrated reductions in major adverse cardiac events in the setting of acute coronary syndromes (ACS), their usefulness has yet to be tested in patients with SIHD.

**β-Blockers**

β-Blockers are indicated in the treatment of patients with a history of MI, IHD, and left ventricular dysfunction and in the management of stable angina. β-Blockers decrease heart rate, rate-BP product, and myocardial contractility, decreasing myocardial oxygen demand and cardiac work, and delay the onset of anginal symptoms. β-Blockers reduce death and recurrent MI among patients with a previous MI and are particularly effective in patients with ventricular tachyarrhythmias in the setting of an ST-segment elevation MI. The benefits of β-blockers in the setting of MI are based on studies that predate contemporary management strategies of early reperfusion and modern medical therapy. However, recent observational data suggest β-blocker therapy may be associated with reduced long-term mortality after PCI for acute MI and preserved systolic function. In SIHD, there is solid evidence to show that β-blockers relieve anginal symptoms and improve myocardial ischemia, and they are considered first-line agents for angina relief in the 2012 SIHD guidelines. However, there has not been an appropriately powered randomized controlled trial to determine if β-blockers
improve prognosis in patients with SIHD with normal left ventricular function and no prior MI. A recent analysis from the REACH registry examined the benefit of $\beta$-blockers in over 21,000 SIHD patients and found that $\beta$-blockade did not reduce the rate of CVD death, MI, stroke, hospitalization, or revascularization, even among potentially higher risk patients with prior MI. With the data available at the time, the 2012 SIHD guidelines gave a class I indication to $\beta$-blocker therapy for 3 years for all patients after MI or ACS.1

**Angiotensin-Converting Enzyme Inhibitors**

ACEi have a strong body of evidence to support their use in SIHD patients. The 2012 SIHD guidelines designate a class I recommendation to prescribe ACEi in all patients with SIHD who also have hypertension, diabetes, left ventricular ejection fraction ≤40%, or CKD, unless contraindicated.1 ACEi have pleiotropic effects and have been shown to decrease angiotensin II and increase bradykinin levels. It is thought that beneficial alterations in the balance between angiotensin II and bradykinin could account for reductions in left ventricular hypertrophy, atherosclerosis progression, plaque rupture, and thrombosis, along with improved left ventricular remodeling.1 Moreover, ACEi lead to beneficial changes in cardiac hemodynamics and the balance in myocardial oxygen supply and demand. Clinical studies have repeatedly demonstrated reductions in MI, unstable angina, and revascularization in patients after MI with left ventricular dysfunction, regardless of etiology.40 Notably, the benefits of ACEi extend to patients with SIHD without left ventricular dysfunction. The HOPE trial, a randomized controlled trial of ramipril in patients with vascular disease or diabetes and 1 additional CVD risk factor, demonstrated a 22% reduction in risk of death, MI, or stroke among patients receiving ramipril.41 The EUROPA trial further advanced support for the use of ACEi in SIHD without left ventricular dysfunction. In this randomized controlled trial of perindopril in SIHD without left ventricular dysfunction, ACEi demonstrated a 20% increase in the duration of time to an IHD event in patients with SIHD without clinical evidence of heart failure.42 While the benefits of ACEi in these 2 studies is noteworthy, other studies including PEACE, QUIET, and IMAGINE (a post-CABG study) presented conflicting evidence on the benefits of ACEi in SIHD without left
ventricular dysfunction. A 2006 meta-analysis of randomized controlled trials of ACEi in SIHD without left ventricular dysfunction demonstrated a 14% risk reduction in MI, a 23% reduction in stroke, and a 7% reduction in need for revascularization with the use of ACEi. The SIHD guidelines also find it reasonable to use ACEi for vascular protection for patients with SIHD or other vascular diseases (class IIa recommendation).

**Angiotensin Receptor Blockers**

Similar to ACEi, angiotensin receptor blockers (ARBs) also have an important role for vascular protection in patients with SIHD. The 2012 SIHD guidelines give a class I recommendation to support the use of ARBs in SIHD patients with hypertension, diabetes mellitus, left ventricular systolic dysfunction, or CKD who have indications for, but are intolerant of, ACEi therapy. Similarly, the SIHD guidelines find it reasonable to use ARBs in other patients who are ACEi intolerant (class IIa). ACEi and ARB have similar BP-dependent effects on risk of stroke, IHD, and congestive heart failure. Interestingly, however, ACEi appear to have BP-independent vascular benefits that are not observed with usage of ARB.

**Influenza Vaccination**

Influenza vaccination is an important therapy that can meaningfully impact morbidity and mortality in SIHD patients. The SIHD guidelines support annual influenza vaccination with a class I recommendation. Influenza contributes to higher risk for mortality and hospitalization and exacerbates underlying medical conditions. Randomized controlled trial evidence of influenza vaccination in SIHD patients does not exist. However, observational study evidence of influenza vaccination in SIHD demonstrated a nearly 40% mortality reduction with the influenza vaccine during winter months.

**IMPLEMENTATION**

Despite the clear benefit of lifestyle and pharmacologic interventions for
secondary prevention, gaps in the attainment of treatment goals for patients with SIHD continue to exist. The AHA and ACC have developed tools to assist in the attainment of guideline-directed goals. The AHA’s Get With the Guidelines and the ACC’s Guidelines Applied in Practice have made substantial progress in achieving specific benchmarks for the management of SIHD inpatients and outpatients, respectively. As an example, >95% of contemporary patients admitted with ACS are prescribed β-blockers, aspirin, and lipid-lowering therapy upon discharge. Over 90% of these patients also receive smoking cessation counseling. However, other evidence indicates continued room for improved use of guideline-directed medical therapy (GDMT) in the care of patients with SIHD. Using data from 2005 to 2009 in the National Cardiovascular Data Registry, Borden et al demonstrated that fewer than half of SIHD patients were receiving GDMT prior to elective PCI, and only two-thirds received GDMT prior to discharge following PCI. Using data from the REGARDS study, Brown et al recently showed that only 16% of REGARDS participants with a self-reported history of CAD met SIHD goals for aspirin, BP, and LDL cholesterol. Attainment of SIHD targets for physical activity and BMI was also low, at 25% and 22%, respectively. There is still a significant gap in the translation of evidence-based guidelines into practice.

**Improving GDMT in the Inpatient Setting**

Admission for an ACS or elective PCI provides an ideal opportunity to initiate GDMT. In 1 study, routine implementation of all secondary prevention guidelines was associated with reductions in 1-year mortality and recurrent MI. In addition to initiating GDMT, counseling on the importance of adherence with GDMT therapy should occur during an inpatient admission. During a hospital admission, SIHD patients and their family members may be more receptive to messages of behavior change and risk factor modification, such as adherence with prescribed therapy, than they may be as outpatients. Therefore, an inpatient admission can be used to emphasize the importance of behavior change and pharmacologic therapy as complementary to revascularization and as an integral part of IHD management. The ACC/AHA have codified recommendations to improve SIHD care on the individual and systems levels, during both inpatient and outpatient care episodes. These recommendations are summarized briefly
Implementation of these processes is often a multidisciplinary process that should include nurses, social workers, nutritionists, pharmacists, and exercise physiologists who should be assigned specific tasks for the patient’s care.\textsuperscript{50} Table 65-4 describes multiple ways in which the inpatient setting and the electronic medical record (EMR) can be used to improve health behaviors for SIHD patients. Another recommended use of the EMR is to routinely trigger referrals of SIHD patients for cardiac rehabilitation, an intervention that can significantly improve the prognosis for SIHD patients.\textsuperscript{1}

Table 65-3 Evidence-Based Approaches for Improving Health Behaviors and Health Factors in the Outpatient Setting\textsuperscript{46}

- Set specific, obtainable goals with a personalized plan to achieve them (e.g., over the next 3 months, increase fish by 1 serving/week).
- Establish self-monitoring. Develop a plan such as dietary or physical activity diary by web-based or mobile applications.
- Schedule regular follow-up (in-person, telephone, written, and/or electronic) with clear frequency and duration.
- Provide feedback on progress toward goals, including using in-person, telephone, or electronic feedback.
- Increase self-efficacy by increasing patient’s perception that he or she can successfully change his or her behavior.\textsuperscript{a}
- Use motivational interviewing when patients are resistant or ambivalent about change.\textsuperscript{b}
- Arrange long-term support of family, friends, or peers for behavior change in workplace, school, or community-based programs.
- Use a multicomponent approach combining 2 or more of the above strategies into the behavior change efforts.

\textsuperscript{a}Examples of approaches include mastery experiences (reasonable, proximal goals that can be achieved); vicarious experiences (see someone with similar capabilities performing the behavior); physiologic feedback (change in their symptoms is related to worse or improved behaviors); and verbal persuasion (persuasion that you believe in their capability to perform the behavior).

\textsuperscript{b}Motivational interviewing is the use of individual counseling to explore and resolve ambivalence toward behavior change. Major principles include fostering awareness and
resolution of ambivalence in a partnership with the counselor or provider.

**Table 65-4 Evidence-Based Approaches for Improving Health Behaviors in the Inpatient Setting**

- EMR systems for scheduling and tracking visits and follow-up contacts while an inpatient.
- EMR systems to help assess, track, and report on specific health behaviors.
- Paper or electronic toolkits for assessment of key health behaviors, during, before, and after provider visits.
- Electronic systems to provide patient feedback during behavior change and other treatment efforts.
- Provider education on evidence-based behavior change strategies, as well as behavioral targets.
- Efforts to integrate care systems to provide multidisciplinary care by teams of providers.

Abbreviation: EMR, electronic medical record.

**Improving GDMT in the Outpatient Setting**

The outpatient setting is key to the long-term attainment of GDMT and risk factor optimization. **Table 65-3** provides a summary of current evidence-based approaches to improve individual health behaviors in the outpatient setting. In addition to individual- and systems-level recommendations such as the use of EMR and standardized referral processes, the outpatient clinical setting can use specialty clinics to optimize risk factor management. If available, specialty clinics can optimize care of SIHD patients with cardiac rehabilitation programs, lipid clinics, hypertension clinics, and dietary consultation.

For a summary of the AHA/ACC guidelines for the management of patients with SIHD, see **Table 65-5**.

**Table 65-5 AHA/ACC Guideline Summary for the Management of Patients with SIHD**
Risk Factor Modification

Lipid Management

Class I

• Lifestyle
• Diet
• Statin therapy

Class II

• Bile acid sequestrants, niacin, or both for patients intolerant of statins

Blood Pressure Management

Class I

• Lifestyle modification
• Initiate therapy for BP >140/90 mm Hg
• ACEi, (ARB if ACEi intolerant), β-blockers, thiazide diuretics, or calcium channel blockers, target ≤140/90 mm Hg

Diabetes Management

Class IIa

• HbA1c <7% reasonable for diabetes of short duration or long life expectancy
• HbA1c 7%-9% reasonable depending on age and medical history/comorbidities

Class IIb

• Pharmacotherapy for HbA1c targets might be reasonable

Class III

• Rosiglitazone should not be initiated in SIHD

Physical Activity

Class I

• 30-60 minutes of moderate-intensity 5-7 days/week
• Physical activity history and/or exercise test recommended to guide prognosis and prescription
• Cardiac rehabilitation and home-based programs recommended for at-risk patients at first diagnosis

Physical Activity

Class IIa
• Resistance training 2 days/week is reasonable

Weight Management
Class I
• BMI and/or waist circumference, weight counseling, for BMI between 18.5 and 24.9 kg/m²
• Initial weight loss goal between 5% and 10% from baseline

Smoking Cessation Counseling
Class I
• Smoking cessation and avoidance of tobacco at work and home encouraged for all SIHD patients
• Ask, Advise, Assess, Assist, Arrange, Avoid recommended for cessation counseling

Additional Medical Therapy to Prevent MI and Death

Antiplatelet Therapy
Class I
• Aspirin 75-162 mg daily should be continued indefinitely for SIHD in the absence of contraindications
• Treatment with clopidogrel is reasonable when aspirin is contraindicated in patients with SIHD

Class IIb
• Aspirin 75-162 mg daily and clopidogrel 75 mg daily might be reasonable in certain high-risk SIHD patients

Class III
• Dipyridamole is not recommended as antiplatelet therapy for SIHD patients

β-Blocker Therapy
Class I
• β-Blocker for 3 years in all patients with normal LV function after MI or ACS
• β-Blocker for all patients with LV systolic dysfunction (LVEF ≤40%) with heart failure or prior MI

Class IIb
• β-Blockers may be considered for chronic therapy for all other patients with coronary or vascular disease
**Renin-Angiotensin-Aldosterone Blocker Therapy**

*Class I*
- ACEi prescribed for SIHD patients with hypertension, diabetes mellitus, LVEF ≤40%, or CKD unless contraindicated
- ARBs are recommended for SIHD patients who are intolerant of but have indications for ACEi (above)

*Class IIa*
- ACEi is reasonable for SIHD patients with other vascular diseases
- It is reasonable to use ARBs in other patients who are intolerant of ACEi

**Influenza Vaccination**

*Class I*
- An annual influenza vaccine is recommended for SIHD patients

Abbreviations: ACC, American College of Cardiology; ACEi, angiotensin-converting enzyme inhibitor; ACS, acute coronary syndrome; AHA, American Heart Association; ARB, angiotensin receptor blocker; BMI, body mass index; BP, blood pressure; CKD, chronic kidney disease; HTN, hypertension; LV, left ventricular; LVEF, left ventricular ejection fraction; MI, myocardial infarction; SIHD, stable ischemic heart disease.

MULTIPLE CHOICE QUESTIONS

1. What is the most appropriate initial medical therapy to reduce low-density lipoprotein (LDL) cholesterol in among patients with stable ischemic
heart disease (SIHD)?
A. Lowest tolerated dose statin
B. High-intensity statin
C. Ezetimibe
D. Niacin
E. At least 30-60 minutes of moderate-intensity daily aerobic activity

2. Which of the following is true for patients with SIHD and a blood pressure (BP) of 140/90 mm Hg or higher?
A. Specific medications used for treatment of high BP should be based on patient characteristics.
B. All patients should be counseled about the need for lifestyle modification.
C. Antihypertensive drug therapy should be instituted for a BP of 140/90 mm Hg or higher in addition to or after a trial of lifestyle modifications.
D. All of the above

3. What can be expected from intensive glucose control in patients with SIHD?
A. Reduced risk of microvascular disease
B. Reduced risk of myocardial infarction
C. Reduced risk of death
D. Reduced risk of hypoglycemia
E. If achieved with rosiglitazone, risk of cardiovascular complications is reduced

4. Which statement below is true about physical activity for patients with SIHD?
   a. Moderate-intensity physical activity is recommended for 20 minutes 3 times per week.
   b. Participation in cardiac rehabilitation reduces mortality risk by 20%.
   c. Physical activity lowers LDL cholesterol.
   d. The risk of sudden death associated with exercise is 1 in 10,000 patient-hours.

5. What is the class I indication for prescribing an angiotensin-converting
enzyme(ACE) inhibitor for SIHD?
A. Hypertension
B. Diabetes
C. Left ventricular ejection fraction ≤40%
D. Chronic kidney disease
E. All of the above

ANSWERS

1. B

Data from randomized clinical trials have demonstrated that lowering of LDL cholesterol is associated with a reduced risk of cardiovascular events and support intensive LDL cholesterol lowering in patients with SIHD. High-intensity statin therapy includes atorvastatin 40 to 80 mg daily or rosuvastatin 20 to 40 mg daily. Compared to lower doses and lower potency statins, randomized trials have demonstrated a consistent benefit in event reduction with use of high-intensity statins.

2. D

In many patients with SIHD, the choice of medications is guided by compelling indications for specific classes of drugs, and effective BP lowering is the most important factor in preventing stroke or myocardial infarction. Treatment of high BP should begin with lifestyle measures, as weight loss, diet, reduction in sodium intake, and regular physical activity have all been shown to reduce blood pressure. In addition to lifestyle measures, antihypertensive drug therapy will frequently be needed to reach the currently accepted target of BP <140/90 mm Hg.

3. A

Numerous studies have found that intensive glycemic control reduces microvascular complications of diabetes. Recent clinical trials in patients with SIHD, however, have failed to show a reduction in myocardial infarction or mortality. Tighter glucose control is associated with a higher risk of hypoglycemia. Rosiglitazone is associated with an excess risk of
cardiovascular complications and should not be initiated in patients with SIHD.

4. B

The SIHD guidelines recommend 30-60 minutes of physical activity 5-7 days per week for all patients (class I). A meta-analysis of 48 randomized controlled trials of exercise interventions of a median of 3 months in duration (95% CI, 0.25-30 months) and with 15 months of follow-up (95% CI, 6-72 months) demonstrated an overall 20% reduction in all-cause mortality and a 26% reduction in total cardiac mortality. Exercise does not lower LDL cholesterol, but it facilitates weight loss and has other beneficial cardiometabolic effects. Exercise in patients with SIHD is safe, with a rate of major adverse cardiac events (MACE) of approximately 1 in 80,000 patient-hours.

5. E

It is a class I recommendation to prescribe an ACE inhibitor to patients with SIHD who also have hypertension, diabetes, LVEF ≤40%, or chronic kidney disease. Angiotensinreceptor blockers have a class I indication for SIHD patients with hypertension, diabetes, LVEF ≤40%, or chronic kidney disease who are intolerant of ACE inhibitors.
Appropriate Use Criteria for Revascularization

Lloyd W. Klein

The Appropriate Use Criteria for Revascularization (AUC) is a vital instrument supporting high-quality interventional practice that presents, in a pragmatic format, the optimal application of the evidence base and existing guidelines to patient selection for percutaneous coronary intervention (PCI). It is a meaningful response to concerns of overutilization, serves as a quality metric, and establishes the relative roles of coronary artery bypass graft surgery (CABG) and medical therapy in patients with both stable ischemic heart disease (SIHD) and acute coronary syndromes (ACS). The original AUC\(^1\) and a focused update\(^2\) set the standard of practice regarding optimal patient selection for PCI. The AUC has broad implications for the future of cardiovascular health care, especially in regard to case selection, treatment options, and reimbursement. In the future, it will become the foundation for tethering payment decisions and quality assessment to patient-centered therapeutic decision making. Limitations of the first version have been extensively articulated, and a subsequent revision has been published to improve the criteria so they more meticulously take into account how interventional cardiologists evaluate scientific data and apply those conclusions to individual revascularization decisions.

WHY DO APPROPRIATE USE
CRITERIA EXIST?

Today’s generation is the recipient of a myriad of astonishing bioengineering, pharmacologic, and technical innovations over the last 3 decades. These advancements have resulted in the growth and maturity of a new field of treatment for coronary artery disease (CAD). The exponential growth in the number of PCI procedures has resulted in an unprecedented escalation in the cost of health care: approximately 600,000 PCIs are performed in the United States each year\(^3\) at a cost exceeding $12 billion. However, this expense is not accompanied by a measurable outcomes benefit.\(^4\) Moreover, the wide geographic variability of the use of PCI in the United States\(^5,6\) has been interpreted as a demonstration that patients are not being referred for the procedure strictly based on scientific evidence. The divergence in cost versus benefit logically demands a formal evaluation of PCI utilization.

The value of PCI in ACS (ST-segment elevation myocardial infarction [STEMI], non–ST-segment elevation myocardial infarction [NSTEMI], and unstable angina) has been definitively demonstrated: by eliminating the causative coronary obstruction, PCI significantly reduces mortality and recurrent myocardial infarction in this setting. However, in SIHD, there is no proven survival benefit or reduction in subsequent myocardial infarction versus medical therapy. PCI in this circumstance reduces or relieves angina but does not contribute to improvement in hard end points. Furthermore, since patients who undergo PCI are exposed to the risk of periprocedural complications, including death, stroke, bleeding, and myocardial infarction, a judicious approach to case selection is required. Deciding which patients are likely to benefit from PCI is as much a matter of clinical judgment as the application of clinical evidence (clinical trials, registries, meta-analyses, retrospective studies confirmed by additional data).\(^7\) In contemporary practice, the decision of whether PCI, medical therapy, or bypass surgery should be the primary strategy in a given patient can no longer be made based simply on the number of vessels diseased, as it was in the past.\(^8\) Not every patient with a hemodynamically significant stenosis, a positive stress test, or angina experiences improved survival or better angina relief from PCI compared to other treatment modalities. For example, in patients with SIHD, PCI provides only a modest population-average improvement in symptom relief compared with medical therapy.\(^9\) No patient wants to endure the pain
and recuperative process of surgery if there is no incremental benefit; conversely, no patient will accept the cost and hassle of multiple medications and their adverse effects if there is a better alternative. Further, it is reasonable to avoid expensive procedures unless there is some measurable improvement over other options. Because it is not possible to quantitatively scale the expected advantages versus the inherent drawbacks and risks, which ultimately is an individual subjective determination, there is no objective way to compare the different rates of success and adverse events of each treatment method; thus, clinical judgment requires an individual assessment in every case.

It is important that expert practitioners set parameters and then determine the extent to which PCI is performed for appropriate versus inappropriate indications to identify procedural overuse and areas for quality improvement and cost savings. Therefore, a means of evaluating the clinical appropriateness of PCI is necessary; good outcomes and high operator volumes alone are not sufficient to define high quality. These surrogate measures in isolation encouraged the performance of large volumes of low-risk procedures of uncertain appropriateness and the avoidance of high-risk but properly selected cases. Concern regarding overutilization is a crucial issue the profession must address if it is to continue to enjoy the privileges of self-referral and self-regulation. Other potential advantages of specific criteria to guide appropriate case selection are also apparent, including providing guidance for clinicians and patients in making difficult decisions, enabling comparison of a laboratory’s or operator’s outcomes versus a national benchmark, assisting in providing the “right therapy at the right time,” and upholding a patient-centered approach.

In contrast to practice guidelines, which summarize published data to classify levels of utility, or performance measures, which distill the guidelines into specific actions that should be taken programmatically, the AUC integrate the guidelines, clinical trial evidence, and clinical experience to specify what clinical decision is usually optimal. The AUC define the strength of the indications for a procedure, weighing both its benefits and drawbacks. The goal of the AUC is to guide decision making by clarifying expected benefits in specific clinical situations. In 2009, the AUC for coronary revascularization were published, and in 2011, rates of appropriateness in the National Cardiovascular Disease Registry (NCDR)
were reported.\textsuperscript{14} A focused update reflecting updated comparative data between bypass surgery and PCI was published in 2012.\textsuperscript{2} Another update was published after this chapter was submitted. It contains substantial changes that will be reflected in the online version of this book.

**BACKGROUND**

Ethical decision making requires of every physician that procedures should not be performed unless they offer potential benefit to the patient; this principle has been an accepted tenet of medicine since the Hippocratic Oath. How to define benefit and how clinical decisions should be evaluated in this context are constantly changing features of modern medicine. In regard to PCI, the initial notion underlying balloon angioplasty was that the treatment of any single high-grade coronary stenosis that was technically feasible offered benefit over medications. In 2006, the OAT trial demonstrated that not all recent occlusions opened percutaneously had improved outcomes, and this provocative trial was followed the next year by the COURAGE trial,\textsuperscript{9} which suggested that optimal medical therapy in multivessel SIHD may produce similar hard end point outcomes (death, myocardial infarction, and stroke) as complete revascularization with stenting. With the development of drug-eluting coronary stents and improved catheter and guide wire technology, it has become even more ambiguous which patients are best treated with pharmacology, bypass surgery, or a percutaneous procedure. Consequently, the nuances and complexity of determining when a PCI is and is not appropriate is a controversial and active area of investigation.

The first large-scale investigation of an evidence-based classification to define appropriateness studied the relationship between the American College of Cardiology (ACC)/American Heart Association (AHA) recommended indications for PCI and short-term in-hospital outcomes and was performed using data from the NCDR.\textsuperscript{15} After excluding STEMI, the remaining 412,617 PCIs were grouped by indication class: class I, evidence and/or agreement that PCI is useful and effective; class IIa, conflicting evidence and/or divergent opinions, weight is in favor; class IIb, usefulness/efficacy is less well established; and class III, evidence and/or agreement that PCI is not useful or effective and may be harmful. Frequency of indications was as follows: class I, 64%; class IIa, 21%; class IIb, 7%; and class III, 8%. Clinical
success declined across the indication classes (92.8%, 91.7%, 89%, and 85.5% for class I, IIa, IIb, and III, respectively; \( P < .001 \)), whereas adverse events increased. The results of this study demonstrated that most procedures were performed for class I indications and that a significant relationship existed between evidence-based indications recommended by the ACC/AHA Task Force and in-hospital outcomes. The authors concluded that closer adherence to guidelines can reduce variations in care and improve quality and may ultimately result in better outcomes.

In a follow-up study,\(^{16}\) the outcomes in each indication class were evaluated after risk adjustment by the NCDR risk adjustment model. A total of 559,273 PCI procedures were analyzed. Increasing frequencies of risk components were observed across classes I, IIa, IIb, and III. Expected mortalities for each class calculated by the risk adjustment model were close to observed values (expected 0.52%, 0.59%, 1.72%, and 1.96%, respectively; observed 0.49%, 0.63%, 1.88%, and 1.60%, respectively). Thus, the ACC-NCDR risk-adjusted mortality model, when linked to the ACC/AHA PCI guidelines, produced mortality risk estimates by indication class close to actual observed values. The critical implication of this finding was that the model, together with the PCI guidelines, could be used as a powerful analytic tool for quality assurance and assessment of the appropriateness of case selection. Indeed, the recognition that the flipside of the development of an accurate risk prediction model for PCI is its application to quality assurance was the crucial step in the evolution to AUC.

### APPROPRIATE USE CRITERIA FOR REVASCULARIZATION

The essential rationale for the AUC is to provide an evidence-based, clinically applicable assessment of procedural appropriateness without regard to financial considerations or socioeconomic status. The ACC convened a committee to develop AUC derived from the PCI guidelines. The process chosen combined evidence-based medicine, guidelines, and practice experience by engaging a technical panel in a modified Delphi exercise as previously described by RAND.\(^1,17\) The technical panel was composed of 4 interventional cardiologists, 4 cardiovascular surgeons, 8 general
cardiologists and other physicians who treat patients with cardiovascular disease or health outcome researchers, and 1 health plan medical officer (also a physician). One hundred eighty scenarios illustrative of commonly observed clinical situations were developed by a writing committee and scored by the separate technical panel on a scale of 1 to 9. Scores of 7 to 9 indicated that revascularization was considered “appropriate” and likely to improve health outcomes or survival. Scores of 1 to 3 indicated revascularization was considered “inappropriate” and unlikely to improve health outcomes or survival. The mid-range (score of 4-6) indicated a clinical scenario for which the likelihood that coronary revascularization would improve health outcomes or survival was considered “uncertain.” These categories are those mandated by the RAND process. For the majority of the clinical scenarios, the panel only considered the appropriateness of revascularization irrespective of whether this was accomplished by PCI or CABG. In a select subgroup of clinical scenarios in which revascularization was generally considered reasonable, the appropriateness of PCI and CABG individually as the primary mode of revascularization was considered.

Because SYNTAX\textsuperscript{18} had not been published in a peer review format at the time of the meeting of the technical panel (November 2008), the initial document\textsuperscript{1} was written explicitly to concur with the existing guidelines (Figs. 66-1 and 66-2). A revised focused update was later published\textsuperscript{2} that incorporated the SYNTAX results (Fig. 66-3).
FIGURE 66-1 Appropriate Use Criteria in acute coronary syndromes. The fact that the use of coronary revascularization for a particular condition is listed in this figure (appropriate, uncertain, or inappropriate) does not preclude the use of other therapeutic modalities that may be equally effective. See the most current American College of Cardiology/American Heart Association UA/NSTEMI and STEMI guidelines.\textsuperscript{15,16} A, appropriate; CAD, coronary artery disease; HF, heart failure; I, inappropriate; LVEF, left ventricular ejection fraction; PCI, percutaneous coronary intervention; STEMI, ST-segment elevation myocardial infarction; U, uncertain; and UA/NSTEMI, unstable angina/non–ST-segment elevation myocardial infarction. The decision to perform coronary revascularization is correctly based on a multitude of factors, including the presence of a stenosis-producing ischemia, the severity of symptoms, application of medical therapy, objective evidence of ischemia, the volume of myocardium at jeopardy, the presence of viable myocardium with the potential for reversible dysfunction, and the demonstration of significant coronary stenoses that are treatable with current techniques. Each of these conditions requires substantial testing to demonstrate, and their interrelationships are notably variable.

The failure to find a quantitative method that resolves the uncertainty that attends the subjective interpretation of angiograms impacts the selection of patients for interventional procedures. Coronary angiography is widely recognized to have many imprecisions, especially with a stenosis in the intermediate range, yet it remains the primary diagnostic tool. Adding a physiologic measure of stenosis severity to angiographic assessment enhances the accuracy of diagnosis and optimizes the selection of patients for expensive and risky treatment options. The structure of the AUC is predicated on an assumption that the size of a defect on nuclear scans can be used as the standard for assessing the significance of a stenosis and the amount of myocardium subtended by a critical stenosis.

For purposes of describing the severity of symptoms, the Canadian Classification was used. To define optimization of medical therapy, an assumption was made that at least 2 antianginal drugs constituted a pragmatic clinical definition of “optimal medical therapy,” as described in COURAGE.19

Two different formats were used to summarize the voting results. An algorithmic or decision-tree approach was chosen for the ACS indications, while a matrix method was chosen to summarize the SIHD portion.

**USE OF THE AUC AS A REPORT CARD**

A multicenter, prospective study of all PCI patients within NCDR undergoing PCI between July 1, 2009, and September 30, 2010, at 1091 US hospitals was undertaken.14 The appropriateness of PCI was adjudicated using the AUC. Of 500,154 total PCIs, 355,417 (71.1%) were for ACS (STEMI, 103,245 [20.6%]; NSTEMI, 105,708 [21.1%]; high-risk unstable angina, 146,464 [29.3%]), and 144,737 (28.9%) were for SIHD. In ACS, 350,469 PCIs (98.6%) were classified as appropriate, 1055 (0.3%) as uncertain, and 3893 (1.1%) as inappropriate. For SIHD, 72,911 PCIs (50.4%) were classified as appropriate, 54,988 (38.0%) as uncertain, and 16,838 (11.6%) as inappropriate. The majority of inappropriate PCIs for SIHD were performed in patients with no angina (53.8%), low-risk ischemia on noninvasive stress testing (71.6%), or suboptimal (≤1 medication) antianginal therapy (95.8%). Furthermore, although variation in the proportion of inappropriate PCI across hospitals was minimal for acute procedures, there was substantial hospital
variation for PCI in SIHD (median hospital rate for inappropriate PCI, 10.8%; interquartile range, 6.0%-16.7%). Overall, the rate of inappropriate PCI was 4.1%; hospitals in the lowest quartile had inappropriate PCI rates of ≤1.73% versus ≥4.62% for the highest quartile hospitals.

The New York State Registry corroborated these findings generally in patients with SIHD. In this mandatory state registry, 14% of PCI patients were found to have inappropriate AUC classification, confirming that a small but definite incidence of inappropriate PCI is not a spurious observation. Furthermore, 28% of all PCIs performed in the state lacked sufficient noninvasive test information to be rated. Most concerning was the relatively low percentage (36.1%) of patients undergoing PCI classed as appropriate by AUC.

Bradley et al evaluated the association between patient selection for PCI and postprocedural outcomes. In 203,531 patients undergoing elective PCI, the association between a hospital’s proportion of nonacute PCIs categorized as inappropriate by the 2009 AUC and in-hospital mortality, bleeding complications, and use of optimal guideline-directed medical therapy at discharge (ie, aspirin, thienopyridines, and statins) was evaluated. When categorized as hospital tertiles, the range of inappropriate PCI was 0.0% to 8.1% in the lowest tertile, 8.1% to 15.2% in the middle tertile, and 15.2% to 58.6% in the highest tertile. Compared with lowest-tertile hospitals, mortality was not significantly different at middle-tertile (adjusted odds ratio [OR], 0.93; 95% confidence interval [CI], 0.73-1.19) or highest-tertile hospitals (OR, 1.12; 95% CI, 0.88-1.43; P = .35 for differences between tertiles). Similarly, risk-adjusted bleeding did not vary significantly (middle-tertile OR, 1.13; 95% CI, 1.02-1.16; highest-tertile OR, 1.02; 95% CI, 0.91-1.16; P = .07 for differences between tertiles) nor did use of optimal medical therapy at discharge (85.3% vs 85.7% vs 85.2% for lowest, middle, and highest tertile, respectively; P = .58). Thus, a hospital’s proportion of inappropriate PCIs was not associated with in-hospital mortality, bleeding, or medical therapy at discharge. This finding suggests PCI appropriateness measures aspects of hospital PCI quality that are independent of operator or technical quality. Therefore, PCI appropriateness and postprocedural outcomes are both important metrics of PCI quality. However, PCI appropriateness was not associated with in-hospital survival.

In a follow-up study, the demographics underlying inappropriate PCI as defined by the AUC were evaluated. Of 211,254 nonacute PCIs, 25,749
(12.2%) were classified as inappropriate. After multivariable adjustment, men (adjusted OR, 1.08; 95% CI, 1.05-1.11; \( P < .001 \)) and whites (adjusted OR, 1.09; 95% CI, 1.05-1.14; \( P < .001 \)) were more likely to undergo an inappropriate PCI in comparison with women and nonwhites. Compared with privately insured patients, those who had Medicare (adjusted OR, 0.85; 95% CI, 0.83-0.88), other public insurance (adjusted OR, 0.78; 95% CI, 0.73-0.83), and no insurance (adjusted OR, 0.56; 95% CI, 0.50-0.61) were less likely to undergo an inappropriate PCI (\( P < .001 \)). In addition, compared with urban hospitals, those admitted at rural hospitals were less likely to undergo inappropriate PCI, whereas those at suburban hospitals were more likely. Thus, for nonacute indications, PCIs categorized as inappropriate were more commonly performed in men, whites, and patients with private insurance. The authors concluded that higher rates of PCI in these patient populations might either reflect potential overuse in privileged patients or underuse in disadvantaged populations. Both are problematic: inappropriate procedures expose the patient to unnecessary risk, while underuse in disadvantaged patient groups leads to disparities in care.

**REACTION TO THE USE OF THE AUC FOR QUALITY ASSESSMENT**

Unfortunately, the AUC and its use as a quality metric have become sources of controversy and dispute. Pervasive media attention was unleashed with publication of the NCDR analysis that labeled 4.1% of PCIs in the United States as “inappropriate.” The media, and much of the lay public, were especially drawn to the finding that 11.6% of nonacute, elective PCIs were classified as inappropriate and, additionally, to the wide variation in the rates of inappropriate nonacute PCI across hospitals (0%-50%). These circumstances led to claims that billions of dollars are being spent on completely unnecessary procedures. Superimposed on widely reported fraudulent behavior on the part of a very few but high-profile PCI operators, widespread concern was raised.

The reaction of the interventional community was to assert that there were 3 problems that rendered the study conclusions incorrect: (1) the NCDR members who contributed the data were unaware that auditing for this
The purpose was ongoing, and therefore, the contributed data were not necessarily accurate; (2) the study results merely reflect the flaws of the AUC and do not capture accurately decision making for revascularization; and (3) labeling procedures performed as “inappropriate” is provocative terminology that is actually incorrect; these procedures likely had indications that were not captured by the AUC. To some extent, each of these criticisms has merit. However, the fundamental finding does reflect quite accurately that PCI is being performed in some SIHD patients for indications outside the evidence base. The critical question raised is whether some of the reasoning employed in clinical decision making went unrecognized in the AUC, altering appropriateness determinations in a substantial number of cases. Although perhaps inaccurate when applied to a small minority of specific, individual cases, given the intention to measure quality, falling inside or outside the normal distribution (95% CI, 3%-25%,) should correctly reflect the overall reasoning of appropriateness used.

LIMITATIONS OF THE CURRENT VERSION OF THE AUC

A large number of cases cannot be classified by the AUC, because either a stress test is not available (50% of unclassifiable cases, 8.5% of all PCIs in the NCDR) or the magnitude of ischemic risk is not documented (42% of unclassifiable cases, 7.2% overall). This high percentage of unclassifiable cases threatens the accuracy of the process and represents a loophole in the methodology. The utilization of the terminology “inappropriate” connotes not merely the lack of supportive evidence but rather the presence of negative studies, which was not true in many of the scenarios graded by the technical panel. Moreover, the technical panel conceived “inappropriate” as being related to specific clinical trial evidence of improved mortality and not to the more difficult to objectify measures of improved quality of life and other symptomatic benefits. The “uncertain” classification may also indicate a meaning at odds with its intent: that the appropriateness could not be definitively classified within existing medical knowledge or the current structure of the AUC. The high rate of uncertain indications for elective PCIs
(38%) suggests that more research is needed to clarify the benefits of PCIs for those patients. To clarify these meanings, the AUC nomenclature will be changed going forward: “uncertain” is now described as “may be appropriate” and “inappropriate” as “rarely appropriate.”

The current PCI AUC are matrix based, which sets a few variables as critically important and not modifiable by other factors known to be influential in actual practice, such as age, patient preference, and desire to improve quality of life. The rigid grading system based on just a few criteria that labels a substantial number of procedures as “inappropriate” even when extenuating circumstances may exist, despite the possibility that additional clinical information not captured in the SIHD matrix may be critically important, may lead to incorrect appropriateness assessment.24 Each patient poses a distinct set of variables to consider, and the overlapping indications and conflicting caveats may reasonably result in disparate decision making, depending on one’s emphasis. Some inappropriate or uncertain indications may actually be appropriate, and some appropriate indications may be inappropriate, when taking into account unique clinical and patient factors.

Reliance on the presence and size of stress test imaging modalities, which are not quantitative methods, to evaluate the amount of myocardium at jeopardy, to the exclusion of the coronary angiogram, has raised numerous concerns.8,23,25 Nuclear and echocardiographic stress tests are not quantitative methods and may be inaccurate in particular circumstances; for example, with multivessel disease, with prior infarction, and when target level of physiologic stress is not achieved. Although based on the nuclear substudy of COURAGE,9 the elevation of a retrospective association between outcomes and the size of thallium defects to the level of being the final arbiter of the volume of myocardium at jeopardy and hence, appropriateness, exceeds the authors’ intent and interpretation.26,27 The angiographic demonstration of a 90% proximal stenosis in a dominant right coronary artery is a more accurate assessment of myocardial jeopardy than a “small” inferior defect. In contemporary intervention, the use of fractional flow reserve (FFR) in ambiguous scenarios is now regarded as best practice. The amount of myocardium at jeopardy as assessed angiographically and the use of FFR to assess stenosis severity will very likely be recognized as the gold standards in the next version.24,28 Moreover, with the increasing utilization of coronary computed tomography angiography to detect stenoses noninvasively, it may
be anticipated that stress testing will be less utilized diagnostically in the future.

One of the most controversial aspects of the AUC process is that just 4 of the 17 technical panel members were interventional cardiologists. Marso et al. suggested that the composition of the technical panel likely impacted the AUC ratings significantly. In a follow-up study evaluating concordance with the AUC, most physicians agreed with most of the ratings; however, there was substantial variability. In one particular scenario, that of patients with less than 3-vessel disease with minimal symptoms and on <2 medications, there were significant differences with the AUC voting. This discrepancy exists because mortality is the primary clinical benefit evaluated in clinical trials and was the main outcome considered by the technical panel; future iterations should include consideration of angina relief and quality of life, which are outcomes in which PCI offers substantial advantages.

Most of the acute cases that were labeled as inappropriate by AUC criteria were STEMI patients who were registered as stable and asymptomatic and had PCI performed >12 hours from symptom onset. In SIHD, the majority of inappropriate PCIs occurred in patients who had 1- to 2-vessel coronary disease that did not involve the proximal left anterior descending artery, were on no anti-ischemic therapy, had no or mild angina symptoms, and had low-risk noninvasive studies for ischemia.

A general list of 10 ways to improve a catheterization laboratory’s or operator’s appropriateness score is given in Table 66-1. In particular, it should be recognized that the vast majority of inappropriate scores occur when the patient is taking <2 antianginal medications, has no or low degree of ischemia, and/or has no angina.

Table 66-1 Ten Ways to Improve Appropriateness

| • Study your cases classified as inappropriate or uncertain to determine why each case was scored as it was. |
| • Know the 5 clinical scenarios responsible for 89% of inappropriate elective cases and especially the 3 scenarios describing 82%: none or few symptoms, normal or low-risk stress test, and ≤1 antianginal agent. |
| • Make sure whoever is responsible for coding is filling in the forms correctly, by prospective review, retrospective audit, and ongoing |
education. Take filling out the forms seriously and take ownership of the process.

- Know the Canadian Classification of angina, especially the difference between class II and class III.
- Use medical therapy when appropriate; 2 or more antianginal drugs put the case in a higher category; 96% of inappropriate cases do not use ≥2 drugs.
- State the stress results concisely and clearly in the documentation.
- Know and include data from outside hospitals.
- Use fractional flow reserve in borderline lesions.
- Use the Appropriate Use Criteria for Revascularization in your practice in real time and teach it in educational conferences.
- Recognize the proven value, and the limitations, of percutaneous coronary intervention in clinical practice: Know the evidence base, follow the guidelines, and recognize exceptions without hiding behind them to rationalize when you do not follow them.

With widespread dissemination of this material and the development of tools within most catheterization laboratories to assure adherence, it is unclear whether the AUC still accurately measures appropriateness. The possibility of “gaming” the criteria and the absence of a requirement for strict documentary proof in classification are loopholes of great concern. Another concern is that some PCI in multivessel SIHD is performed after surgeons have declined to operate out of apprehension for high risk, a condition that is not captured in the NCDR.

There is also increasing concern that the AUC as formulated have never been linked to outcomes, as described earlier, even though the original concept was linked to outcome. A recent study from a single institution did not link PCI appropriateness, as determined by the AUC for coronary revascularization, with 30-day or 1-year outcomes. In a cohort of non-ACS patients including 3817 patients in their analysis, 47% (n = 1494) of the cases were considered appropriate, 1.8% (n = 54) were inappropriate, and 51% (n = 1604) were uncertain. Despite similar procedural complications in the 3 groups, a significantly higher rate of in-hospital complications was observed in the inappropriate PCI group (inappropriate, 11%; appropriate, 1.9%; uncertain, 2.4%; $P < .001$). However, this did not translate to a higher rate of
major adverse cardiac events at either 30 days (inappropriate, 7%; appropriate, 3.2%; uncertain, 4.1%; \(P = .32\)) or 1 year (inappropriate, 11.8%; appropriate, 13.1%; uncertain, 15.3%; \(P = .32\)). In multivariable analysis, no associations were observed between procedural appropriateness and either inhospital or 1-year outcomes.

### ADDITIONAL APPROACHES TO APPROPRIATENESS: SCORECARDS AND BENCHMARKING

There have been public reporting and scorecard systems in place in various states for many years. The development of the “Hospital Compare” and, more recently, the “Physician Compare” websites has further expanded public reporting for hospitals and providers. It has never been studied objectively whether these modalities alter referral patterns or incentivize patients away from less expert centers or individuals, and there have been questions raised as to what is their purpose. Although no one can criticize the right of consumers to know more about the person and program to whom they are placing their lives in trust, it is doubtful that the average person comprehends the nature of risk assessment or how to use the figures reported to make rational choices.\(^{31}\) Most lay people, often including hospital administrators, believe that the highest quality operator will have zero mortality, not realizing that adverse outcomes are in fact primarily influenced by high-risk case selection, not competence. The “optimal” goal actually should be in the mid-range of risk-adjusted events.\(^{11}\) Accordingly, there is concern that public reporting impedes the aggressive use of PCI in high-risk but appropriate cases with patients who have no other reasonable options, yet underutilization in these patients is not usually conceived as a significant problem.\(^{32}\)

The NCDR CathPCI Registry, in its quarterly reports to participants, assesses AUC in PCI procedures and benchmarks these to a national reference point.\(^{33}\) The major message from the initial experience is that the indication for every PCI case, particularly those in nonacute clinical scenarios, should be carefully considered and scrutinized. Programs and operators need to be attentive to appropriate documentation of the patient
symptom complex, presentation, ischemic evaluation, anatomy, and whether the patient is on optimal medical therapy.

Duffy\textsuperscript{34} has proposed equating “real value” with appropriateness (Table 66-2). He suggests that appropriateness as currently described is just 1 factor that expresses the value of PCI; the others include clinically defined outcomes, patient-expected outcomes, and relative cost. The fact that a number of factors of great importance in clinical decision making (patient age, comorbidities, patient wishes, cost, ability to take medications, and the risk of the procedure) are not considered in the AUC is cited as a flaw. Defining the “real value” of a procedure would be the preferable route (see Table 66-2).

Table 66-2 Value: New Criteria of Appropriateness

| • How much does the benefit of this procedure (or approach to care) outweigh the risk? |
| • How much will this person’s quality of life improve? |
| • How much will it reduce long- and short-term morbidity (future complications)? |
| • How much will it extend this person’s life expectancy with the quality of life anticipated? |

Nallamothu et al\textsuperscript{35} recently developed a set of performance measures dedicated to PCI focused primarily on elective PCI. They include both accountability measures, which are acceptable for public reporting and for facilitating comparisons across providers, and quality improvement measures, which are intended to drive internal quality improvements. The 4 quality measures include the need for an appropriate indication for elective PCI, based on the AUC. The 7 performance measures involve comprehensive documentation before and after the procedure of variables associated with improved short-term outcome.

**IMPLICATIONS FOR**
Reimbursement for revascularization will likely soon be dependent on its appropriateness, which will be assessed using the AUC or a close modification. Since the AUC and its structure were never intended as a means to determine payment for procedures, there is substantial trepidation within the interventional community over its application for this purpose. Whether or not criteria originally intended for quality assessment and professional improvement can be transferred and accurately used for denial of payment is unexplored. Moreover, as pay-for-performance and other connections between quality and reimbursement are advocated and developed, the flaws in the AUC, which were understandable in a first version, could result in incorrect assessments of operator quality, with significant repercussions for all involved. When the AUC were initially developed, the intention was for application to broad quality assessment; the determination in a particular case was less critical than whether the overall performance of an operator or a laboratory was within 2 standard deviations of the mean. If the AUC did not adequately capture the reasoning for a particular procedure, although annoying, it had no important consequence, but that would no longer be apposite if third-party payers can disallow payment because of an inconsistent stress test result or a low class of angina.

The widespread apprehension is whether, after creating an inflexible matrix of factors that define appropriateness, there is sufficient room in their interpretation to game these criteria and diminish their discrimination (eg, size of stress test defect or number of antianginal medications). The fear all along has been whether physicians, who understand very well the vagueness of such indicators, will continue to be objective in reporting them, recognizing that reimbursement depends on the answers. But further, if the appropriateness decision is made by a person whose job is to find ways to save expenses for a third-party payer, could this vagueness be gamed by insurers and used as an excuse to deny payment even when PCI was appropriate, a fear complicated when administrative rather than medical databases are used to obtain these data.

In 2013, the New York State Medicaid Fee for Service and Medicaid Managed Care disallowed payment for elective cases categorized as rarely appropriate. New York State is also planning a retrospective analysis to
provide the foundation for requesting repayment for cases deemed “inappropriate” performed prior to that date based on the state’s interpretation of the AUC. Payments would be recouped before any medical review is conducted. Analysis would be based on the state’s administrative database and its own algorithm. These initiatives may be just the first step in which the AUC is used by regulatory agencies to link payment to appropriateness.

The Centers for Medicare & Medicaid Services (CMS) has announced a new Recovery Audit Contractor demonstration program to assess whether Medicare payments are going toward procedures that are medically appropriate and necessary.37 This program was implemented in 11 states for a 3-year period starting January 2012. The program is an attempt to revise the current “pay and chase” model of tracking down improper Medicare payments after the fact. The theory is that the most effective way to limit the amount of taxpayer dollars lost to improper payment is to review the medical record and other supporting documentation for the claim before the billing is paid. To date, CMS has given no details as to what “medically appropriate and necessary” criteria they use, whether it is based on the current published guidelines, including the AUC, or a formula of their own choosing.

FUTURE DIRECTIONS

Evaluating the procedural appropriateness of PCI is a complex undertaking requiring comprehensive patient assessment and documentation. The expected benefit associated with all 3 of the available therapeutic approaches varies widely from patient to patient, and a fundamental part of the physician’s job is to determine—based on clinical experience and a grasp of the current medical literature—which treatment is most appropriate for the patient at hand. Moreover, the benefits are usually not homogeneous throughout every population. Even if studies show that a procedure is beneficial for an overall study population, the benefit may be large for some subgroups and negligible (or even harmful) for others. How to incorporate these factors into a quality metric is problematic.

Table 66-3 summarizes the myriad considerations that should go routinely into decision making for revascularization. Although it is probably impossible to construct a decision tree or algorithm that covers every conceivable situation, future iterations of the AUC must do a better job...
simulating the decision making process in order that the physician’s judgment and the patient’s desires and best interests are placed in the forefront. In this regard, the concepts of “value” and “cost-effectiveness” may add significantly to the resolution of the controversy. The most important appropriate use approach is complete and accurate communication of potential risks and benefits of a particular procedure. Clinical judgment and comprehensive patient communication should always be the guide. There will be times when what is best for the individual patient is at variance with AUC and other guidance documents, and future versions of the AUC should incorporate this understanding in its structure.

Table 66-3 Factors Influencing Revascularization Appropriateness

1. Documentation of the presence and anatomic severity of coronary stenosis (angiography, intravascular ultrasound)
2. Correlation with physiologic metrics of stenosis severity (stress testing, fractional flow reserve)
3. Presence, recent changes, and severity of anginal symptoms
4. Triggers of angina
5. Utilization of antianginal medications
6. Prior coronary artery bypass graft or percutaneous coronary intervention?
7. Patient age and activity/stress levels (eg, frailty)
8. Exercise duration
9. Comorbid conditions/life expectancy
10. Complete versus incomplete revascularization
11. Risk of the procedure
12. Does the patient want/is patient able to try medications first? (ie, expected patient compliance)
13. What are the patient’s short- and long-term goals of therapy? (eg, elderly)
14. Which outcomes/benefits can be anticipated? (eg, survival, improved quality of life, diminished angina, less congestive heart failure, presence of viable myocardium, or substantial myocardium at jeopardy)
CONCLUSIONS

The importance of the AUC to the future of public health policy and the role of PCI in treating CAD cannot be overstated. There is increasing recognition by most members of the interventional community that the long-time reliance on operator volume and complication rates as the sole criteria for PCI quality promoted unprecedented growth and expansion, but also resulted in unanticipated negative consequences, including high cost with little population-level outcome benefit, especially in SIHD. Additionally, overutilization by a few ethically challenged individuals superimposed on the unavoidable ambiguity of appropriate case selection and formal indications resulting from continually improving technology, greater technical experience, and limitations in trial design has, understandably, raised serious questions by those who pay for the procedures. The ongoing delay in establishing and standing by criteria for appropriateness creates a vacuum that outside organizations now threaten to fill, by developing their own criteria to regulate the field. Moreover, given the lack of confidence in the current AUC, CMS and other agencies have attempted to define appropriateness, but thus far, these have been mainly superficial and primarily economically inspired. Future versions of the AUC will hopefully successfully address these complex and critical issues.

The vast majority of PCIs are performed in patients who meet criteria that suggest potential benefit based on the existing evidence base. However, the data also show that there are opportunities to improve patient selection for PCI, as well as to design future studies that evaluate outcome benefits of PCI other than mortality and provide objective evidence that properly impacts clinical decision making. Reversing our failure thus far to develop and faithfully implement a system that accurately evaluates interventional decision making and that is truly focused on improving outcomes for our patients is the single most pressing challenge we face. How our profession responds will characterize our field for years to come.

Note: After submission of this chapter a new update to the AUC was issued and the revised chapter will reflect these changes in the online version of this book. Among the changes are new nomenclature for classification: appropriate, may be appropriate and rarely appropriate. Also a new panel was assembled to vote on classification resulting in fewer scenarios falling into
the rarely appropriate category.\textsuperscript{38}

**MULTIPLE CHOICE QUESTIONS**

1. A 64-year-old man presents to the emergency department with a history of chest pain that began 2 days ago and has now been worsening for the past 3 hours. Electrocardiogram (ECG) shows ST elevations in leads II,
III, and aVF and ST depressions and T inversions in V₁ to V₃. The patient is taken to the cath lab immediately and found to have a 100% occlusion of the right coronary artery, a 70% stenosis of the first obtuse marginal (OM1) branch, and an 80% stenosis of the proximal left anterior descending artery (LAD). The occluded right artery is stented successfully. The operator then proceeds to stent the LAD and OM1 branches. How would the appropriateness of the interventions on the nonculprit lesion be classified?
A. Appropriate
B. May be appropriate
C. Rarely appropriate
D. Indeterminate

2. A 72-year-old man with hypertension and hypercholesterolemia presents with stable angina for 3 months. He is able to walk 3 blocks before getting tired. ECG shows Q waves inferiorly. Medications include aspirin, a β-blocker, and a statin. A stress test shows a fixed inferior defect. Cardiac catheterization shows a 100% occlusion of a very large OM branch filling by collaterals from a diagonal and no other significant disease. The ejection fraction is 45% with an akinetic inferior wall. PCI and stenting of the OM is successful. At 1-month follow-up, the chest pain syndrome has resolved. How would the appropriateness of this procedure be classified?
A. Appropriate
B. May be appropriate
C. Rarely appropriate
D. Indeterminate

3. A 58-year-old attorney presents with severe chest pain that occurs only when he is in court. He is able to play racquetball at his club and golf on the weekends without limitation. He smokes 1 pack per day, has hypertension, and has never had a lipid panel checked. He takes a baby aspirin but refuses to take β-blockers due to erectile dysfunction or nitrates due to headache. Stress nuclear test shows ischemia, with an intermediate risk defect of the anteroapex. Coronary angiography shows a proximal 80% stenosis before the first septal branch and minimal nonobstructive disease in other segments.
Part 1: If a stent was placed, how would the appropriateness of this procedure be classified?
   A. Appropriate
   B. May be appropriate
   C. Rarely appropriate
   D. Indeterminate

Part 2: If fractional flow reserve was performed and was calculated to be 0.78, then how would the appropriateness of stenting be classified?
   A. Appropriate
   B. May be appropriate
   C. Rarely appropriate
   D. Indeterminate

4. An 85-year-old nondiabetic man presents with mild edema consistent with congestive heart failure. He has no chest pain or exertional symptoms. An echocardiogram shows an ejection fraction of 40% with global hypokinesis and moderate mitral insufficiency. The ECG shows left bundle branch pattern. After diuresis and vasodilator therapy are initiated, he improves significantly. Coronary angiography shows significant obstructive disease of all 3 arteries amenable to either stenting or bypass surgery. Which of the following statements is NOT true?
   A. He is not an optimal candidate for coronary artery bypass graft (CABG) due to his age and decreased cardiac function; therefore, multivessel PCI is preferred.
   B. If his SYNTAX score is not low, CABG is a preferable option.
   C. There is insufficient information given to decide on which revascularization strategy, or optimal medical therapy, is best.
   D. There is no rationale to performing a stress test, since it will be highly abnormal, confirming the findings of the angiogram.

5. A 55-year-old man presents with a history of experiencing a single episode of chest pain while on a 30-mile bike ride with friends and family this past weekend and has had no symptoms since then. He has no risk factors and is in excellent health. An ECG shows nonspecific ST changes. He is taken immediately to the cath lab and found to have a 90% mid-LAD coronary stenosis, which is stented. How would the appropriateness
of this procedure be classified?
A. Appropriate
B. May be appropriate
C. Rarely appropriate
D. Indeterminate

ANSWERS

1. C
Nonculprit lesion percutaneous coronary intervention (PCI) at the time of ST-segment elevation myocardial infarction (STEMI) in the absence of hemodynamic compromise is classified as rarely appropriate by the Appropriate Use Criteria, which were developed before Preventive Angioplasty in Acute Myocardial Infarction (PRAMI).

2. C
This patient has no stress test, is not on at least 2 antianginal medications, and is asymptomatic. Performing PCI of a chronic total occlusion in this setting cannot be rationalized.

3. Part 1: B; Part 2: A
It is not possible to know if PCI is warranted based only on the angiogram, according to the Appropriate Use Criteria, since maximal medical therapy has a high likelihood of treating symptoms in this setting. Since this is a proximal LAD stenosis, it would be considered as “may be appropriate.” However, when the fractional flow reserve is performed and shows the lesion to be significant, then stenting is appropriate.

4. C
Age alone does not exclude a patient from candidacy for CABG if frailty, either mental or physical, does not exist. A low SYNTAX score signifies that either PCI or CABG may be reasonable. One can not intuit the findings of a stress test from the coronary anatomy alone since the stress results also integrate medical therapy, exercise tolerance, and conditioning. Either PCI or
CABG may be reasonable in this patient, and medical therapy may also be a judicious strategy if this patient is not an optimal candidate for dual antiplatelet therapy or a surgical procedure.

5. D

It is not possible to know if the stenosis is or is not significant based only on the angiogram, according to the Appropriate Use Criteria. A stress test is required, or it cannot be classified. Even a 90% angiographic finding is insufficient, according to the Appropriate Use Criteria.
Part VII  Preclinical and Clinical Trials

- 67 Preclinical Laboratory Functions
- 68 Cell Therapy for Cardiovascular Diseases
- 69 The Core Laboratory: Quantitative Coronary Angiography
- 70 Reading Clinical Trials
- 71 Publishing Interventional Cardiology Research
Although innovators brainstorm ideas for novel therapies often while working in the clinical setting, these ideas see the earliest translation into reality in the preclinical laboratory. The goal of the preclinical lab is to provide hands-on testing in the animal model to guide focused revisions of a new device or treatment. This is the realm in which devices and treatments move beyond basic prototype, into early versions of an eventual finished product for clinical use in patients. These early versions get tested, revamped, and retested, with the goal of evaluating feasibility, safety, and efficacy. The preclinical lab is also a common ground where interventional cardiologists, engineers, veterinarians, scientists, and industry can meet to collaborate.

The goal of this chapter is to review some of the important requirements of a preclinical laboratory and suggest insights into what makes a preclinical lab successful in the current landscape of translational cardiovascular research.

**HISTORICAL FOUNDATIONS OF THE INTERVENTIONAL PRECLINICAL LABORATORY**
Although animal studies have historical roots over millennia, the field of interventional cardiology and the vital role of the preclinical interventional cardiology lab can be directly traced back to Andreas Gruentzig, the first interventional cardiologist. Gruentzig developed percutaneous coronary balloon angioplasty, building on the work of Mason Sones, Charles Dotter, and Melvin Judkins. In 1958 during an aortogram, Mason Sones inadvertently cannulated and performed an angiogram of the right coronary artery, ultimately demonstrating the diagnostic potential of coronary angiography.

Subsequently, Charles Dotter in 1963 inadvertently recanalized an occluded right iliac artery when he was obtaining access to the abdominal aorta for an aortogram in a patient with renal artery stenosis, demonstrating the potential for transluminal angioplasty. In 1964, Judkins (Dotter’s trainee) and Dotter conducted the first intentional and successful transluminal angioplasty of a short superficial femoral artery stenosis for a patient with a gangrenous toe and nonhealing ulcer who refused surgical intervention. After learning the Dotter technique, Gruentzig added balloons to the Dotter catheters (ultimately iterating until he developed a polyvinylchloride-based double lumen catheter). Between 1972 and 1975, he performed peripheral balloon angioplasty in animals and then transitioned to humans. By 1976, Gruentzig had revised his device to a size appropriate for coronary intervention and continued to demonstrate feasibility, safety, and efficacy of his prototype in the preclinical lab. Specifically, Gruentzig performed a partial ligation of the circumflex artery via thoracotomy in a canine model. He then performed angiography to demonstrate the stenosis as well as to measure the transstenotic pressure gradient. He positioned his balloon at the stenosis and intervened on it by inflating the balloon until he broke the ligature, ultimately resolving the stenosis and the transstenotic pressure gradient. These results were presented at the American College of Cardiology meeting in 1976 in Miami, Florida (Fig. 67-1). By 1977, Gruentzig successfully performed the first human use of coronary angioplasty in a 38-year-old patient with focal, proximal left anterior descending artery stenosis in the setting of unstable angina and positive stress testing. This constituted the invention of the field of interventional cardiology as we know it today, demonstrating the vital role of the preclinical lab.
Since that time, the preclinical interventional cardiology lab has become a mainstay in the vertical integration of the device-based innovation process. The flow from idea to engineering to bench top testing to reengineering to animal lab testing to reengineering and finishing with further animal lab testing was demonstrated by Gruentzig; it has since flourished worldwide.

With foundations in the preclinical lab, many significant device-based contributions to the field of cardiovascular medicine have been developed, ranging from vascular, to hemodynamic, to structural, to electrophysiologic. Given the continuously evolving field of invasive cardiology and the ethos of innovation in the field, preclinical labs have had to evolve in lock step with technologic advancement. For example, some preclinical labs have been focused mainly on coronary disease models, and their accompanying diagnostics and interventions. However, with the rise in structural interventions such as transcatheter aortic valve replacement, mitral interventions, and ventricular assist devices, the expertise of the lab must
evolve to meet the demands of both the new disease models and the new diagnostics/therapeutics to be assessed.

ENVIRONMENT FOR THE INTERVENTIONAL PRECLINICAL LABORATORY

There are currently a number of preclinical interventional cardiology labs across the world. Most either currently operate within or had roots in the academic medical setting. Given the interdisciplinary demands of the type of work done in the interventional cardiology preclinical lab, the academic environment is naturally conducive to it. Innovators can brainstorm with colleagues from different specialties and capitalize on diverse expertise by collaborating across different departments, such as engineering and chemistry. Additionally, university-based administrative groups can assist with management of regulatory issues and contracts.

However, the infrastructure and often bureaucratic nature of the academic setting has not traditionally been designed to function optimally under conditions in which entrepreneurial hands are involved. Specifically, most academic settings have not evolved to provide services to those who comprise the majority of “customers” to the interventional cardiology preclinical lab—often small and large industry partners.

The goal of research sponsored by industry is to generate data in their research and development path, often focused on feasibility, safety, or efficacy. For example, an innovator backed by a small corporate sponsor may have a novel mitral annular repair device that they bring to the preclinical lab for proof-of-concept testing in animals; then after device improvements, they return for further efficacy and safety testing in animals. The generated safety and efficacy data are used for submission in the United States to the Food and Drug Administration as part of an Investigational New Device filing.

With these types of research goals, there are 3 main hurdles that often arise for the typical party wanting to perform translational research in the academic preclinical lab: (1) costs (institution-wide overhead/indirect costs), (2) contractual obligations (intellectual property and publication rights), and (3) regulatory obligations (extended timing for regulatory approval of animal
studies). For example, to investigate the feasibility of a new percutaneous ventricular assist device in a swine systolic heart failure model, an inventor may be burdened with a 50% overhead/indirect cost to the university, may have to sign over all intellectual property and publication rights from the research, and may sink months of time attempting to obtain Institutional Animal Care and Use Committee approval to start the experiment. Although the lab may be incentivized to be involved with cutting edge work, the infrastructure in this example is burdensome. Although some academic centers understand the importance and benefits of such research and are devising new means to accommodate research needed by corporate entities, many are either unable or unwilling to make the necessary adjustments.

Given the practical demands of device development in the United States, the academic interventional preclinical lab requires 3 interconnected types of outputs to thrive and be sustainable: academic, teaching, and industry. While these outputs ideally function together seamlessly, a tailored infrastructure is required to ensure that each aspect is prioritized. If a laboratory’s aim is only academic output, then it is dependent on only traditional and shrinking funding sources for survival. If only industry output is focused on, then the ethos of the lab may be lost. Additionally, as adapted from Suzuki et al, the role of the animal lab should be not only in device development but also in training clinicians in optimal techniques involving new procedures. This diversified approach allows for financial sustainability and academic creativity; however, achieving this trifecta is not an easy task. Academic preclinical labs must face the growing competition of preclinical labs based at independent research institutions, which often have streamlined systems in place to accommodate the accelerating demands of the modern preclinical lab customer. Such environments can be designed to prioritize the needs of the biomedical device, pharmaceutical, and biotechnology industries, while maintaining high academic standards.

**FACILITIES AND EQUIPMENT**

With advances in interventional cardiology spanning vascular to structural disease as well as expansion into hybrid procedures with surgical colleagues, there now exists both a new minimum requirement for preclinical labs as well as opportunity for specialization depending on the research goals of the
institution. Overall, the appearance of the preclinical interventional laboratory resembles that of a clinical cardiac catheterization laboratory. In terms of the various levels of diagnostic capabilities required, this can be preliminarily categorized into vascular versus structural work.

At a minimum for vascular work, a large-animal cardiac catheterization suite is needed, because the core of translational research in our field is the testing of interventional vascular devices and associated drug or biotechnology therapies in clinically relevant, large-animal preparations. Fluoroscopy remains the primary method of imaging for angiography and experimental intervention. For intraluminal assessment, quantitative coronary angiography (QCA) is a basic tool for accurate vessel measurement in the sizing of stent implants and angioplasty balloon catheters. Comprehensive hemodynamic assessment must be possible in order to perform diagnostic evaluation of catheterization procedures but also for basic safety requirements. This includes measurement of left- and right-sided cardiac pressures and cardiac output. Other ancillary equipment items such as activated clotting time (ACT) machines, infusion pumps, and similar apparatus may seem like minor details, but are necessary for a fully functional lab. Figure 67-2 shows a typical preclinical catheterization laboratory.
For structural work, although not previously a mainstay in all preclinical labs, echocardiography is now an essential adjunct both for the analytical assessment of cardiac function and dimensions and as guidance for catheter-based procedures such as endoventricular intramyocardial injection. There are important roles for the various echocardiographic modalities: intracardiac echocardiography (ICE) offers a unique viewpoint from within the cardiac chambers that can assist in real-time navigation during intervention; transthoracic echocardiography (TTE) offers guidance and monitoring of cardiac structure and function before, during, and after an intervention; and transesophageal echocardiography (TEE) offers similar guidance but with enhanced views and resolution. Although less used these days, ventriculography and its associated hardware and software needs are still a requirement. The addition of hardware and software for pressure-volume loop analysis is an additional tool that can help quantify physiologic impacts of interventions throughout the cardiac cycle. Additional newer technologies that provide insight into the performance of intravascular devices and the nature of the vessel wall include intravascular ultrasound (IVUS), optical coherence tomography (OCT), and near-infrared (NIR) spectroscopy. Although not a requirement, the data obtained using these methods can help to differentiate the value of new technologies in the maturing market of intravascular interventions. Finally, magnetic resonance imaging (MRI) and computed tomography (CT) imaging can be of incredible utility if there is a dedicated program to optimize the output from these diagnostics. For example, MRI with contrast agents such as gadolinium or manganese can be used to assess structure, function, pathology, and benefits of interventions, such as stem cell implantations. With advances in hybrid structural procedures, a hybrid suite with dual surgical and interventional capabilities will likely become a necessity in the near future. Figure 67-3 shows a typical preclinical surgical suite, and Figure 67-4 shows a typical preclinical MRI suite.
FIGURE 67-3 Preclinical surgical suite.
Additionally, there are a number of other resources that may be needed based on the device being tested. In the academic setting, these can often be found via interdisciplinary collaboration; a prearranged setup is ideal. To analyze tissue/devices postmortem in the preclinical lab, the ability to prepare, process, analyze, and capture the histologic analysis digitally is necessary. Histologic evaluations of blood vessels, myocardium, and other tissues implanted with devices or other experimental treatments frequently
provide critical data in preclinical research studies (Fig. 67-5).

**FIGURE 67-5** Histology of stented arteries. A. Portion of plastic-slide histotechnology laboratory: (1) water bath; (2) Leica heavy-duty microtome; (3) slide review station; (4) Exakt precision grinder. B. Light microscopy of hematoxylin and eosin–stained methacrylate section of pig coronary artery fixed 1 month after implant of polymer-coated metal stent; remnant of polymer coating (arrows) is seen in stent-strut void (S).
Finally, there are a number of specific intervention-based diagnostic and therapeutic competencies that are required based on the trajectory of the specific preclinical lab. These may include capabilities to evaluate device or vessel thrombogenicity and vasomotor reactivity, assess biochemical components, perform cell and tissue culture, determine gene expression patterns, and potentially fulfill other research needs. One particularly timely example is with regard to the development of stem cells for post–ST-segment elevation myocardial infarction implantation in the left ventricle. Additional core competencies to achieve this will be required on the basic science side. In addition, specific equipment, such as guiding catheters to navigate the ventricle, will also be required. Each of these facilities and equipment requirements are unique to the particular analytic approach; the extent to which they are required depends on the degree of sophistication applied to the study design.

It is important to realize that especially since the preclinical lab interfaces with earlier stage research than the technology used in the clinical lab, it must constantly and aggressively adapt to meet the advancing needs of the innovative research investigator.

**PERSONNEL**

One of the most important aspects of a successful preclinical lab is the staff who run it. The ideal staff are hard-working problem-solvers who are smart, experienced, dedicated, and enthusiastic. The culture of the lab is set by the senior staff who run it, so the selection of these people cannot be underestimated. The current competitive environment of device development demands that a “customer service” approach is taken; otherwise, innovators need not hesitate to select competitor preclinical labs. The reputation of a lab is also paramount. Many researchers will select a lab to work with based on reports of prior experiences from colleagues, so each encounter, whether small or large, must be approached with the utmost professionalism, responsiveness, and attention to detail.
THE MISSION: CONDUCTING TRANSLATIONAL RESEARCH

The preclinical lab plays an essential role in the translation of idea to usable device for humans. In the current environment of device development, this role is becoming progressively challenging to fulfill. Financial burdens, compliance with federal regulations, finding appropriate personnel, and adapting to the rapidly changing demands of the field are just some of the daily challenges that a preclinical lab faces. However, the mission of the preclinical lab remains of utmost importance: to provide the means to perform translational research, such that ideas can be transformed into new effective treatments to improve the care of patients suffering from cardiovascular disease.

REFERENCES

INTRODUCTION

Ischemic heart disease and heart failure continue to be the predominant causes of morbidity and mortality worldwide. Acute myocardial infarction is the most common cause of heart failure and triggers a series of cellular and molecular changes leading to apoptosis, necrosis, hypertrophy of cardiomyocytes, impaired neovascularization, interstitial fibrosis, inflammation, reduced contractility, and pathologic remodeling.\(^1\) Despite advances in medical and device therapy, hospitalization rates and mortality for heart failure continue to remain high, with 1 in 5 patients dying within 12 months of diagnosis.\(^2\) Medical therapy has centered on the treatment of underlying risk factors and on the initiation of antiplatelet, lipid-lowering, $\beta$-adrenergic receptor, and angiotensin antagonist therapy. Interventions designed to facilitate cardiovascular regeneration were not initially pursued because it was assumed that the adult heart is a terminally differentiated postmitotic organ where the number of cardiomyocytes are established at birth, with no potential for regeneration after damage.\(^3\)

Over the last 2 decades, irrefutable evidence has emerged that challenges these concepts due to the discovery of a population of bone marrow–derived
and resident progenitor/stem cells that promote cardiomyocyte and vascular renewal and proliferation. It is now clear that human cardiomyocytes renew throughout a person’s lifespan at a rate that decreases from 1% annual turnover at age 25 to 0.45% at age 75 years.\(^4\) Regeneration of infarcted myocardium requires massive cell replenishment, possibly in the order of a billion cardiomyocytes together with functional integration with supporting cell types.\(^5\) The adult heart, however, has a relatively low number of cardiac progenitor cells with a low proliferation rate that cannot compensate for the large losses of cardiomyocytes seen after an acute myocardial infarction. Cell-based therapies offer a novel strategy to repair and regenerate injured and nonviable cardiac and vascular tissue.

In the past decade, there has been an influx of clinical trials investigating the safety and efficacy of both autologous and allogeneic stem/progenitor cells for cardiovascular repair and regeneration. To date, phase I and phase II cell therapy trials have been conducted in patients with refractory angina pectoris, acute myocardial infarction, ischemic and nonischemic heart failure, and peripheral vascular disease. While a variety of cell types and delivery techniques have been used, the majority of clinical trials have used a catheter-based approach to target delivery of cells to areas of ischemia or dysfunction. Herein we will review potential mechanisms of action of stem cells, mechanisms of cellular delivery, and cell types currently being studied for cardiovascular regeneration, and review ongoing clinical trials. Characteristics of stem cells being investigated in cardiovascular cell therapy are summarized in Table 68-1.

Table 68-1 Characteristics of Stem Cells Used in Cardiovascular Cell Therapy
MECHANISMS OF ACTION

Mechanisms by which cell therapy leads to cardiovascular repair and regeneration remain a subject of controversy (Fig. 68-1). Although differentiation or transdifferentiation into new cardiac or vascular cells was initially believed to be the primary mechanism, recent studies suggest that stimulation of endogenous precursor cells, secretion of growth factors and cytokines (paracrine effect) that promote vasculogenesis and prevents apoptosis, or rarely, fusion of donor cells with host cells may be potential mechanisms. Together, these cellular changes result in enhanced perfusion, reduced infarct size, improved left ventricular remodeling, and ultimately improved cardiac function and patient mortality.
FIGURE 68-1 Potential mechanisms underlying the cardioprotective actions of stem cells: differentiation into cells of cardiac lineages; activation of antiapoptotic signaling; promotion of angiogenesis and reendothelialization; paracrine effects on resident progenitors and myocytes leading to cellular proliferation; and favorable paracrine effects on the extracellular matrix. (Reproduced from Sanganalmath SK, Abdel-Latif A, Bolli R, Xuan YT, Dawn B. Hematopoietic cytokines for cardiac repair: mobilization of bone marrow cells and beyond. Basic Res Cardiol. 2011;106:709-33, with permission from Springer.)

CELL DELIVERY

The main objective of cell therapy is to deliver the ideal concentration of cells needed for cardiac regeneration with the lowest risk to the patient. The clinical setting and underlying cardiac pathology influence local signaling and affect transplanted cell survival and retention. Currently, stem cells can be delivered for cardiac diseases into the coronary arteries or veins, systemically by intravenous injection, or by direct intramyocardial injection using open surgical or transendocardial approaches (Table 68-2).
<table>
<thead>
<tr>
<th>Mechanism</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Cardiovascular Disease</strong></td>
<td></td>
</tr>
</tbody>
</table>
| 1. Intravenous infusion                       | Cells are delivered intravenously. Relies on physiologic homing signals for cells to home to injured tissues.  
*Disadvantages:* Lower level of cell delivery to target areas. |
| 2. Intracoronary artery administration        | Cells delivered directly to myocardial regions via standard angioplasty balloon catheter into coronary artery lumen with either (1) balloon deflated or nonocclusive or (2) stop-flow method using intermittent balloon arterial occlusion. In the stop-flow method, the balloon is placed at the site of the former infarct-vessel occlusion. With the balloon inflated at low pressures for 2 to 4 minutes, 2 to 3 mL of cell suspension is infused. Balloon inflation prevents backflow of cells while facilitating infusion of cells into the infarcted zone.  
*Advantages:* Direct infusion into areas of interest and homogenous cell engraftment.  
*Disadvantages:* Cannot deliver cells into occluded arteries. Large cells may cause embolization of coronary microvasculature. Modest cell retention rates compared to intramyocardial injection. |
| 3. Catheter-based intramyocardial administration | Cells are delivered via a percutaneous catheter either transendocardially or by transcoronary venous injection.  
*Advantages:* Less invasive than surgical injection. Procedure can be repeated over time.  
*Disadvantages:* Increased risk of perforation. |
| 3a. Transendocardial injection                | Injection needle catheter is advanced retrograde across the aortic valve and positioned against the endocardial surface. Often combined with catheter mapping systems to localize delivery to viable, ischemic, or scarred myocardium. |
| 3b. Retrograde transcoronary venous Injection  | Injection needle catheter is advanced into the coronary sinus through the right atrium. Cells are injected directly into the myocardium.  
*Advantages:* Utilizes the venous system. Offers alternative delivery mechanism for patients with occluded coronary arteries. |
| 4. Direct surgical intramyocardial injection   | Cells are injected into infarct border zones or ischemic or infarcted myocardium under direct visualization during open revascularization procedures.  
*Advantages:* Allows targeting of localized myocardium without disturbing surrounding tissue and vasculature.  
*Disadvantages:* Invasive procedure with increased risk to patient. |
| 5. Engineered monolayer tissue transplantation | Cells are mounted on physical scaffolds to enhance cell adherence and survival. Multiple materials are under investigation. Can be implanted epicardially or by myocardial injection.  
*Advantages:* Novel solution to poor cell engraftment and survival.  
*Disadvantages:* Regulatory and rejection hurdles. |
| **Peripheral Vascular Disease**               |                                                                                                                                              |
| Intramuscular                                 | Cells are directly injected into affected muscles of the lower extremity. Goal is to create a collection of cells with paracrine activity in the ischemic area. The fate of injected cells is unknown, and cell retention rates vary between 0.44% and 10% after 4 days. Cells are either injected in a symmetric grid with a fixed number of injections in the ischemic muscle or along the occluded native arteries. The latter approach benefits from preformed collaterals, which have the highest density parallel to the axial arteries.  
*Advantages:* Direct delivery of large numbers of cells to target areas. |
| Intra-arterial                                | Cells are directly injected into occluded arteries of the lower extremity. Target limb arteries were selectively cannulated through a transfemoral approach with an over-the-wire catheter balloon that is advanced as distally as possible and positioned proximal to the occlusive vascular lesions, typically at the distal femoral or popliteal artery. At this point, the balloon is inflated to block antegrade blood flow, and the cells are slowly infused over 3 minutes. After infusion, the balloon is deflated, and antegrade blood flow is restored.  
*Advantages:* Direct infusion into areas of interest and homogenous cell engraftment.  
*Disadvantages:* Difficult to deliver cells to areas subtended by occluded arteries. |
Intravenous infusion of stem cells is associated with the lowest rates of cell retention. Even in the setting of acute myocardial infarction where local release of cytokines enhances homing of stem cells, the majority of intravenously infused cells become trapped in the pulmonary, hepatic, and splenic microvasculature, and few reach areas of infarcted myocardium. Moreover, the size of stem cells affects delivery to target areas, with a greater percentage of larger mesenchymal stem cells (20 μm) being trapped in the pulmonary vasculature than smaller bone marrow mononuclear cells (7 μm).

Intracoronary infusion circumvents the pulmonary and hepatic first-pass effect by delivering cells directly into target areas of myocardium and is the most common strategy used in acute myocardial infarction trials. After over-the-wire positioning of a balloon catheter in the stented area of the infarct-related artery, coronary blood flow is stopped for approximately 2 to 4 minutes by inflation of the balloon at low pressures while the cell product is infused into the coronary artery (stop-flow technique). Mechanistically, cessation of flow maximizes contact between stem cells and the microcirculation of the infarct-related artery and optimizes cellular “homing time”; however, studies have demonstrated conflicting results. Advantages include direct infusion into the infarct and peri-infarct territory, but intracoronary infusion of larger mesenchymal stem cells has been associated with embolization of the microvasculature. Finally, uptake of stem cells into the ischemic myocardium is considerably lower than that achieved by intramyocardial delivery but is better than intravenous administration.

Percutaneous retrograde delivery via the coronary sinus is an alternative method for delivery of cellular products. Although only a few studies have used it for the delivery of stem cells, this technique has been used for many years to deliver cardioplegic solutions during cardiovascular surgery and for protection against myocardial ischemia in patients undergoing high-risk percutaneous coronary intervention. The technique involves placement of a catheter into the coronary sinus via cannulation of either the internal jugular or femoral vein. A single or double balloon is inflated, followed by infusion of the cell product for 5 to 30 minutes at a pressure approximately 20 mL higher than sinus pressure. In comparison to other methods of cell delivery, retrograde coronary sinus delivery appears to be safe, allow for more homogenous delivery across the myocardium, and have similar retention rates to intramyocardial delivery. This technique also allows for delivery of
stem cells to ischemic areas of myocardium in patients with occlusive coronary artery disease and severe subtotal aortic stenosis.\(^{14}\)

Transendocardial injection is performed percutaneously with retrograde advancement of the injection-needle catheter across the aortic valve and positioned against the endocardial surface. Cells are injected directly into the desired endocardial surface by advancing a small-caliber injection needle into the myocardium.\(^7\) Injection sites may be localized to the desired segment of the myocardium by mapping catheter systems. The NOGA injection catheter (Myostar; Cordis Corporation, Miami Lakes, FL) enables 3-dimensional electromechanical mapping of the left ventricle and provides real-time voltage and linear shortening data for delivery of transendocardial injections. In humans, normal regional myocardial function is indicated by high electrical activity and high local linear shortening. The presence of an abnormal or low unipolar potential (≤6 mV) and impaired mechanical activity (low linear shortening ≤4%) is interpreted as abnormal electromechanical activity and characterizes infarcted areas. When mechanical activity is impaired but electrical activity is normal or near normal, the area of interest can represent ischemic, stunned, or hibernating myocardium (Fig. 68-2).\(^{15}\)

Direct intramyocardial cell delivery can also be performed under direct visualization during coronary bypass surgery or using a percutaneous laparoscopic approach (mini-thoracotomy).\(^{16}\) Although these techniques are more invasive and associated with adverse effects, including perforation and pericardial effusion, cell retention is greatest with intramyocardial injection, and higher numbers of cells can be injected without risk of downstream embolization.\(^{17}\) While routinely used in clinical trials in patients with chronic heart failure (Table 68-3), its safety has not been studied in the setting of acute myocardial infarction, where injured myocardium is more vulnerable to rupture.\(^7\)
FIGURE 68-2 Unipolar voltage and local linear shortening maps with the corresponding 2-dimensional quantitative polar maps. Red color indicates the normally low unipolar voltage at the base of the heart (mitral valve area) with concomitant loss of electrical activity at the basal septal and anterior regions and akinesis in the entire septal wall and partial akinesis in the anterior wall. Blue color indicates a normal voltage signal (normal myocardium), whereas green and yellow colors indicate decreased viability and wall motion at the infarct border zone, respectively. The obvious discrepancy between viable myocardium and severe wall motion disturbance in the anteroseptal areas suggests the presence of hibernating myocardium. Brown points represent the locations of the NOGA-guided intramyocardial injections at the border zone of infarction, in diaphragmatic septal areas. LLS, local linear shortening; RAO, right anterior oblique.\textsuperscript{15} (Reprinted by

</table>
Less frequently used methods of delivery include direct surgical intramyocardial injection and engineered monolayer tissue transplantation. Both methods are invasive and require direct visualization of the myocardium. They are summarized in Table 68-2.

### STEM AND PROGENITOR CELLS USED IN CARDIOVASCULAR DISEASES

#### Embryonic Stem Cells
Human embryonic stem cells are pluripotent cells derived from blastocysts that can differentiate into a multitude of adult cells including cardiomyocytes, endothelial, and smooth muscle cells. After aggregation to form embryoid bodies, embryonic stem cells form spontaneously contracting cardiomyocytes within 1 to 4 days. When injected into infarcted rodent myocardium, embryonic stem cell–derived cardiomyocytes regenerated the infarcted myocardium, leading to reduced ventricular dilation and preserved regional and global contractile function. However, their therapeutic use is complicated by immunologic rejection, propensity for teratoma formation, and ethical considerations. The risk of teratoma formation may be mitigated by grafting ex vivo predifferentiated embryonic stem cell–derived cardiomyocytes.

**Induced Pluripotent Stem Cells**

Induced pluripotent stem cells (iPSCs) mitigate the legal and ethical concerns related to embryonic stem cells. iPSCs are somatic cells that have been reprogrammed to express an embryonic phenotype. Seminal experiments by Takahashi and Yamanaka used oct4, sox2, nanog, lin28, klf4, and c-myc transgenes to reprogram adult murine somatic cells into iPSCs with subsequent differentiation into functional cardiomyocytes. Treatment of human iPSCs with activin A and bmp4 can direct differentiation into human cardiac fibroblasts, and injection of these transgenes into murine models of myocardial infarction results in improved cardiac function and adverse ventricular remodeling. iPSCs can also be generated using microRNAs. Mouse fibroblasts converted to the cardiomyocyte phenotype by transfection with microRNAs 1, 133, 208, 499, and JAK inhibitor I expressed cardiomyocyte-specific genes and proteins and exhibited sarcomeric organization, spontaneous calcium oscillations, and mechanical contractions characteristic of cardiomyocytes. Despite these promising results, use of iPSCs in humans has been limited due to concerns over their oncogenicity. Potent oncogenes (c-myc) used for reprogramming, involvement of the p53 pathway, and the epigenetic memory of iPSCs increase their risk for somatic tumor development.

**Skeletal Myoblasts**
Skeletal myoblasts are skeletal muscle precursors that possess a contractile phenotype and are relatively resistant to ischemia and oxidative stress.\textsuperscript{29} Although skeletal myoblasts can differentiate into functionally competent myofibers after engraftment, they suffer a high attrition rate, and only 7.4% of transplanted cells survive at 72 hours.\textsuperscript{30} Surviving myofibers fail to develop intercalated discs and remain electromechanically isolated from host myocardium, which may promote the generation of ventricular arrhythmias.\textsuperscript{31} In human studies, autologous skeletal myoblasts harvested from the quadriceps muscle and cultured in vitro were transplanted using the NOGA-guided catheter into areas of scarred myocardium (unipolar voltage \(<7.0 \text{ mV}\)). Although initial studies claimed benefits, there was an associated increase in arrhythmias (see Table 68-3).\textsuperscript{29,32} The Myoblast Autologous Grafting in Ischemic Cardiomyopathy (MAGIC) trial randomized 97 patients undergoing coronary artery bypass surgery with reduced left ventricular ejection fraction (LVEF; \(<35\%\)) to receive either autologous myoblast injections (4.0 \(\times\) \(10^8\) or 8.0 \(\times\) \(10^8\) cells) or placebo. At 6 months, myoblast transfer did not improve regional or global LVEF compared to controls. While cell therapy was associated with a higher number of arrhythmic events, it did not result in significant differences in major adverse cardiac events.\textsuperscript{16} However, administration of periprocedural amiodarone may be successful in reducing the number of arrhythmic events.\textsuperscript{33}

Bone Marrow–Derived Stem and Progenitor Cells

Ischemic tissue damage stimulates recruitment and homing of endogenous bone marrow–derived progenitor and stem cells via the release of numerous cytokines including granulocyte colony-stimulating factor (G-CSF), stem cell factor, vascular endothelial growth factor, stromal cell–derived factor-1 (SDF-1), and erythropoietin.\textsuperscript{34} Locally derived SDF-1 augments vasculogenesis and subsequently contributes to ischemic neovascularization in vivo by augmenting endothelial progenitor cell recruitment to ischemic tissues.\textsuperscript{35} In addition, the SDF-1/CXCR4 axis regulates progenitor cell proliferation and survival as well as several intracellular signaling pathways.\textsuperscript{36}

Bone marrow–derived stem and progenitor cells are attractive candidates for cell therapy because of their accessibility and renewability. The human
bone marrow houses several progenitor cell populations including hematopoietic stem cells, endothelial progenitor cells, mesenchymal stem cells, and others. The largely paracrine mechanisms underlying the regenerative potential of bone marrow–derived stem/progenitor cells include (1) release of antiapoptotic cytokines that improve survival of cardiomyocytes in the infarct border zone,37 (2) secretion of angiogenic factors that promote angiogenesis and vasculogenesis,38 (3) stimulation of resident cardiac and vascular stem cells,39 and (4) induction of mitosis.40 To date, unselected bone marrow mononuclear cells, selected CD34+ progenitor cells, selected CD34+/CD133+ progenitor cells, and mesenchymal stem cells have been employed in human clinical trials in a variety of clinical settings.

**Bone Marrow Mononuclear Cells**

**Acute Myocardial Infarction**

Several trials have been conducted in patients with acute ST-segment elevation myocardial infarction (MI) using intracoronary infusions of bone marrow mononuclear cells (see Table 68-3). The Transplantation of Progenitor Cells and Regeneration Enhancement in Acute Myocardial Infarction (TOPCARE-AMI) trial was an early randomized controlled trial to demonstrate functional improvement.41 Cells were harvested by bone marrow aspiration and delivered into the infarct-related artery using the stop-flow technique at 4.9 ± 1.5 days after ST-segment elevation MI in 29 subjects, and circulating mononuclear cells were given to 30 controls. After 4 months, LVEF significantly increased (50% ± 10% to 58% ± 10%, \( P < .001 \)), and end-systolic volumes significantly decreased (54 ± 19 mL to 44 ± 20 mL, \( P < .001 \)) without differences between the 2 cell groups.42 In the Bone Marrow Transfer to Enhance ST-Elevation Infarct Regeneration Trial (BOOST), 60 patients were randomized to receive either autologous bone marrow mononuclear cells (mean 2.5 × 10⁹) or placebo, delivered 4.8 ± 1.3 days after ST-segment elevation MI and percutaneous coronary intervention (PCI).43 At 6 months, LVEF was significantly improved in the cell therapy versus control group (6.7% vs 0.7%, respectively; \( P = .0026 \)). However, early improvements in LVEF did not persist at 18 months and did not translate into decreased major adverse cardiovascular events at 5 years.44
of Enriched Progenitor Cells and Infarct Remodeling in Acute Myocardial Infarction (REPAIR-AMI) trial is the largest trial to date using bone marrow mononuclear cells in acute MI. 45 Two hundred four patients were randomized to receive intracoronary infusion of either bone marrow mononuclear cells (2.4 ± 1.7 × 10⁸ cells) or placebo after 4.4 ± 1.4 days after ST-segment elevation MI and PCI. At 4 months, the improvement in LVEF was significantly greater in the cell therapy group compared to controls (5.5% ± 7.3% vs 3.0% ± 6.5%, \( P = .01 \)). 45 At 12 months, the occurrence of major adverse cardiovascular events was significantly lower in the cell therapy group compared to controls (23 vs 40 events, respectively, \( P = .01 \)). 45 Finally, the Finnish Stem Cell (FINCELL) study randomized 80 subjects to receive intracoronary infusion of autologous bone marrow mononuclear cells (4.0 ± 2.0 × 10⁸ cells) or placebo 2 to 6 days after ST-segment elevation MI and PCI. 46 At 6 months of follow-up, the bone marrow mononuclear cells treatment group had significant improvement in LVEF compared to the placebo group (4.0% ± 11.2% vs –1.4% ± 10.2%, \( P = .03 \)). There were no differences in major adverse cardiovascular events or arrhythmias between the 2 groups. 46

In contrast, several trials have failed to demonstrate benefit from intracoronary administration of bone marrow mononuclear cells. The randomized, double-blind, placebo-controlled Timing in Myocardial Infarction Evaluation trials (TIME and Late TIME) found that intracoronary infusion of bone marrow mononuclear cells either 3 to 7 days (TIME) after MI or 14 to 21 days (Late TIME) after MI had no effect on recovery of global or regional left ventricular function compared to placebo. 47, 48 The Intracoronary Infusion of Mononuclear Cells From Bone Marrow or Peripheral Blood Compared With Standard Therapy in Patients After Acute Myocardial Infarction Treated by Primary Percutaneous Coronary Intervention (HEBE) trial randomized 200 patients with acute MI to receive either intracoronary infusion of bone marrow mononuclear cells, circulating mononuclear cells, or standard therapy without placebo infusion 3 to 8 days after acute MI. 49 At 4 months, there were no significant differences in LVEF, infarct size, or major adverse cardiac events. 50 Similarly, the Intracoronary Injection of Mononuclear Bone Marrow Cells in Acute Myocardial Infarction (ASTAMI) trial reported no significant change in LVEF or major adverse cardiovascular event rates at 6 or 36 months. 51, 52
Several meta-analyses of trials evaluating efficacy of intracoronary autologous bone marrow mononuclear cell therapy in ST-segment elevation MI have been conducted.\textsuperscript{53–56} In a recent meta-analysis of 22 trials enrolling 2037 patients, of whom 1218 received bone marrow mononuclear cell therapy, treatment was found to be safe and was associated with modest improvements in LVEF (±2.1%), reduction in infarct scar size (−2.7%), and preservation of left ventricular end-systolic volume (−4 mL) without increase in short-term adverse event rate.\textsuperscript{56} Subgroup analyses revealed that improvements in LVEF were more likely among patients (1) with lower baseline LVEF, (2) who received more than $1 \times 10^6$ cells, and (3) who received treatment 5 to 30 days after infarction.\textsuperscript{54} In another meta-analysis of 50 studies enrolling 2625 patients with ischemic heart disease (either acute or chronic), treatment with bone marrow mononuclear cells was associated with a modest improvement in LVEF (±3.95%), smaller infarct size (−4.03%), and reduced LV end-systolic volume (−5.23 mL).\textsuperscript{57} Similarly, subgroup analysis revealed that improvements in LVEF were greater among patients with (1) lower baseline LVEF and (2) patients who received more than $4 \times 10^7$ cells.\textsuperscript{57} Both analyses highlight the importance of timing, dose, and MI size as determinants of response to stem cell therapy in patients with acute MI. Importantly, compared to patients who received standard therapy, patients treated with bone marrow mononuclear cells experienced significant decreases in all-cause mortality (odds ratio [OR], 0.39), cardiac mortality (OR, 0.41), recurrent MI (OR, 0.25), and in-stent thrombosis (OR, 0.34). There were no statistical differences in ventricular arrhythmias between groups.\textsuperscript{57}

**Chronic Heart Failure**

The Effect of Shock Wave-Facilitated Intracoronary Cell Therapy on LVEF in Patients With Chronic Heart Failure (CELLWAVE) trial randomized 103 patients with chronic postinfarction heart failure in 2 steps.\textsuperscript{58} Patients were first randomized (2:2:1; single-blind) to receive echocardiographically guided low-dose (0.014 mJ/mm$^2$), high-dose (0.051 mJ/mm$^2$), or placebo shock wave targeted to the left ventricular anterior wall 24 hours prior to cell administration. Preconditioning of chronic ischemic tissue with shock wave therapy has been shown to improve recruitment of circulating endothelial
progenitor cells via enhanced expression of chemoattractant factors (ie, SDF-1, vascular endothelial growth factor [VEGF]) in animal models.\textsuperscript{59} Patients receiving shock wave pretreatment were then randomized in a second step (1:1; double-blind) to receive intracoronary infusion of either bone marrow mononuclear cells or placebo, whereas patients receiving placebo shock wave received intracoronary infusion of bone marrow mononuclear cells.\textsuperscript{58} At 4 months, compared to patients receiving shock wave therapy alone, patients receiving shock wave therapy and bone marrow mononuclear cells had significantly improved LVEF (1.0\% vs 3.2\%, respectively, \( P = .02 \)), regional wall thickening (0.5\% vs 3.6\%, respectively, \( P = .01 \)), and decreased incidence of major adverse cardiac events (hazard ratio, 0.58; \( P = .02 \)).\textsuperscript{58} The Transendocardial Delivery of Autologous Bone Marrow Mononuclear Cells on Functional Capacity, Left Ventricular Function, and Perfusion in Chronic Heart Failure (FOCUS-CCTRN) trial randomized 92 patients with ischemic cardiomyopathy with LVEF ≤45\% to receive transendocardial injection of 9.9 ± 0.6 × 10\(^7\) bone marrow mononuclear cells or placebo in a 2-to-1 ratio. At 6 months, patients who received bone marrow mononuclear cells demonstrated significant improvements in LVEF compared to control (1.4\% vs −1.3\%, \( P = .03 \)).\textsuperscript{60} However, no change in end-systolic volume, maximal oxygen consumption, or reversibility of ischemia on single-photon emission computed tomography was observed. In exploratory analysis, higher CD34\(^+\) or CD133\(^+\) cell counts were associated with greater absolute unit increase in LVEF. Every 3\% higher level of CD34\(^+\) cells was associated with an average of 3.0\% greater absolute unit increase in LVEF in multivariable regression modeling. Similarly, every 3\% higher level of CD133\(^+\) cells was associated with an average of 5.9\% greater absolute unit increase in LVEF.\textsuperscript{60} These findings support the concept that both cell type and number of cells infused may be important factors in determining the benefit derived from cell therapy.

**Selected Bone Marrow–Derived Stem Cells**

**CD34\(^+\) Bone Marrow Mononuclear Cells**

Whether selected populations of bone marrow mononuclear cells enriched for progenitor cells are likely to be more effective than unselected mononuclear
cells has been explored in several early-phase trials. CD34+ cells are enriched for progenitor cells and localize more avidly to peri-infarct regions than unselected cells. CD34+ bone marrow mononuclear cells are relatively uncommon (1%-2%) and are capable of transdifferentiating into hematopoietic, endothelial, and smooth muscle cells, and rarely to cardiomyocytes in vivo. Coexpression of CD34 with CD133 identifies cells enriched for early precursor cells. In addition, coexpression of VEGF receptor-2 on CD34+ cells may constitute a phenotypically and functionally distinct population of cells enriched for endothelial progenitors.

**Acute Myocardial Infarction**

The Myocardial Regeneration by Intracoronary Infusion of Selected Population of Stem Cells in Acute Myocardial Infarction (REGENT) trial randomized 200 patients with acute MI and reduced LVEF (<40%) to receive intracoronary infusion of 1.8 × 10^8 unselected bone marrow mononuclear cells, 1.9 × 10^6 selected CD34+/CXCR4+ cells, or placebo 7 days following ST-segment elevation MI. At 6 months, treatment with either CD34+ or mononuclear cells did not improve LVEF or volumes compared to controls. However, in patients with baseline postinfarction LVEF <37% (median), infusion of unselected cells had a median LVEF improvement of 6.0% (P = .007), and selected CD34+/CXCR4+ cells had a median LVEF improvement of 7.0% (P = .01), indicating that cell therapy may provide the most benefit in patients with the most severely impaired LVEF after MI. In addition, there was a trend toward a greater proportion of patients receiving CD34+/CXCR4+ cells to improve LVEF compared to those receiving unselected cells, suggesting that selected CD34+ cells may be more therapeutic than unselected mononuclear cells. Finally, Bartunek et al randomized 35 patients with acute MI treated with PCI to receive intracoronary administration of CD133+/CD34+ bone marrow cells (1.3 ± 2.2 × 10^7 cells) 11.6 ± 1.4 days after infarction or standard medical care. At 4 months, patients receiving cell therapy experienced improvements in LVEF (from 45.0% ± 2.6% to 52.1% ± 3.5%, P < .05) and perfusion defect size (from 28.0% ± 4.1% to 22.5% ± 4.1%, P < .05) compared to controls. However, patients receiving intracoronary cell therapy had significantly higher rates of in-stent restenosis.
Chronic Heart Failure

Vrtovc et al\textsuperscript{68} randomized 110 patients with dilated cardiomyopathy to receive intracoronary administration of CD34\textsuperscript{+} cells (1.1 ± 0.3 × 10\textsuperscript{6} cells) or placebo. CD34\textsuperscript{+} cells were mobilized with G-CSF and collected via apheresis. Patients underwent myocardial scintigraphy, and cells were injected in the artery supplying segments with the greatest perfusion defect. At 1 and 5 years, CD34\textsuperscript{+} cell therapy was associated with increased LVEF, increased 6-minute walk distance, and decreased N-terminal B-type natriuretic peptide.\textsuperscript{68,69} LVEF improvement was more significant in patients with higher myocardial homing of injected cells as determined by cell labeling.\textsuperscript{69} During the 5-year follow-up, mortality was lower in the cell therapy group compared to controls (14\% vs 35\%, \( P = .01 \)).\textsuperscript{69} The Danish Stem Cell Study–Congestive Heart Failure (DANCELL-CHF) trial studied the benefit of repeated bone marrow mononuclear cell infusions in patients with chronic ischemic heart failure.\textsuperscript{70} Thirty-two patients with LVEF <45\% received 2 treatments of intracoronary CD34\textsuperscript{+} bone marrow stem cells 4 months apart. Patients received a mean of 6.5 ± 3.8 \times 10^{8} bone marrow cells on the first infusion and 8.9 ± 3.6 \times 10^{8} cells on the second infusion. At 12 months, there was no change in LVEF.\textsuperscript{70} At 7 years, post hoc analysis revealed increased CD34\textsuperscript{+} cell count was significantly associated with survival (hazard ratio, 0.9; \( P = .04 \)), indicating that repeated injections of high numbers of CD34\textsuperscript{+} cells may improve long-term survival in patients with chronic ischemic heart failure.\textsuperscript{71}

Chronic Ischemia

In a phase II randomized controlled trial, 167 patients with refractory angina were randomized to receive 1 of 2 doses (1 × 10\textsuperscript{5} or 5 × 10\textsuperscript{5} cells/kg) of mobilized autologous CD34\textsuperscript{+} cells or an equal volume of placebo.\textsuperscript{72} Treatment was distributed into 10 sites of ischemic but viable myocardium as determined by the NOGA mapping system, as described previously. At 6 months, patients in the low-dose cell therapy group had significantly decreased angina frequency and improved exercise tolerance as compared to patients receiving placebo. Interestingly, there was a lack of dose response, and patients receiving high-dose cell therapy did not experience the same improvements in angina frequency and exercise tolerance seen in the low-
dose cell therapy group. Clinical trials evaluating the use of CD34+ bone marrow mononuclear cells in the treatment of cardiovascular diseases are ongoing and are summarized in Table 68-4.

Abbreviations: ABI, ankle-brachial index; ADRC, adipose-derived regenerative cell; BMMNC, bone marrow mononuclear cell; CABG, coronary artery bypass graft; CSC, cardiac stem cell; EPC, endothelial progenitor cell; G-CSF, granulocyte colony-stimulating factor; LVAD, left ventricular assist device; LVEF, left ventricular ejection fraction; MACE, major adverse cardiovascular events; MI, myocardial infarction; MLHFO, Minnesota Living With Heart Failure Questionnaire; MSC, mesenchymal stem cell; TCIM, transcatheter intramyocardial; TEIM, transendocardial intramyocardial.

**Mesenchymal Stem Cells**
Mesenchymal stem cells are rare, nonhematopoietic, multipotent cells of mesodermal origin that constitute 0.01% to 0.001% of bone marrow nucleated cells. The most abundant source of mesenchymal stem cells is the bone marrow, but they can be derived from the umbilical cord, amniotic fluid, placenta, testis, and adipose tissue. The International Society for Cell Therapy defines mesenchymal stem cells as cells that (1) adhere to plastic in standard culture conditions; (2) express CD73, CD90, and CD105 in the absence of CD34, CD45, HLA-DR, CD14, CD11b, CD79a, or CD19 surface molecules; and (3) have capacity for differentiation to osteoblasts, adipocytes, and chondroblasts in vitro. Mesenchymal stem cells maintain endogenous stem cell niches; contribute to the creation and maintenance of cardiovascular, connective, and skeletal tissues; and are attractive candidates for cell therapy because of their ease of proliferation in culture, potential for both myocardial and vascular repair, and immune-privileged status.

Mesenchymal stem cells influence neighboring cells by direct cell-to-cell interaction and by paracrine release of an array of soluble growth factors and cytokines that include SDF-1, chemokine receptor (CXCR)-4, hepatocyte growth factors, insulin-like growth factor-1, basic fibroblast growth factor, hypoxia-inducible factor-1α, VEGF, angiopoietin-1, tumor necrosis factor-α, interleukin-1, interleukin-6, and plasminogen activator. Intracoronary administration of human mesenchymal stem cell–conditioned medium in a murine model of acute MI increased capillary density, reduced myocardial infarct size, and improved systolic and diastolic function.

Unlike other bone marrow–derived cells, mesenchymal stem cells possess immune properties that make them potential candidates for safe allogeneic therapy in immunocompetent patients. Their relatively immune-privileged phenotype prevents activation of host immune cells because they lack surface expression of major histocompatibility complex class II antigens and costimulatory molecules for T-cell induction. Furthermore, mesenchymal stem cells downregulate lymphocyte proliferation and suppress the maturation and function of immune cells via the secretion of soluble factors. Under optimal conditions, the progeny of colony-forming unit–fibroblasts can be expanded for upward of 50 population doublings.

Experimental studies of mesenchymal stem cell transplantation in acute MI and ischemic cardiomyopathy have reported biologic and functional benefits that include attenuation of myocardial scar and infarct size,
improvement in regional and global ventricular function, and increased vascular density and myocardial perfusion.\textsuperscript{80–82} In murine models of acute MI, intramyocardial injection of human-mesenchymal stem cells or cells expressing Akt resulted in a dose-dependent increase in vascular density and neovascularization, with accompanying improvements in LVEF.\textsuperscript{83,84} Potential hazards of mesenchymal stem cells include risks of off-target tissue growth such as ossification and/or calcification, cardiac nerve sprouting, and arrhythmogenicity.\textsuperscript{85,86} Additionally, intracoronary injection of the relatively large mesenchymal stem cells has been associated with cell aggregation and embolization.\textsuperscript{11,87}

Clinical trials using autologous and allogeneic mesenchymal stem cells have been conducted in patients with acute MI, chronic heart failure, and stable angina (see Table 68-3).

**Acute Myocardial Infarction**

Hare et al\textsuperscript{88} conducted a randomized, double-blind, placebo-controlled trial using intravenous allogeneic human mesenchymal stem cells (Prochymal; Osiris Therapeutics, Baltimore, MD) in 53 patients with acute MI. Human mesenchymal stem cells were isolated from bone marrow aspirates obtained from a single unrelated donor who was not human leukocyte antigen matched to recipients. Patients were randomized to receive either a single intravenous infusion of Prochymal (at 3 dose-escalation cohorts of 5, 16, and $50 \times 10^5$ cells/kg body weight) or placebo suspension delivered at a rate of 2 mL/min.\textsuperscript{88} At 6 months, there was reduced ventricular tachycardia and improved expiratory volumes in the Prochymal-treated patients compared to controls. While the study was not powered to detect differences in LVEF, cardiac magnetic resonance imaging performed in a subgroup of patients (20 Prochymal patients and 14 placebo patients) demonstrated a progressive increase in LVEF relative to baseline in Prochymal- but not in placebo-treated patients ($+5.2\% \pm 1.9\%, P = .003$).\textsuperscript{88} Importantly, there were no differences in major adverse event rates between groups, indicating that intravenous infusion of allogeneic mesenchymal stem cells is safe in patients with acute MI. A larger phase II clinical trial is currently recruiting (see Table 68-4).
Chronic Ischemia

In the Direct Intramyocardial Mesenchymal Stromal Cell Injection in Patients With Severe Refractory Angina Trial, 31 patients with stable coronary artery disease, moderate to severe angina, LVEF >40%, and no further revascularization options received autologous mesenchymal stem cells (mean 2.2 × 10^7 cells). Bone marrow mesenchymal stem cells were culture expanded for 6 to 8 weeks, stimulated with VEGF for 1 week, and injected into ischemic but viable areas of myocardium as determined by the NOGA mapping system. Autologous mesenchymal cells were safe and resulted in improved exercise duration, quality of life, and angina frequency at 12 months.

Chronic Heart Failure

The Comparison of Allogeneic Versus Autologous Bone Marrow–Derived Mesenchymal Stem Cells Delivered by Transendocardial Injection in Patients With Ischemic Cardiomyopathy (POSEIDON) trial studied 30 patients with ischemic heart failure and LVEF <50% who were randomized to receive transendocardial injection of 20 × 10^6, 100 × 10^6, or 200 × 10^6 autologous or allogeneic mesenchymal stem cells. At 1 year, relative to baseline, autologous but not allogeneic cell therapy was associated with an improvement in the 6-minute walk test and the Minnesota Living with Heart Failure Questionnaire score. While both allogeneic and autologous cells reduced end-diastolic volumes, this did not translate into significantly improvements in LVEF. No significant donor-specific immune reactions were observed with allogeneic mesenchymal stem cells, and several trials evaluating their use are under way (see Table 68-4).

The Cardiopoietic Stem Cell Therapy in Heart Failure (C-CURE) trial randomized 48 patients with chronic ischemic heart failure (LVEF <40%) to receive either lineage-specified cardiopoietic cells derived from autologous mesenchymal stem cells or standard of care. In the cell therapy arm, bone marrow was harvested and isolated mesenchymal stem cells were exposed to a cardiogenic cocktail. Derived cardiopoietic stem cells were delivered by endomyocardial injections guided by electromechanical (NOGA) mapping. At 24 months, patients receiving cell therapy demonstrated a 7.0%
improvement in LVEF compared to controls, in whom LVEF remained unchanged ($P < .0001$). In addition, cell therapy was associated with a reduction in left ventricular end-systolic volume ($-24.8 \pm 3.0 \text{ mL vs } -8.8 \pm 3.9 \text{ mL}, P < .0001$) and improved 6-minute walk distance ($+62 \pm 18 \text{ m vs } -15 \pm 20 \text{ m, } P < .01$) compared with controls.\textsuperscript{91}

The Transendocardial Mesenchymal Stem Cells and Mononuclear Bone Marrow Cells for Ischemic Cardiomyopathy (TAC-HFT) trial randomized 65 patients with ischemic cardiomyopathy and LVEF <50% to receive endomyocardial injections of mesenchymal stem cells, bone marrow mononuclear cells, or placebo.\textsuperscript{92} At 1 year, there were no differences in serious adverse events between groups. Compared to placebo, treatment with mesenchymal stem cells resulted in improved symptoms, increased 6-minute walk distance, and reduced left ventricular infarct size. In comparison, treatment with bone marrow mononuclear cells resulted in improved symptoms only.\textsuperscript{92}

Finally, the Safety and Efficacy of Ixmyelocel-T trial was a randomized phase IIA clinical trial using Ixmyelocel-T (Vericel, Ann Arbor, MI) in the treatment of dilated ischemic and nonischemic cardiomyopathy.\textsuperscript{93} Ixmyelocel-T is an expanded multicellular therapy cultured from autologous bone marrow mononuclear cells and is composed of myeloid and lymphoid cells that express CD45 and CD90, which are hallmarks of mesenchymal stromal cells.\textsuperscript{94} Compared to bone marrow, Ixmyelocel-T contains approximately 50- and 200-fold the number of M\textsubscript{2}-like macrophages and mesenchymal stromal cells, respectively.\textsuperscript{93} A total of 61 patients were randomized to receive Ixmyelocel-T (up to $1.5 \times 10^6$ cells) administered via intramyocardial injection directed by the NOGA injection catheter or by direct visualization via mini-thoracotomy.\textsuperscript{93} At 1 year, patients with ischemic cardiomyopathy treated with Ixmyelocel-T experienced significantly fewer major adverse cardiac events compared to controls (14% vs 56%, respectively, $P < .05$). In addition, cell therapy was associated with improved New York Heart Association (NYHA) class, 6-minute walk distance, and Minnesota Living with Heart Failure Questionnaire scores. However, there was no benefit of cell therapy in nonischemic cardiomyopathy (see Table 68-3).\textsuperscript{93}

This was followed by the Ixmyelocel-T for Patients With Heart Failure Trial, a prospective, randomized, double-blind, placebo-controlled, phase IIB
trial that recruited 126 patients with NYHA class III or IV symptomatic heart failure due to ischemic cardiomyopathy with an implanted defibrillator, LVEF ≤35%, who were ineligible for revascularization. Ixmyelocel-T (n = 60) or placebo (n = 66) was injected via a NOGA catheter into the viable myocardium. The primary efficacy end point of all-cause death or rehospitalization for heart failure was observed in 49% of patients in the placebo group and 38% of patients in the Ixmyelocel-T group, a 37% reduction in cardiac events (risk ratio, 0.63; \( P = .034 \)). In addition, 75% of placebo participants had serious adverse events compared to 53% in the Ixmyelocel-T group (\( P = .02 \)). To date, this has been the largest cell therapy trial in patients with ischemic heart failure that has demonstrated significant reduction in clinical cardiac events in patients receiving cell therapy.

**Adipose-Derived Progenitor Cells**

Adipose tissue has emerged as a promising source of stem cells for cell-based therapies. The stromal vascular fraction represents 10% of adipose tissue and contains a mixed, multipotent population of cells including preadipocytes, fibroblasts, vascular smooth muscle cells, endothelial cells, resident monocytes/macrophages, lymphocytes, and adipose-derived progenitor cells. Adipose-derived progenitor cells can be easily obtained by liposuction and prepared as fresh cells for immediate autologous transplantation without need for culture and expansion. They share many cell surface markers with bone marrow–derived mesenchymal stem cells or stromal cells and skeletal muscle–derived cells and can differentiate into multiple cell lineages including cardiomyocytes and endothelial and smooth muscle cells. Furthermore, stem cell yields from adipose tissue are significantly greater than from bone marrow; the average frequency of adipose-derived stem cells in processed lipoaspirate is 2% of nucleated cells, and their yield is approximately 5000 fibroblast colony-forming units per gram of adipose tissue, compared with approximately 100 to 1000 colony-forming units per milliliter of bone marrow. Current methods used for isolating stem cells rely on collagenase digestion followed by centrifugal separation to isolate the stromal vascular fraction from adipocytes. Isolated adipose-derived stem cells are then expanded in monolayer culture on standard tissue culture plastics with a basal medium containing 10% fetal
bovine serum.\textsuperscript{102} The beneficial effect of adipose-derived progenitor cells is predominantly due to paracrine effects of their soluble factors rather than their differentiation into mature lineages.\textsuperscript{96}

The Adipose-Derived Regenerative Cells in Patients With Ischemic Cardiomyopathy (PRECISE) trial randomized 36 patients with chronic ischemic cardiomyopathy (LVEF ≤45%) in a 3:1 ratio to receive adipose-derived progenitor cells or placebo.\textsuperscript{103} Progenitor cells were isolated from adipose tissue harvested by liposuction, and $4.2 \times 10^7$ cells or placebo was injected into areas of viable myocardium using the NOGA injection catheter. At 6 months, patients treated with cell therapy demonstrated increased left ventricular mass (from $128.1 \pm 26.0$ to $149.5 \pm 32.4$, $P < .001$) and wall motion score index on magnetic resonance imaging (from $2.1 \pm 0.6$ to $1.7 \pm 0.9$, $P = .04$) compared to patients receiving placebo, who remained unchanged from baseline. However, this did not translate into significant differences in LVEF or major adverse cardiovascular events.\textsuperscript{103}

**Resident Cardiac Progenitor Cells**

Resident cardiac progenitor cells that promote cardiomyocyte renewal and proliferation include side population cells, Sca-1$^+$, Islet-1$^+$, and c-kit$^+$ cardiac progenitor cells, cardiospheres, and epicardium-derived progenitor cells. While relatively rare, these cells are likely committed to a cardiomyocyte fate, giving them a distinct advantage over other progenitor cells for heart failure therapy (Fig. 68-3).
Side Population Cardiac Progenitor Cells

Side population cells are characterized by their ability to efflux Hoechst dye in an ABC transporter-dependent manner and are found in skeletal muscle, bone marrow, and cardiac tissue. Within the heart, side population cells range from 0.03% to 3.5% of total mononuclear cardiac cells. When cultured with adult or neonatal cardiomyocytes, they differentiate into functional cardiomyocytes and express muscle-specific transcription factors and cardiac specific proteins, including α-sarcromeric actinin and troponin-I. When infused intravenously into infarcted rats, side population cells have been shown to engraft into injured myocardium and differentiate into cardiomyocytes and endothelial and smooth muscle cells. In humans, side population cells are located in the atria but demonstrate the ability to mobilize to areas of ischemic myocardium. No clinical trials have so far been performed with these cells.

Sca-1+ Cardiac Progenitor Cells

Stem cell antigen-1 (Sca-1) is a member of the ly-6 family, initially reported as a cell surface marker for hematopoietic stem cells. Sca-1+ cells are found in the bone marrow, myocardium, skeletal muscle, and blood vessels. In vitro, Sca-1+ cells differentiate into cardiomyocytes, smooth muscle cells, and endothelial cells. Transplantation of Sca-1+ cells derived from human fetal hearts into mice with acute MI resulted in improved LVEF and ventricular remodeling at 3 months. Sca-1+ cells generated human cardiomyocytes and blood vessels without fusion of human and murine nuclei. To date, there have been no clinical trials with Sca-1+ cells.

Islet-1+ Cardiac Progenitor Cells
Islet-1\(^+\) is a LIM-homeodomain transcription factor that plays a crucial role during cardiac embryogenesis and gives rise to the right ventricle, outflow tract, and atria.\(^{111}\) While abundant in neonatal hearts, Islet-1\(^+\) cells rapidly decline with age.\(^{112}\) In murine models, intramyocardial gene transfer of Islet-1\(^+\) to the border zone of infarcted hearts resulted in improved left ventricular function, enhanced vascularization, and reduced myocardial fibrosis.\(^{113}\) Transplanted Islet-1\(^+\) cells differentiated into endothelial and smooth muscle cells 25 days after injection. No clinical trials using Ilset-1\(^+\) cells have been conducted.

**C-kit\(^+\) Cardiac Progenitor Cells**

C-kit is a tyrosine kinase receptor for stem cell factor. In the heart, c-kit\(^+\) cells are heterogeneous but rare (1 per 10,000 myocytes), and only a minority (7%-10%) express early cardiac transcription factors such as GATA4, Mef2, and Nkx2.5. C-kit\(^+\) cells from human myocardial samples differentiate predominantly into cardiomyocytes and to a lesser extent into endothelial and smooth muscle cells. When injected into the infarcted myocardium of immune-deficient rodents, human c-kit\(^+\) cells form new cardiomyocytes, arterioles, and capillaries.\(^{114}\) Endothelial progenitor cells derived from c-kit\(^+\) cells express Flk-1, can differentiate into cardiomyocytes, and can be found on the walls of coronary arteries.\(^{115}\)

The Administration of Cardiac Stem Cells in Patients With Ischemic Cardiomyopathy (SCIPIO) trial was a first-in-human, phase I, randomized, open-label trial of autologous c-kit\(^+\) cells in patients with ischemic cardiomyopathy and LVEF ≤40% in need of coronary artery bypass grafting.\(^{116}\) A total of 33 patients were randomized to receive either intracoronary infusion of 1 million c-kit\(^+\) cells (n = 20) or standard-of-care therapy (n = 13). C-kit\(^+\) cells were harvested from the right atrial appendage during coronary artery bypass grafting, processed, and reinfused intracoronarily into patients 4 months after surgery. Compared to controls, patients receiving c-kit\(^+\) cells demonstrated improved LVEF (from 27.5% ± 1.6% to 41.2% ± 4.5%, \(P = .013\)), reduced infarct size (–9.8 ± 3.5 g, \(P = .039\)), and increased left ventricular mass (+31.5 ± 11.0 g, \(P = .035\)) at 1 year.\(^{116}\) There were no adverse events associated with stem cell harvest.
during coronary artery bypass grafting.

**Cardiosphere and Cardiosphere-Derived Cells**

Cardiospheres are outgrowth cells derived from cultured cardiac explants that grow as self-adherent clusters in vitro. Cardiosphere cells from mice and humans are clonogenic, express stem and endothelial progenitor cell antigens/markers, and appear to have properties of adult cardiac stem cells. They are capable of long-term self-renewal and can differentiate in vitro and after ectopic or orthotopic transplantation to cardiomyocytes, endothelial cells, and smooth muscle cells. Cardiospheres are heterogeneous and contain cardiac progenitor cells in the center surrounded by mesenchymal cells, endothelial cells, and cardiomyocytes in the periphery. To obtain enough cardiosphere cells for therapeutic use, cells can be cultured and expanded as a monolayer of cardiosphere-derived cells over many passages. Human cardiosphere-derived cells are capable of differentiating into all 3 cardiovascular cell types, in vivo and in vitro. They can be easily isolated from a small amount of endocardium and expanded without losing differentiation potential.

The Intracoronary Cardiosphere-Derived Cells for Heart Regeneration After Myocardial Infarction (CADUCEUS) trial was a prospective, randomized, phase I study to evaluate the safety and efficacy of cardiosphere-derived cells in patients with reduced LVEF (≤45%) secondary to ischemic cardiomyopathy. Autologous cardiosphere-derived cells were harvested and expanded from endomyocardial biopsies. Twenty-five patients were randomized to receive infusion of either 12.5 to 25 × 10⁶ cardiosphere-derived cells or placebo into the infarct-related artery 45 to 90 days after MI. Compared to controls, patients treated with cardiosphere-derived cells showed reduction in scar mass (–11.9 ± 6.8 g vs –1.7 ± 7.8 g, respectively, \( P = .008 \)), increased viable heart mass (22.6 ± 9.4 g vs 1.8 ± 8.7 g, respectively, \( P < .001 \)), and improved regional contractility (35.9% ± 31.8% vs 28.4% ± 22.4%, respectively, \( P = .008 \)) at 1 year. These promising initial results have led to the initiation of a larger phase III study using allogeneic cells in patients with recent anterior MI (see Table 68-4).

**Epicardium-Derived Progenitor Cells**
Epicardium-derived progenitor cells are identified by the transcription factors Wilms tumor 1 and/or T-box 18 and can differentiate into cardiomyocytes or endothelial or smooth muscle cells. Wilms tumor 1+ epicardial cells arise from progenitors that express Nkx2.5 and Islet-1, suggesting that they share a developmental origin with these multipotent progenitors. In murine models, MI induces quiescent epicardial cells to become pluripotent epicardium-derived progenitor cells that express stem cell markers c-kit+ and CD34+. During cardiac development, thymosin β4, an actin monomer-binding protein, is expressed in the myocardium, providing a paracrine stimulus to epicardium-derived progenitor cells to promote their inward migration and differentiation into coronary smooth muscle cells. Treatment of cultured adult murine heart explants with thymosin β4 stimulates capillary-like tube formation of adult coronary endothelial cells and increases embryonic endothelial cell migration and proliferation in vitro. Together these studies demonstrate that epicardium-derived progenitor cells provide an attractive population of cells to be used in cardiac regeneration and/or repair. However, these findings must first be validated in humans.

Mobilization of Stem Cells

Granulocyte Colony-Stimulating Factor

G-CSF is a 25-kDa cytokine that regulates both growth and differentiation of hematopoietic progenitor cells and has been routinely used for the treatment of neutropenia and for bone marrow transplantation as it mobilizes bone marrow cells. Various mechanisms have been proposed for the beneficial effects of G-CSF in the infarcted heart, including acceleration of the healing process, protection of salvaged cardiomyocytes from apoptosis, reduction of myocardial fibrosis, and regeneration of the myocardium. The G-CSF receptor is expressed on cardiomyocytes, and it activates the Janus family tyrosine kinase 2 (Jak2) and downstream signaling molecule signal transducer and activator of transcription 3 (STAT3) to prevent cardiomyocyte apoptosis. Importantly, G-CSF mobilizes bone marrow cells, especially CD34+ mononuclear cells, that home to the infarcted myocardium.
**Acute Myocardial Infarction**

There have been several clinical trials studying the utility of G-CSF in acute MI (see Table 68-3). The first was the Effect of Intracoronary Infusion of Peripheral Blood Stem Cells Mobilized With G-CSF on LVEF and Restenosis After Coronary Stenting in Myocardial Infarction (MAGIC) trial.\(^{132}\) Twenty-seven patients with MI who underwent coronary stenting were randomized into 3 groups: G-CSF alone (10 μg/kg × 4 days), G-CSF–mobilized peripheral blood cells (1.0 \(\times 10^9\) cells), or placebo. At 6 months, patients receiving intracoronary infusion of G-CSF–mobilized cells had significant improvements in LVEF. These improvements were not seen in patients who received G-CSF alone.\(^{132}\) Despite these promising results, the study was terminated early due to the high rate of in-stent restenosis observed in patients who received G-CSF (70%) compared to controls. The Front-Integrated Revascularization and Stem Cell Liberation Evolving Acute Myocardial Infarction by Granulocyte Colony-Stimulating Factor (FIRSTLINE-AMI) Trial randomized 30 patients with acute ST-segment elevation MI undergoing PCI to receive subcutaneous G-CSF at 10 μg/kg for 6 days.\(^{133}\) G-CSF mobilized CD34\(^+\) cells with a 20-fold increase from baseline to day 6, and LVEF improved from 48% to 54% at 4 months and to 56% at 12 months.\(^{133}\)

However, these promising initial results were not repeated in subsequent clinical trials. The Stem cell Mobilization Induced by Subcutaneous Granulocyte Colony-Stimulating Factor to Improve Cardiac Regeneration After Acute ST-Elevation Myocardial Infarction (STEMMI) Trial and the Regenerate Vital Myocardium by Vigorous Activation of Bone Marrow Stem Cells (REVIVAL-2) trial randomized 78 patients and 114 patients with ST-segment elevation MI, respectively, with a similar treatment protocol, but found no effect at 6 months.\(^{134,135}\) Meta-analyses of 10 trials including 445 patients using stem cell mobilization with G-CSF in patients with ST-segment elevation MI found no significant improvement in infarct size or LVEF, although those with lower LVEFs may derive a benefit.\(^{136}\) Importantly, no increase in cardiovascular events or incidence of in-stent restenosis was observed with G-CSF treatment.\(^{132,136}\)

**Chronic Heart Failure**

The G-CSF Stimulation and Coronary Reinfusion of Mobilized Circulating
Mononuclear Proangiogenic Cells in Patients With Chronic Ischemic Heart Disease (TOPCARE-G-CSF) trial randomized 32 patients with previous MI (>3 months) and left ventricular dysfunction to receive either 5 or 10 μg/kg of G-CSF followed by targeted intracoronary infusion of mobilized and cultured circulating mononuclear cells into the infarct-related artery. Although safe, at 5 years, there were no appreciable differences in NYHA class, global left ventricular function, and cardiopulmonary exercise capacity between treatment groups.

FUTURE OF CARDIAC CELL THERAPY

Several large phase II and phase III clinical trials evaluating the use of various stem cells in patients with both acute MI and chronic ischemic heart failure are under way (see Table 68-4). The largest is the Effect of Intracoronary Reinfusion of Bone Marrow–Derived Mononuclear Cells on All-Cause Mortality in Acute Myocardial Infarction (BAMI) trial (ClinicalTrials.gov identifier: NCT01569178). BAMI is a 3000-patient, multinational, multicenter, randomized, controlled, phase III study evaluating the effect on all-cause mortality of a single intracoronary infusion of autologous bone marrow–derived mononuclear cells in patients with ischemic cardiomyopathy (LVEF <45%) after successful reperfusion for acute MI. The Double-Blind, Randomized, Sham-Procedure-Controlled, Parallel-Group Efficacy and Safety Study of Allogeneic Mesenchymal Precursor Cells (CEP-41750) in Patients With Chronic Heart Failure due to Left Ventricular Systolic Dysfunction of Either Ischemic or Nonischemic Etiology Trial will randomize 1730 patients with chronic heart failure to receive transendocardial injection of allogeneic mesenchymal precursor cells or placebo (ClinicalTrials.gov identifier: NCT02032004).

Early clinical experience with largely autologous cell therapy in humans with advanced cardiovascular disease has been somewhat disappointing when compared to the dramatic results observed in experimental animals. These discrepancies are partly because experimental studies are conducted in models without chronic disease and exhaustion of endogenous progenitor cell capacity, which are important considerations in humans with advanced disease. The number and functionality of autologous bone marrow–derived cells are sensitive to pathologic states such as aging, inflammation, and
cardiovascular risk factors. Thus, angiogenic capacity and numbers of transplanted cells are lowest in those with the most advanced cardiovascular diseases.\textsuperscript{139,140} Moreover, recipient characteristics may be equally important in determining efficacy. Little attention has been paid in early clinical trials to the dose of cells administered; cell doses have varied by more than a 1000-fold. There is increasing evidence that higher doses of intracoronary-delivered mononuclear cells after acute MI are accompanied by greater therapeutic effect. Delivery methods and their feasibility have important impact on cell retention and safety. In certain cases, timing of cell therapy, particularly after acute MI, is crucial because very early administration may lead to poor survival of injected cells due to the hostile environment with inflammatory cell infiltration, and delayed administration is likely to encounter irreversible fibrosis and scar. Because of the aforementioned limitations of autologous stem cells and the expense and time it takes for ex vivo expansion, the potential of allogeneic “off-the-shelf” cell therapy using cells from young healthy donors poses an attractive alternative and is currently being investigated in several trials (see Table 68-4).

**CELL THERAPY FOR PERIPHERAL ARTERIAL DISEASE**

Peripheral arterial disease (PAD) is a common and underdiagnosed pathologic condition afflicting over 8 million Americans and over 200 million patients worldwide.\textsuperscript{141} Symptoms of PAD include claudication and walking limitation, progressing to critical limb ischemia with rest pain; nonhealing ulcers; and amputations.\textsuperscript{142} The most common cause of PAD is atherosclerosis, but rarely, it is secondary to thromboangiitis obliterans.\textsuperscript{143} Despite surgical or endovascular revascularization, up to 30% of patients have unrevascularizable disease that allows use of cell-based regenerative therapies as alternative treatment modalities.\textsuperscript{144}

Multiple cell types have been investigated in preclinical and clinical trials for the treatment of PAD (Table 68-5). These include unselected bone marrow and peripheral blood mononuclear cells, selected mononuclear cells, adipose-derived cells, and mesenchymal stem cells. These trials have been conducted in subjects with claudication and those with critical limb ischemia.
In addition, cytokine-induced mobilization of bone marrow mononuclear cells has been performed for apheresis of mobilized bone marrow mononuclear cells. The goal of cell therapy in PAD is to promote neovascularization and enhance collateral formation to improve blood flow to ischemic tissue, thereby alleviating symptoms and enhancing limb preservation.

Abbreviations: ABI, ankle-brachial index; ADRC, adipose-derived regenerative cells; BMMNC, bone marrow–derived mononuclear cells; G-CSF, granulocyte colony-stimulating factor; NA, not applicable; PBMC, peripheral blood–derived mononuclear cells; TcPO2, transcutaneous oxygen pressure.

**Clinical Trials in PAD With Bone Marrow Mononuclear Cells**

The Therapeutic Angiogenesis Using Cell Transplantation (TACT) trial was the first randomized controlled trial to evaluate the use of bone marrow mononuclear cells in the treatment of PAD.145 In the first arm, 25 patients with unilateral leg ischemia (ankle-brachial index <0.6) received intramuscular injections of bone marrow mononuclear cells (mean 1.6 billion cells) into the gastrocnemius muscle of the ischemic limb and saline into the
less ischemic limb. In the second arm, 22 patients with bilateral leg ischemia received intramuscular injections of bone marrow mononuclear cells in one leg and peripheral blood mononuclear cells in the other. At 4 weeks, ankle-brachial index and transcutaneous oxygen pressure were significantly improved in limbs injected with bone marrow mononuclear cells with concomitant relief in rest pain and pain-free walking time.

Huang et al randomized 28 diabetic patients with critical limb ischemia to receive intramuscular injections of G-CSF mobilized mononuclear cells or placebo. Mononuclear cells were isolated from peripheral blood samples collected after 5 days of daily subcutaneous G-CSF injections. At 3 months, patients receiving cell therapy had significantly improved ankle-brachial index, improved limb ulcer healing, and decreased rates of limb amputation compared to controls. Using a similar protocol, Ozturk et al randomized 40 diabetic patients with critical limb ischemia to receive G-CSF mobilized peripheral blood mononuclear cells or placebo. At 12 weeks, patients receiving cell therapy had significantly improved ankle-brachial indexes, transcutaneous oxygen measurement, and 6-minute walking distance. In both studies, treatment with G-CSF and mononuclear cells was safe and well tolerated.

**Selected Bone Marrow Mononuclear Cells**

Ixmyelocel-T (also known as tissue repair cells) is a closed-culture system expanded patient-specific mixture of bone marrow mononuclear cells enriched for CD90+ cells (expressed on mesenchymal stem cells) and CD45+/CD14+/autofluorescence+ cells (expressed on activated macrophages). The expansion of these 2 cell lines is thought to provide both the endothelial progenitor cells and the cytokine-induced supportive environment needed for angiogenesis and tissue repair. The Use of Tissue Repair Cells in Patients With Peripheral Arterial Disease to Treat Critical Limb Ischemia (RESTORE-CLI) trial is a phase II trial that randomized 86 patients with critical limb ischemia with no options for revascularization to receive intramuscular injections of Ixmyelocel-T or placebo. Patients underwent a mini-bone marrow harvest, and cells were administered by >20 intramuscular injections. At 12 months, treatment with Ixmyelocel-T cells significantly prolonged the time to treatment failure defined as major
amputation, all-cause mortality, doubling of total wound surface area from baseline, or de novo gangrene.\textsuperscript{149} The encouraging results of the RESTORE-CLI trial have led to the initiation of a larger phase III clinical trial.

The Autologous CD34\textsuperscript{+} Cell Therapy for Critical Limb Ischemia (ACT34-CLI) trial is a phase II study evaluating the benefit of autologous G-CSF mobilized CD34\textsuperscript{+} mononuclear cells in patients with critical limb ischemia.\textsuperscript{150} Twenty-eight patients were randomized to receive $10^5$ or $10^6$ CD34\textsuperscript{+} cells/kg or placebo administered by intramuscular injection into 8 sites within the ischemic lower extremity. At 12 months, a dose-dependent trend toward reduced amputation rate was observed with CD34\textsuperscript{+} cell therapy.\textsuperscript{150}

\textbf{Clinical Trials in PAD With Adipose-Derived Regenerative Cells}

The mechanism of ulcer healing by adipose-derived stem cells is based on direct differentiation toward lineage-committed cells or on the production of angiogenic growth factors.\textsuperscript{151} In 10 patients with chronic nonhealing ulcers, 270 g of fat was suctioned from the abdomen, and adipose-derived progenitors were isolated using the Celution system and injected around the ulcer edges.\textsuperscript{152} At 3 months, there was reduction in both diameter and depth of the ulcer, decreased pain, and complete healing of the ulcer in 60% of cases.\textsuperscript{152} This has prompted the initiation of a larger randomized control trial (see Table 68-4).

\textbf{Clinical Trials in PAD With Mesenchymal Stem Cells}

In 41 type 2 diabetic patients with bilateral critical limb ischemia and foot ulcers, bone marrow mesenchymal stem cells, bone marrow–derived mononuclear cells, or normal saline was injected intramuscularly. The ulcer healing rate of the mesenchymal stem cell group was significantly higher than that of mononuclear cell group at 6 weeks and reached 100% 4 weeks earlier than the mononuclear cell group. After 24 weeks, the improvements in limb perfusion induced by the mesenchymal stem cell transplantation were more significant than those by mononuclear cells in terms of pain-free walking time, ankle-brachial index, transcutaneous oxygen pressure, and
magnetic resonance angiography analysis.\textsuperscript{153}

**Clinical Trials in PAD With Bone Marrow Mobilization**

Both experimental and current clinical data indicate that granulocyte-macrophage colony-stimulating factor (GM-CSF) has the capacity to mobilize a variety of progenitor cells including endothelial progenitors that promote neoendothelialization of denuded arteries and improve ischemia in experimental models.\textsuperscript{154,155} A phase I (G-PAD-1) study in subjects with PAD and intermittent claudication demonstrated feasibility and potential efficacy of thrice-weekly subcutaneous injections of GM-CSF at doses ranging from 3 to 10 μg/kg for 2 weeks in improving endothelial dysfunction and symptoms of claudication compared to placebo. In a follow-up phase IIA (G-PAD-II) study, 4 weeks of thrice-weekly treatment with GM-CSF (500 μg/d) improved treadmill walking time and quality of life in subjects with PAD and intermittent claudication. There was a significant but modest improvement of approximately 1 minute in treadmill exercise time after 3 months of therapy.\textsuperscript{156}

A recent meta-analysis by Fadini et al\textsuperscript{143} of 37 cell therapy trials in 701 patients with PAD found that autologous cell therapy was effective at improving ankle-brachial index (from a mean of 0.46 to 0.63), improving pain-free walking distance (from 76 to 402 seconds), and increasing rates of ulcer healing (OR, 3.54). Intramuscular administration of bone marrow mononuclear cells appeared to be more effective than either intra-arterial administration or use of mobilized peripheral blood cells. Overall, procedures for harvesting and administration of progenitor cells were well tolerated.\textsuperscript{134} Wang et al\textsuperscript{157} recently published a meta-analysis of 31 studies involving 1214 patients with PAD. Treatment with autologous bone marrow–derived cells results in significantly improved ankle-brachial indexes at 12, 24, and 48 weeks ($P < .05$) and improved TcO\textsubscript{2} values at 4 and 8 weeks ($P < .001$). Cell therapy was also associated with decreased pain in the short term (<8 weeks; $P < .05$) as well as increased amputation-free survival at 1 and 3 years ($P < .00001$ and $P = .0003$, respectively).\textsuperscript{157} Treatment with autologous bone marrow stem cells was safe and well tolerated and may provide benefit in patients with PAD who are not eligible for revascularization.\textsuperscript{157}

To date, there have been very few randomized clinical trials evaluating
cell therapy in the treatment of PAD (see Table 68-5). Most studies have recruited relatively small numbers with varying degrees of PAD severity ranging from intermittent claudication to critical limb ischemia, and the cell products have largely been autologous bone marrow–derived cells. Reported end points in critical limb ischemia studies have included ankle-brachial index, transcutaneous oxygen saturation, angiography, amputation-free survival, and pain scales. In claudication trials, pain-free walking time/distance, total walking times on treadmill, and walking questionnaires have been also used. Larger clinical trials are under way (see Table 68-4).

CONCLUSION

Although at this time no data support either cell-based or specific stem cell therapies as standard clinical practice for cardiovascular repair, there is a wealth of early clinical data demonstrating the safety, feasibility, and early efficacy of cell-based therapy. The mechanisms by which stem/progenitor cells improve cardiovascular function continue to be investigated with evidence supporting paracrine effects that lead to increased angiogenesis, decreased apoptosis, and induction of endogenous stem cells. Several questions being addressed include (1) the optimal cell type for each disease state, (2) the use of autologous versus allogeneic cells, (3) the optimal cell number, (4) the ideal route of delivery, (5) the timing and frequency of cell therapy in each clinical scenario, and (6) the regulatory and commercial challenges for advancement of this field. Stem cell therapy has the potential to help millions of patients with advanced cardiovascular disease, but its role and clinical practice remains to be defined.

**MULTIPLE CHOICE QUESTIONS**

1. Which of the following is not a proven mechanism for cell therapy–mediated cardiovascular repair and regeneration?
A. Differentiation or transdifferentiation into new cardiac or vascular cells
B. Secretion of growth factors and cytokines that promote vasculogenesis and prevent apoptosis
C. Stimulation of endogenous cardiac precursor cells
D. Entire organogenesis from injected stem cells

2. Which of the following cellular delivery mechanisms results in the highest retention of delivered cells to the myocardium?
   A. Intracoronary arterial administration to areas of interest with intermittent balloon catheter inflation (stop-flow)
   B. Intravenous injection into a peripheral vein
   C. Direct intramyocardial injection using open surgical or catheter-based approaches
   D. Engineered monolayer tissue transplantation

3. The injection of which stem cell type has been associated with increased risk of ventricular arrhythmias?
   A. Skeletal myoblasts
   B. Bone marrow–derived stem and progenitor cells
   C. Mesenchymal stem cells
   D. Resident cardiac progenitor cells

4. Which of the following are factors that affect the success of stem cell transplantation in the treatment of cardiovascular disease?
   A. Type of stem or progenitor cells transplanted
   B. Ease and feasibility of cell harvesting and culture
   C. Timing of cell therapy
   D. Number of cells administered and retained in target areas
   E. All of the above

5. Which of the following characteristics make mesenchymal stem cells ideal for allogeneic (ie, off the shelf) transplantation?
   A. Paracrine release of soluble growth factors and cytokines
   B. Lack of expression of major histocompatibility complex class II antigens
   C. Downregulation of lymphocyte proliferation and suppression of
immune cell maturation
D. Ability and potential for ex vivo culture and expansion of >50 population doublings
E. All of the above

ANSWERS

1. D
Mechanisms by which cell therapy leads to cardiovascular repair and regeneration remain a subject of controversy. Although differentiation or transdifferentiation into new cardiac or vascular cells was initially believed to be the primary mechanism, recent studies suggest that stimulation of endogenous precursor cells, secretion of growth factors and cytokines (paracrine effect) that promote vasculogenesis and prevent apoptosis, or rarely, fusion of donor cells with host cells may be potential mechanisms. Together, these cellular changes result in enhanced perfusion, reduced infarct size, improved left ventricular remodeling, and ultimately improved cardiac function and patient mortality. Entire organs are not formed from administered stem cells. Most of the regenerated tissue is formed from endogenous cells.

2. C
Intravenous infusion of stem cells is associated with the lowest rates of myocardial cell retention as the majority of intravenous infused cells become trapped in the pulmonary, hepatic, and splenic microvasculature. Intracoronary infusion circumvents the pulmonary and hepatic first-pass effect by delivering cells directly into target areas of myocardium. When delivered using a stop-flow method with intermittent balloon arterial occlusion, there is increased homing to the supplied areas. However, infusion of larger mesenchymal stem cells has been associated with embolization of the microvasculature. Although more invasive and associated with a greater risk of myocardial perforation, transendocardial injection leads to the greatest rates of cell delivery and retention, especially when used in conjunction with electromagnetic mapping catheter systems. Although promising, the use of engineered monolayer tissue transplantation has not been studied in human
Skeletal myoblasts are skeletal muscle precursors that possess a contractile phenotype and are relatively resistant to ischemia and oxidative stress. Although skeletal myoblasts can differentiate into functionally competent myofibers after engraftment, they suffer a high attrition rate. Surviving myofibers fail to develop intercalated discs and remain electromechanically isolated from the host myocardium, which may promote the generation of ventricular arrhythmias. While cell therapy was associated with a higher number of arrhythmic events, it did not result in significant differences in major adverse cardiac events, and the administration of periprocedural amiodarone may be successful in reducing the number of arrhythmic events.

Initial clinical trials involving stem cells were heterogeneous, and the number of cells delivered and retained differed by more than a 1000-fold. There is increasing evidence that higher doses of intracoronary-delivered mononuclear cells after acute myocardial infarction are accompanied by greater therapeutic effect. Delivery methods and their feasibility have important impact on cell retention and safety. In certain cases, timing of cell therapy, particularly after acute myocardial infarction, is crucial as very early administration may lead to poor survival of injected cells due to the hostile environment with inflammatory cell infiltration and delayed administration is likely to encounter irreversible fibrosis and scar. Due to limitations in autologous stem cells and the expense and time it takes for ex vivo expansion, the potential of allogeneic “off-the-shelf” cell therapy using cells from young healthy donors poses an attractive alternative.

Mesenchymal stem cells are rare nonhematopoietic, multipotent cells of mesodermal origin that constitute 0.01% to 0.001% of bone marrow nucleated cells. They influence neighboring cells by direct cell-to-cell interaction and by paracrine release of an array of soluble growth factors and cytokines. Unlike other bone marrow–derived cells, mesenchymal stem cells possess immune properties that make them potential candidates for safe
allogeneic therapy in immune-competent patients. Their relatively immune-
privileged phenotype prevents activation of host immune cells because they
lack surface expression of major histocompatibility complex class II antigens
and costimulatory molecules for T-cell induction. Furthermore, mesenchymal
stem cells downregulate lymphocyte proliferation and suppress the
maturation and function of immune cells via the secretion of soluble factors.
Under optimal conditions, the progeny of colony forming unit fibroblasts can
be expanded for upward of 50 population doublings. Their immune-
privileged phenotype and capacity for ex vivo expansion make them ideal
candidates for allogeneic transplantation.
The Core Laboratory: Quantitative Coronary Angiography

Vivian G. Ng
Alexandra J. Lansky
Johan H. Reiber

BASIC PRINCIPLES OF CORONARY ANGIOGRAPHY AND IMAGING

Coronary angiography remains the gold standard for imaging coronary anatomy and defining the extent and precise location of coronary artery disease. Optimal coronary angiography is dependent on a thorough knowledge of coronary anatomy and a systematic imaging sequence protocol that enables visualization of all coronary segments, particularly areas of vessel overlap, bifurcations, or tortuous anatomy. A basic map of the coronary anatomy is delineated in Figure 69-1, and the optimal views for imaging each coronary segment are summarized in Table 69-1 (Figs. 69-2 through 69-5). Although standard views are generally consistent from one patient to the next, the precise angulations tend to vary based on the variations in anatomic orientations. A number of coronary segment numbering systems have been established; the most commonly used is the Coronary Artery Surgery Study (CASS) numbering system derived from the Bypass Angioplasty Revascularization Investigation (BARI) study,\(^1\) which assigns a unique number to each coronary vessel segment and its branch.
vessels and has gained wide acceptance in interventional clinical trials (Table 69-2).

Abbreviations: LAD, left anterior descending (artery); PDA, peripheral distal artery; PLSA, posterolateral spinal artery; RCA, right coronary artery; RV, right ventricle. A prefix of “1” is added to the CASS segment to designate saphenous vein grafts and numbered according to the location of the distal anastomotic insertion site of the conduit; a prefix of “2” is affixed to designate an arterial grafts.
The progression and regression of coronary atherosclerotic lesions is a dynamic process.\textsuperscript{2,3} Compensatory mechanisms, known as \textit{coronary artery remodeling}, is a complicating factor in the angiographic evaluation of the severity and extent of coronary atherosclerosis. \textit{Coronary artery remodeling} is characterized by a compensatory enlargement of the atherosclerotic coronary artery that occurs in the early stages of plaque formation\textsuperscript{4,5} and results in the preservation of the luminal cross-sectional area (and angiographic appearance) of the artery, thus minimizing the hemodynamic effects of the atherosclerotic plaque. As the maximal stretching capacities of the vessel are reached, the expansion of the vessel stops, and further plaque deposition begins to impinge on the lumen. It is only once the lumen of the vessel becomes compromised that it becomes visible on x-ray arteriography, which visualizes only the 2-dimensional contrast-filled lumen.

\textbf{Qualitative Angiography}

Typically, atherosclerosis is characterized angiographically as a series of focal narrowings on a background of diffuse atherosclerosis within the entire coronary artery system. Because x-ray arteriography depicts only the coronary lumen, it tends to underestimate the presence of diffuse atherosclerosis and is essentially unable to detect the early stages of coronary atherosclerosis. Cross-sectional imaging of the coronary arteries is better assessed in these early stages by intravascular ultrasound (IVUS), which can provide real-time high-resolution cross-sections of the arterial wall and demonstrate the presence or absence of plaque deposition and compensatory arterial enlargement.

\textbf{Qualitative Assessment of Lesion Morphology}

Several angiographic morphologic characteristics have been identified that have short- and long-term prognostic implications on outcome after coronary intervention with balloon angioplasty and stent implantation.\textsuperscript{6} Recent studies evaluating the prognostic implication of morphologic characteristics on patients undergoing intracoronary stenting demonstrate that these remain predictors of angiographic success, but not clinical outcome. Specific lesion morphologic criteria that contribute to the complexity of a lesion include:
1. Lesion location (proximal, mid, distal, ostial, or anastomotic). Ostial lesions begin within 3 mm of the origin of a major epicardial artery. Anastomotic lesions begin within 3 mm of the insertion of a saphenous vein graft (SVG) or arterial conduits into the native vessel.

2. Lesion length, which is classified as discrete (<10 mm in length), tubular (10-20 mm in length), or diffuse (≥20 mm in length).

3. Eccentricity of the lesion.

4. Angulation of the lesion (Fig. 69-6), classified as mild (<45°), moderate (45°-89°), or severe (≥90°).
FIGURE 69-6 Left anterior oblique (LAO) view of the right coronary artery. Demonstrates a moderately angulated stenosis on a 90° bend.

5. Presence of thrombus (Fig. 69-7).
FIGURE 69-7 Left anterior oblique view of the right coronary artery. This view demonstrates a classic large globular thrombus at the lesion site.

6. Vessel tortuosity (Fig. 69-8), classified by the number of bends present before reaching the target lesion: none/mild (<2 bends), moderate (2 bends >75° or 1 bend >90°), or severe (2 bends >90°).
FIGURE 69-8 Left anterior oblique view of the right coronary artery. This view demonstrates a moderately to severely tortuous vessel with 2 bends more than 90° prior to reaching the stenosis.

7. Calcification.
8. Ulceration, defined by the presence of a crater or lumen flap in the area of
9. Aneurysm, defined by a lumen expansion of at least 50% in the region of maximum stenosis (Fig. 69-9).

![FIGURE 69-9](image)

**FIGURE 69-9** Left and right anterior oblique views of the right coronary artery (RCA). This view demonstrates a large coronary aneurysm in the proximal segment of the RCA.

10. The presence of a bifurcation of the parent vessel with a branch vessel.

These criteria have been used to define the complexity of a lesion and are the basis of the modified American Heart Association (AHA)/American College of Cardiology (ACC) complexity score. Although this scoring system was initially created and validated for predicting outcomes after balloon angioplasty, its utility persists in the modern era of percutaneous coronary interventions. In the Acute Catheterization and Urgent Intervention Triage Strategy (ACUITY) trial, patients with moderate- or high-risk non-ST-segment elevation myocardial infarctions were randomized to heparin plus a glycoprotein IIb/IIIa inhibitor, bivalirudin with glycoprotein IIb/IIIa inhibitor, or bivalirudin alone. After angiography, the patients were triaged to medical therapy, percutaneous intervention, or coronary artery bypass grafts. Among patients treated with percutaneous coronary interventions and who had formal angiographic analysis, patients with type C lesions had higher 30-day rates of mortality (1.2% vs 0.6%; \( P = .049 \)) compared to those without type C lesions. By multivariable analysis, type C lesions were independently
associated with myocardial infarction (odds ratio, 1.37; 95% confidence interval [CI], 1.04-1.80; \( P = .02 \)) at 30 days. Thus, angiographic lesion complexity continues to provide important prognostic information.

1. Type A lesions are characterized by focal (<10 mm length) concentric lesions with smooth contours, little or no calcification, less than totally occlusive, nonangulated (<45° bend), not ostial, without major side branch involvement, and without thrombus.

2. Type B lesions are categorized as type B1 or B2 lesions depending on whether a single or more than 1 B characteristic is present. These include tubular lesions (10-20 mm length), with moderate to severe calcification, eccentric plaque, moderate proximal tortuosity, irregular contour, angulation 45° or more and less than 90°, ostial location, involving a bifurcation, or containing thrombus.

3. Type C lesions have 1 or more of the following complex characteristics: diffuse (≥2 cm length), degenerated SVG, total occlusion, excessive proximal tortuosity, or extreme angulation (≥90°).

**Assessment of Collaterals**

Many factors contribute to the growth of collaterals, including hypoxemia and the release of angiogenic factors. Collateral identification and quantification are important in the context of clinical trials assessing growth factors and revascularization techniques. Collaterals are defined by their site of origin as ipsilateral (collateral between the left anterior descending [LAD] artery and left circumflex [LCx] artery or vice versa), as bridging (collateral originates from the same coronary artery) (Fig. 69-10), or as contralateral (collateral from the left to right coronary artery or vice versa) (Fig. 69-11). The Rentrop Collateral Classification grades the collateral according to the extent of filling of the major epicardial vessel the collateral is supplying.\(^8\) Other less well-validated parameters that have been used for assessing collaterals include the collateral size; the collateral frame count, measured by the number of frames from opacification of the guiding catheter to the filling of the collaterals; and collateral density, measured as the number of collaterals (>1 mm) per square centimeter in a region of interest.\(^9\)
FIGURE 69-10 Right anterior oblique view of the right coronary artery (RCA). Demonstrates a total occlusion in the mid-RCA, with bridging right to right collaterals filling the distal vessel.
Assessment of Flow

The traditional method for assessing and grading epicardial flow was defined by the Thrombolysis in Myocardial Infarction (TIMI) Study Group and was graded according to the following criteria:

1. Grade 0 refers to no anterograde flow beyond the point of arterial occlusion.
2. Grade 1 is defined by the appearance of contrast beyond the point of arterial obstruction but fails to opacify the entire distal coronary bed.
3. Grade 2 is defined by contrast opacification of the entire coronary bed.
distal to the stenosis but at a rate of entry and/or clearance that is slower than in the other epicardial vessels unaffected by the stenosis. Complete filling of the artery and its major and minor branches occurs after more than 3 full cardiac cycles, or alternatively, delayed contrast washout in the target lesion territory may occur, compared with comparable areas of myocardium not perfused by the target lesion.

4. Grade 3 is defined as complete or normal perfusion, with anterograde flow of contrast and complete filling of the artery with its major and minor branches within 3 full cardiac cycles.

Other measures of epicardial perfusion include continuous variables. The TIMI frame count is defined by the number of frames necessary for the contrast column to completely fill the coronary artery at a constant acquisition frame rate. The corrected TIMI frame count is a similar measure that corrects for variability in coronary lengths by using specific anatomic landmarks and specifically corrects for the longer length of the LAD coronary artery.  

The prognostic importance of establishing TIMI-3 flow in patients with acute myocardial infarction has been demonstrated to be the predominant determinant of survival after thrombolytic and primary intervention reperfusion strategies.  

Patients reperfused with primary angioplasty within 2 hours of symptom onset have lower mortality and greater myocardial salvage after primary percutaneous transluminal coronary angioplasty (PTCA) than patients with delayed reperfusion. The importance of early reperfusion is also emphasized in patients spontaneously achieving TIMI-3 flow prior to primary PTCA, as demonstrated in 10% to 20% of patients at the time of initial angiography. Factors influencing early spontaneous reperfusion may include endogenous fibrinolysis and/or pretreatment with aspirin, adenosine diphosphate (ADP) antagonists, and heparin. In an analysis of the 2507 patients from the 4 major Primary Angioplasty in Myocardial Infarction (PAMI) trials, TIMI-3 flow was present at initial angiography (spontaneous reperfusion) in 16% of patients. No baseline demographic characteristics clearly predicted spontaneous reperfusion; however, early reperfusion with initial TIMI-3 flow prior to PTCA was a powerful and independent predictor of in-hospital and late survival in patients undergoing a mechanical reperfusion strategy. The independent impact of initial TIMI-3 flow on survival persisted even when
corrected for postprocedural TIMI-3 flow.\textsuperscript{23} This observation suggests that early pre-PTCA reperfusion has benefits independent of promoting the ultimate restoration of TIMI-3 flow. Furthermore, in the contemporary era of drug-eluting stents, dual antiplatelet therapy, and glycoprotein IIb/IIIa infusions, spontaneous recanalization of the culprit artery continues to be associated with improved outcomes. In the HORIZONS-AMI trial, ST-segment elevation myocardial infarction (STEMI) patients were randomized to either bivalirudin or heparin plus glycoprotein IIb/IIIa inhibitors. Patients with spontaneous TIMI-2 or -3 flow on baseline angiography had lower 1-year mortality rates compared to patients with TIMI-0 or -1 (2.5\% vs 3.9\%, \( P = .04 \)). In addition, spontaneous reperfusion was an independent predictor of improved 1-year survival.\textsuperscript{24}

In contrast, in non–ST-segment elevation myocardial infarctions (NSTEMI), TIMI flow may be less predictive of outcomes. In the ACUITY trial, patients with TIMI-0/1, TIMI-2, or TIMI-3 flow had similar mortality rates at 1 year. Although patients with TIMI-0/1 flow were less likely to achieve TIMI-3 flow postprocedurally, TIMI-0/1 flow was not an independent predictor of 1-year mortality (\( P = .61 \)). Thus, reduced epicardial flow in moderate- and high-risk patients undergoing percutaneous coronary intervention (PCI) is not predictive of outcomes.\textsuperscript{25} It is unclear whether this is related to the pathophysiologic differences between the STEMI and NSTEMI patients. Nevertheless, these results suggest that emergent intervention to restore TIMI-3 flow early is less critical in NSTEMI patients compared to STEMI patients.

Although the main focus of coronary revascularization has been to restore normal epicardial blood flow, it is now widely accepted that normal epicardial blood flow does not necessarily equate to normal microvascular perfusion. Among patients with normal TIMI flow after revascularization, only 19\% to 28\% of patients achieve normal microvascular flow.\textsuperscript{26-29} Reduced perfusion at the tissue level after revascularization may be related to myocardial edema, microvascular spasm, or loss of microvascular integrity as well as distal thromboemoboli.\textsuperscript{30-32} Myocardial blush grade (MBG) is an angiographic surrogate of myocardial perfusion.\textsuperscript{33} The myocardial blush scoring system is based on the extent of ground-glass appearance within the myocardial territory subtended by the coronary artery of interest (Fig. 69-12). MBG is graded as follows:
FIGURE 69-12 Right anterior oblique view of the left coronary artery after primary intervention for acute myocardial infarction of the left anterior descending artery (LAD). A. Region of interest demonstrates minimal myocardial blush in the myocardial territory of the LAD (blush score = 0/1). B. Region of interest demonstrates normal myocardial blush (ground-glass appearance) in the myocardial territory of the LAD (blush score = 3).

1. MBG 0 suggests no ground-glass appearance.
2. MBG 1 is minimal ground-glass appearance.
3. MBG 2 is incomplete opacification of myocardium.
4. MBG 3 is normal myocardial opacification.

Although survival is lowest among patients without TIMI-3 flow after revascularization, MBG has also been shown to be independently predictive of mortality in acute myocardial infarctions after thrombolytic therapy and
after mechanical reperfusion.\textsuperscript{26,27,34} Furthermore, MBG provides risk stratification even among patients with TIMI-3 flow. Thus, despite achieving normal TIMI-3 flow after reperfusion therapy, patients with abnormal microvascular perfusion (MBG 0/1) have a persistently elevated mortality rate compared with patients with TIMI-3 flow and normal MBG.\textsuperscript{28,29,35}

In addition to the importance of MBG in risk stratifying STEMI patients, studies suggest that MBG is predictive of outcomes in NSTEMI patients. In the ACUITY trial, 3115 patients with non–ST-segment elevation acute coronary syndromes (NSTEMI) underwent PCI and had MBG analyzed by a core laboratory. MBG 0/1 was associated with higher rates of composite ischemia (death, myocardial infarction, or ischemia-driven revascularization) at 30-day follow-up and was an independent predictor of 30-day ischemia-driven revascularization. Furthermore, even if TIMI-3 flow was achieved in the culprit vessel, MBG-0/1 was still associated with worse 30-day outcomes. However, at 1 year, patients with or without normal myocardial perfusion had similar outcomes. Thus, MBG provides prognostic information for short-term outcomes in patients with NSTEMI.\textsuperscript{35} Additionally, abnormal myocardial perfusion in areas supplied by nonculprit vessels has also been associated with worse outcomes even when TIMI-3 flow is restored to the culprit vessel.\textsuperscript{36–40} When nonculprit MBG was evaluated in the ACUITY trial, patients with nonculprit MBG 0/1 had higher mortality rates even when there was TIMI-3 flow in the culprit vessel. In fact, in a multivariable analysis, MBG 0/1 in a nonculprit vessel was the strongest predictor of 1-year mortality in patients with culprit vessel TIMI-3 flow. Although abnormal myocardial perfusion in the culprit vessel is often attributed to the distal embolization of thrombus, this mechanism cannot explain impaired perfusion in nonintervened vessels. Instead, impaired perfusion in nonintervened vessels may be related to diffuse inflammation that is triggered by activation of inflammatory pathways locally at the site of plaque disruption.\textsuperscript{36} Therefore, impaired myocardial blush in culprit and nonculprit vessels provides important risk stratification information in NSTEMI patients.

**SYNTAX SCORE**

The SYNTAX score was developed in the SYNTAX (Synergy Between PCI With Taxus and Cardiac Surgery) trial as a means to characterize the
location, severity, and complexity of coronary artery lesions.\textsuperscript{41} The coronary tree is divided into 16 segments, and the segments are weighted by a multiplication factor based on the amount of blood flow normally provided to the left ventricle by each segment. In addition to weighing the amount of myocardium in jeopardy because of a lesion, the SYNTAX score also takes into consideration the severity and complexity of the lesion based on morphologic features such as bifurcation disease, trifurcation disease, ostial lesions, length, tortuosity, heavy calcification, thrombus, and diffuse disease. A score is provided for each lesion, and a summated score is provided for an overall SYNTAX score. Higher SYNTAX scores reflect more disease and possibly more complex disease. An interactive online program consisting of 12 preliminary questions with follow-up subquestions aids in calculating the SYNTAX score (\url{www.syntaxscore.com}). Within the SYNTAX trial, patients with low or intermediate scores had similar outcomes when treated with PCI or coronary artery bypass grafting. However, patients with high SYNTAX scores had worse outcomes when treated with PCI instead of coronary artery bypass grafting. Thus, in addition to providing a method of quantifying the complexity and severity of coronary artery disease, the SYNTAX score could potentially help guide revascularization therapy. However, the complexity of performing this scoring tool may limit its routine use in clinical practice. Although the SYNTAX score has an acceptable interobserver reproducibility and intraobserver reproducibility when performed by core lab technicians,\textsuperscript{42,43} there is poor reproducibility among untrained cardiologists.\textsuperscript{43} The reproducibility among cardiologists improves after additional training with core lab staff.\textsuperscript{43}

**PRINCIPLES OF VENTRICULOGRAPHY AND ANALYSIS CONSIDERATIONS**

Left ventriculography is most accurately performed using 30° right anterior oblique (RAO) and 60° straight left anterior oblique (LAO) (to minimize overlap of the apex and the diaphragm) projections. To evaluate function and wall motion abnormalities quantitatively, the end-diastolic and end-systolic
frames with the minimum and maximum volumes are selected from a well-opacified normal (nonpremature ventricular contraction) sinus beat. Endocardial contours can be traced using commercially available software. Wall motion is most commonly measured by the centerline method along 100 chords constructed perpendicular to a centerline midway between the end-systolic and end-diastolic contours and normalized by the end-diastolic perimeter to standardize chord lengths. This results in a dimensionless shortening fraction, a linear equivalent of the volume ejection fraction. Abnormality in chord motion is reported in units of standard deviation from the mean of normal biplane left ventriculograms, with negative values indicating hypokinesis and positive values indicating hyperkinesis. The centerline method has been extensively validated.

To minimize measurement variability and increase sensitivity and specificity using this method, wall motion in each territory is computed from the average motion of the chords confined to the most abnormally contracting 50% of the territory. The region of the left ventricle in the RAO and LAO projections considered the territory of each coronary artery has been defined from patients with isolated stenoses and infarcts of the LAD, the right coronary artery (RCA), and the LCx (Table 69-3). LCx disease results in widely variable hypokinesis over the entire contour of the left ventricle that spans both anterior and inferior distributions. This is a consequence of the variable anatomy of the LCx, with left dominant systems exhibiting inferior distribution hypokinesis, and right or balanced systems exhibiting anterior hypokinesis. Extended search chord regions have been identified based on patients with known LCx infarcts to increase the sensitivity of detecting LCx regional hypokinesis. In the 30° RAO view, chords 48 to 80 are specific to the LCx (chords 0-21 and 81-100 are excluded because of variability associated with overlap from RCA and LAD territories, making these regions nonspecific to the LCx). The RAO view is less specific than the LAO view for assessing LCx disease. In the 60° LAO view, LCx infarcts result in longer regions of hypokinesis compared to the RAO view, with extended LCx-specific chords spanning from chords 10 through 100 being more sensitive than the previously defined limited chord region of 19 to 67. The LAO view is more specific and sensitive in evaluating the LCx in a right dominant coronary system.

**PRINCIPLES OF QUANTITATIVE CORONARY ANGIOGRAPHY**

The field of quantitative coronary angiography (QCA) has evolved tremendously since the mid-1980s concurrently with advances in image acquisition.\(^47\) First-generation QCA systems, developed in the 1980s, were based on 35-mm cine-film analysis. However, cine-film–based x-ray systems were rapidly replaced by complete digital systems. The wide acceptance of the cineless cardiac catheterization laboratory has been spurred by several advantages, including a reduction in radiation exposure necessary for equivalent image processing, reduction in storage space with online image archiving and retrieval, and universal networking.\(^48\)

Second-generation QCA systems (1990-1994) had further improvements in the quality of the edge detection, more frequently applied to digital images (which is not a mere application of the algorithm for cine-based analysis to digital analyses), and included corrections for the overestimation of small vessel sizes (< ~1.2 mm).\(^49\) Digital systems are characterized by well-defined and constant nonlinear functions (the white compression), absence of grain noise, and ability to apply edge enhancement, all of which improve image quality.

Third-generation (1995-1998) QCA systems provided solutions for the quantitative analysis of complex lesion morphology using, for example, the Gradient Field Transform (GFT)\(^50\) and improved diameter function calculations.\(^51\) Fourth-generation QCA systems, available since 1999, are characterized by simplified portability to digital DICOM (Digital Imaging
and Communication in Medicine) viewers, network connectivity, improved reporting and database facilities, and options for specialized QCA functions, such as drug-eluting stent analyses. Although most modern QCA packages are based on the linear programming approach (ie, minimal cost algorithm) for contour detection, there are still differences in the qualities of these packages that must be documented by extensive validation reports.

**Basic Principles of Quantitative Coronary Arteriography**

For a QCA package to be applicable in a routine clinical or research environment, a number of requirements must be met, which include the following: (1) minimal user interaction in the selection and processing of the coronary segment to be analyzed; (2) minimal editing of the automatically determined results; (3) short analysis time (10 seconds or less); and (4) highly accurate and precise results, with small systematic and random errors. These criteria should be demonstrated by extensive validation studies using phantom and routinely acquired clinical studies.

**Basic Principles of Automated Contour Detection**

The general principles and characteristics of a modern QCA software package that satisfies these requirements are best illustrated by the QCA-CMS (Clinical Measurement Solutions, MEDIS) algorithms. The QCA operator selects (Fig. 69-13A) the coronary segment to be analyzed by defining the start and end points of the arterial segment. An arterial pathline through the arterial segment is computed automatically (Fig. 69-13B). The contour-detection procedure is carried out in 2 iterations relative to a model. In the first iteration, the detected pathline is the model. To detect the contours, scanlines are defined perpendicular to the model (Fig. 69-13B). For each point or pixel along such a scanline, the corresponding *edge-strength value* (local change in brightness level) is computed as the weighted sum of the corresponding values of the first- and second-derivative functions applied to the brightness values along these scanlines (Fig. 69-14). The resulting edge-strength values are input to the minimal cost analysis (MCA) contour-detection algorithm, which searches for an optimal contour path along the entire segment (Fig. 69-13C). The individual left and right vessel contours detected in the first iteration now serve as models in the second iteration, in
which the MCA contour-detection procedure is repeated relative to the new models.

**FIGURE 69-13** Basic principles of the minimum cost analysis (MCA) contour-detection algorithm. A. Initial segment. B. Scanlines defined. C. Straightened for analysis; contours calculated. D. Contours returned to initial image; diameter measurements performed.
FIGURE 69-14 Schematic presentation of the brightness profile of an arterial vessel assessed along a scanline perpendicular to the local pathline direction and the computed first derivative, second derivative, and the combinations of these first and second derivative functions; the maximal values of the last functions determine the edge positions.

To correct for the limited resolution of the entire x-ray system, the MCA algorithm is modified in the second iteration based on an analysis of the quality of the imaging chain in terms of its resolution, which is of particular importance for the accurate measurement of small diameters, as in coronary obstructions. If such a correction were not applied, significant overestimation of vessel sizes smaller than approximately 1.2 mm would occur. If the QCA operator does not agree with 1 or more parts of the detected contours, they
can be edited in various ways. However, each manual editing is followed by a local MCA iteration, so that the newly detected contours are truly based on the local brightness information. In other words, the operator indicates roughly where the contour should be detected, and the MCA algorithm searches for the final contour based on the available image information (Fig. 69-13D).

**Calibration Procedure**

Image calibration is performed on a nontapered portion of the contrast-filled catheter using an MCA edge-detection procedure similar to that applied to the arterial segment. In this case, however, additional information is used in the edge-detection process because this part of the catheter is characterized by parallel boundaries. Catheter calibration is frequently the weakest link in the analysis chain because of the variable image quality of the displayed catheters and the potential problem of out-of-plane magnification, which can occur when the catheter and the coronary segment are positioned at different distances from the image intensifier. Biplane calibration can overcome this limitation\(^{56-58}\) but is rarely applied in routine QCA.

**Coronary Segment Analysis**

A diameter function is determined from the contours of the arterial segment (Fig. 69-15). Calculation of the width of a vessel segment along its trajectory is not a trivial task, especially not in a situation of complex anatomy.\(^{51}\) The most widely used parameter to describe the severity of a coronary obstruction is the percentage of diameter narrowing. Calculation of this parameter requires computation of a reference diameter, which can be derived in 1 of 2 ways: (1) a “user-defined” reference diameter is identified by the user at a so-called normal portion of the vessel, or (2) the interpolated reference diameter value is calculated, requiring no user interaction and accounting for vessel taper. The interpolated reference diameter function is calculated by an iterative regression technique that excludes the influence of obstructions or ectatic segments. In cases of extensive ectatic segments, the user can “flag” the portion of the vessel segment (Fig. 69-16B), and the corresponding diameter values are excluded in the subsequent calculation of the reference diameter function. However, correction cannot be made in the presence of
diffuse atherosclerosis along the vessel segment, because angiography is a 2-dimensional lumenogram. The difference in area between the detected lumen contours and the interpolated reference contours is a measure for the atherosclerotic plaque (see Fig. 69-15).

**FIGURE 69-15** The results of the minimal cost analysis, including the reconstructed original vessel contours, plaque area (shaded), and the diameter function, are presented for QCA-CMS V4.0. All the derived absolute and relative quantitative coronary angiography (QCA) parameters are presented in the QCA DICOM box (left).
FIGURE 69-16 Example of a vessel with an ectatic area. A. Straightforward application of the reference diameter function would lead to arbitrary, erroneous results; in this case, in significant tapering of the reference diameter function (arrow). B. By “flagging” the proximal ectatic area, a nontapering reference diameter function (arrow) results with appropriately reconstructed vessel reference contours.

The interpolated reference diameter value corresponding to an obstruction is taken as the value of the reference diameter function at the site of the obstruction, thereby neither overestimating nor underestimating the reference. From the reference diameter value and the obstruction diameter, the percent diameter narrowing is calculated. This automated approach has been found to
be very reproducible. From the calculated diameter function, many
parameters can be determined including obstruction symmetry, inflow and
outflow angles, and the area of the atherosclerotic plaque.

Modern contour detection approaches are based on the MCA algorithm,
which has been demonstrated to be fast and robust for images that may vary
significantly in image quality. This approach has been shown to work very
well as long as the vessel and lesion outlines are relatively smooth. However,
complex vessel morphology may occur before (ulcerated lesions) and after
coronary intervention (dissections).

Densitometry

Because the x-ray arteriogram is a 2-dimensional projection image of a 3-
dimensional structure, measured vessel sizes may be of limited value in
vessels with very irregular cross-sections. Many efforts have been devoted to
deriving information from densitometric measures based on the brightness
within the coronary arteries. If a valid relation between density and arterial
dimensions could be established, other parameters such as the arterial cross-
sectional area could be derived from a single angiographic view.

Unfortunately, densitometry has not provided reliable results, particularly
from cine film,\textsuperscript{59} and as a result, the interest in it has largely diminished. It
may be of interest to revisit the densitometric approaches for the digital
systems in which the entire transfer function of the x-ray system is better
controlled and more stable than with the use of cine film.

QCA of Bifurcations

Bifurcation lesions are coronary artery lesions that are located near or involve
the ostium of a side branch.\textsuperscript{60} A single description based on the section of the
coronary artery and percent stenosis do not adequately characterize the
involvement of the side branch. The Medina Classification classifies
bifurcation lesions by dividing the bifurcation into 3 segments: (1) main
branch proximal, (2) main branch distal (MBD), and (3) side branch (SB). A
binary value (0, 1) is assigned to each branch in the above described order
representing whether a lesion with a >50\% stenosis is present (assigned 1) or
not (assigned 0).

Conventional QCA methodologies cannot be directly applied to
bifurcation lesions because of several obstacles, including image acquisition, defining vessel segments, and accurately identifying reference vessel diameter. For example, while standard QCA requires 2 orthogonal views that are at least 30° apart, there is often only 1 view in which bifurcation lesions are well visualized without foreshortening of either vessel and without vessel overlap. Furthermore, accurately determining the reference vessel diameter of the parent vessel and of the branches is a fundamental challenge to QCA analysis of bifurcation lesions. The diameters of coronary vessels decrease as the proximal main vessel bifurcates, a phenomenon well described in the coronary vasculature and defined by Murray’s law ($D_1^3 = D_2^3 + D_3^3 + \ldots$). Thus, the diameter of the main vessel “steps down” after the branch point. This is problematic because traditional QCA algorithms assume minimal vessel tapering. This results in the reference vessel diameter of the proximal segment of the main branch being underestimated while the reference vessel diameter of the distal main branch is overestimated.

Two dedicated QCA programs are available to improve QCA analysis of bifurcation lesions by decreasing the amount of editing by the user, systematic and random error, and processing time: the Medis Medical Imaging Systems bifurcation application (QAngio XA V 7.3, Leiden, the Netherlands) and CAAS 5 Pie Medical Bifurcation Imaging software (Maastricht, the Netherlands). In both systems, the user defines the proximal start point and the 2 distal branches. Pathlines are created semi-automatically and may be adjusted manually. The arterial contour is generated for all 3-vessel segments following a minimum cost algorithm.

The programs differ in how they define the bifurcation and its measurements. Medis Medical uses 2 bifurcation models depending on the angulation of the side branch. A T-shaped bifurcation model is used when there is a wide angle between the distal main branch and the side branch, whereas a Y-shaped bifurcation model is used when there is a narrow angle between the distal main branch and the side branch. Three separate reference vessel diameters are calculated for the 3 segments (proximal main branch, distal main branch, and side branch) using the conventional Medis straight analysis. The reference vessel diameter for the carinal region is determined from a reconstruction of the 3 segments. In contrast, the carinal region in the CAAS 5 Pie Medical Bifurcation Imaging software is defined as a best fit circle drawn with its center located where all the centerlines meet (point of
bifurcation) and with its edges touching the carina and both vessel walls. The centerlines are lines drawn through the center of each segment. A polygon of confluence is then drawn by drawing lines connecting the luminal walls bounding the circle. This defines the carinal region. Areas outside of the polygon of confluence are analyzed like single vessels.

These systems have been validated in a phantom validation study looking at 6 bifurcation models created in Plexiglas. As expected, the conventional QCA programs underestimated the reference vessel diameter in the main branch while overestimating the reference vessel diameter in the side branch. However, both the CAAS 5 Pie and the Medis Medical software showed high and comparable accuracy and precision in determining the reference vessel diameter and mean luminal diameter and should be used for any bifurcation analysis.65

Functional Assessment of Coronary Artery Lesions

The goal of coronary artery interventions has moved away from revascularization of coronary artery obstructions solely based on visual characteristics to revascularization of coronary artery disease that has objective evidence of ischemia. Fractional flow reserve (FFR)-guided PCI is a major advance in the diagnosis of ischemia in the catheterization laboratory. When patients with stable angina are selectively treated with PCI based on FFR, there is a reduction in major adverse cardiac events rates (death, myocardial infarction, repeat revascularization) compared to angiography-guided PCI alone66 or compared to optimal medical therapy.67 FFR is now a class IA recommendation in the European Society of Cardiology and a class IIa (Level of Evidence A) recommendation in the US joint guidelines.68,69 However, this procedure is not risk-free and requires systemic anticoagulation and the placement of an intracoronary wire. Recently, a method of determining FFR via QCA (FFRQCA) has been developed.70

The current FFRQCA application is simple and can be obtained using standard diagnostic angiographic techniques. Two angiographic projections of each coronary artery with minimal overlap and foreshortening are obtained at least 25° apart. At least 1 projection should be obtained during intracoronary or intravenous adenosine-induced hyperemia in addition to using intracoronary nitroglycerin. A 3-dimensional reconstruction is built based on these images and the hyperemic volumetric flow rates derived from
TIMI frame count and adjusted to parent and daughter vessel flow distribution. The patient’s hematocrit and mean arterial pressure are also inputted into the FFRQCA software. FFRQCA is then derived from computational fluid dynamics applied to the reconstruction of the patient’s entire coronary tree including side branches. By including side branch evaluations, the software can better approximate the amount of myocardium at risk. This method eliminates the risk associated with guide wire and intracoronary wire placement. The processing time for a complete longitudinal FFR computation of each coronary vessel and its side branches is expected to be less than 2 minutes in a fully integrated and automated program. In addition to individual lesion evaluations, FFRQCA would allow for a complete evaluation of the coronary tree.

FFRQCA has been demonstrated to have good diagnostic accuracy (88%), negative predictive value (91%), and positive predictive value (82%) compared with invasive FFR, with an area under the receiver operating characteristic curve of 0.93 in a patient population with intermediate lesions.\(^7^0\) The ease of performing this analysis with minimal impact on routine image acquisition could lead to rapid incorporation of this technology. This diagnostic tool will likely prove valuable in risk stratifying patients with ischemic heart disease by aiding in the identification of lesions causing significant ischemia and by reducing revascularization of insignificant lesions.

**FUTURE DIRECTIONS**

Further development and refinements of networking capability from the catheterization laboratory to the cardiologist’s office and referring hospitals will have major implications on the rapidity and cost of transfer of vital patient information in the form of electronic medical records (EMR), for improved patient care, clinical research, and patient and physician education. Integration of other quantitative modalities, such as QCA and quantitative intravascular ultrasound,\(^5^6\) and in the future, novel diagnostic modalities such as infrared imaging will facilitate and guide the optimal interventional therapy for patients with established obstructive coronary disease and vulnerable plaque. Other angiographic measurement options including 3-dimensional reconstruction\(^5^6,7^1\) and other derived data such as wall shear
stress based on computational fluid dynamics, stress, and strain on the vessels in relation to the sites of the development of local atherosclerosis will further complement derived patient-specific data parameters to optimize therapeutic decision making and outcomes.

50. van der Zwet PM, Reiber JH. A new approach for the quantification of complex lesion morphology: the gradient field transform; basic principles and validation results. *J Am Coll Cardiol.* 1994;24:216-224.

On September 16, 1977, Andreas Gruentzig performed the first coronary angioplasty on a 38-year-old businessman with unstable angina and a discrete proximal left anterior descending (LAD) artery lesion. The procedure was a success, and on subsequent angiograms at 10 years and 23 years, the patient continued to have a patent artery.\textsuperscript{1,2} Gruentzig reported his first series of favorable results and immediately called for a prospective randomized trial comparing it to bypass surgery.\textsuperscript{3,4} The field of interventional cardiology was born, and percutaneous transluminal coronary angioplasty (PTCA) quickly spread, with multiple operators in many countries gaining experience.

Today, percutaneous coronary intervention (PCI) is the dominant form of coronary revascularization. The practice of interventional cardiology has changed dramatically to include numerous diagnostic, pharmacologic, and technologic advances. The challenge for the practicing interventionalist is deciding when to adopt new therapies or technologies, in which patients and clinical situations to apply them, and at what cost. Fortunately, in keeping with Gruentzig’s initial emphasis, the field now requires rigorous scientific
studies to evaluate these new therapies and technologies. As a consequence, the interventional cardiologist is faced with a large body of medical literature of varying quality.

Therefore, a framework for reading and evaluating the medical literature is necessary to make the best decisions for patient care. This practice, termed evidence-based medicine, is defined by Sackett et al\(^5\) as “the conscientious, explicit, and judicious use of current best evidence in making decisions about the care of individual patients.” Much of the general framework used in this chapter and in most of the current practice of evidence-based medicine has been adapted from the in-depth guide on evaluating and teaching the medical literature provided by Sackett et al.\(^6\) The goal of this chapter is to provide some tools and specific examples that help the reader become facile at reading and evaluating the medical literature, specifically clinical trials with a focus on interventional cardiology.

Sackett and colleagues\(^5,6\) have identified 3 steps as integral to the practice of evidence-based medicine. They are as follows: (1) asking a clinical question and finding an answer, (2) reading the answer article, and (3) applying the results to individual patient care. The first step, asking a clinical question and finding an answer, is not addressed directly in this chapter. With the increase in electronic resources, including PubMed, MEDLINE, and additional online references, most clinicians have access to the medical literature. The majority of the discussion focuses on reading the clinical trial article. Finally, there is a section on applying the results to the care of the individual patient. Many of the principles used in this chapter for evaluating the medical literature can be found in detail in the *JAMA User’s Guide to the Medical Literature* series.\(^7-10\)

**CASE SCENARIO**

You are in the cardiac catheterization lab with a cardiology fellow seeing a 62-year-old businessman with hypertension. The patient recently presented with increasing angina, for which he was admitted to the hospital and ruled out for a myocardial infarction. He was treated with 300 mg of clopidogrel on the night of admission and is now referred for cardiac catheterization. After discussing the diagnostic and potential interventional procedure with the patient, the fellow asks you if it would appropriate to treat the patient with
bivalirudin and provisional glycoprotein IIb/IIIa inhibitor (GPI), because she recalls reading a trial on its benefits. You tell the fellow that is a good question, and she should bring the REPLACE-2 trial to the next catheterization lab meeting for discussion. During your discussion with the fellow, you learn that another patient, a 70-year-old gentleman with an ST-segment elevation myocardial infarction is being brought to the catheterization lab. You ask the fellow to also bring the EUROMAX trial to the next cath lab meeting.

DOES THIS ARTICLE ADDRESS THE QUESTION?

To determine if an article answers a clinical question, a clearly defined clinical question is required. The clinical question is made up of 4 parts: the population or clinical problem, the intervention, the control, and the outcome of interest. The population or clinical problem should be defined as clearly as possible. For instance, in the case presented earlier, this could be a patient with unstable angina and obstructive coronary artery disease. The intervention should be easy to define in many of the clinical situations in interventional cardiology. These can range from pharmacologic to device therapies. Again, in the case of the 62-year-old gentleman above, the intervention is percutaneous intervention with bivalirudin and provisional GPI use. The comparison group may either be a placebo or the current standard of care. This also may be a pharmacologic therapy, interventional device, or usual standard care practices. In this case, the comparison group is heparin and GPI use. Finally, the outcome of interest can be many things. Often, the reader can determine if the outcome measure used in the clinical trial is of interest and clinically important. Death, myocardial infarction (MI), need for urgent target vessel revascularization, or bleeding might all be considered important outcomes for this clinical situation.

In this example, the clinical question could be phrased as, “In patients with coronary artery disease, does percutaneous intervention with bivalirudin and provisional GPI use compared to heparin and GPI use decrease death, MI, urgent target vessel revascularization, or bleeding?” Using these simple
criteria, many clinicians will be able to glance quickly through article titles to determine if the question is addressed. Once this first step in reading a clinical trial is accomplished, the reader can move to step 2, determining if the results are valid.

ARE THE RESULTS VALID?

Determining if the results reported in a clinical trial are valid is the most important and time-consuming step in reading an article. The goal of determining the validity of a study design is to ensure the results reported are accurate. If the experiment or the clinical trial was set up in an unbiased manner, then the results are believable. However, if there is a major flaw in the experimental design, then the reader may interpret the results cautiously and potentially disregard the results. Unfortunately, for many clinical questions about therapeutics, there is no perfect clinical trial design. Therefore, many trials have some aspects that are well designed and conducted and others that are not. The practice of applying the rigorous criteria for validity and determining each trial’s strengths and weaknesses helps lend weight to findings and ultimately helps makes clinical decisions. This ability to weigh different study results helps the reader practice the “judicious use of the best available evidence.”

In addition, understanding clinical trial design helps put future clinical trial results into the context of prior findings with an understanding of previous limitations in the medical literature. The criteria for evaluating the validity of a study depend on the type of study question: therapy, prevention, diagnosis, etiology, or harm. In this section, we review the validity methodology for therapy questions, as these are the most common questions addressed in the medical literature. However, the criteria for the other types of studies are also easily available for review in the JAMA series on using the medical literature.10,13,14

Step 1

Assess Randomization

The first step in determining the validity of a clinical trial evaluating a
therapy is to determine if the study was randomized and follow-up was complete. Randomization is a crucial step in evaluating a therapy and should be considered one of the cornerstones of good trial design. Randomization assures the equal distribution of both measured and unmeasured characteristics that may have an effect on the measured outcome. Not all methods of randomization are the same. Patients can be randomized to a therapy by simple, block, and stratified randomization methods.

Simple randomization is random allocation of either the experimental therapy or the control therapy to the patients. This is usually accomplished with computer-generated random numbers. However, in trials with smaller numbers of patients, there can sometimes be imbalances in the number of patients in each arm of the trial depending on where in the random number sequence enrollment is completed. For this reason, block randomization is used. Block randomization creates blocks (eg, of 4 or 6) in which there are equal numbers of patients receiving the experimental or control therapy. In this fashion, even if enrollment stops in the middle of a block, the imbalance between the numbers of patients in each group is limited.

Stratified randomization is used to achieve balance between important characteristics that may affect the outcome without losing the benefits of randomization. For example, the number of diabetic patients receiving an interventional therapy such as a type of stent may play an important role on the rate of restenosis, the outcome of interest. In this case, a separate randomization sequence would be developed for diabetic and nondiabetic patients. In this manner, the trial would continue to be randomized and have equal numbers of diabetic patients in each group.

The value of randomization cannot be emphasized enough, particularly in interventional cardiology trials. Numerous unmeasured variables that may affect the pharmacologic and device therapies used in addition to the experimental therapy are best controlled with randomization. Without randomization, observational cohorts must attempt to control for these factors by first identifying all of the variables and then applying statistical methods. For this reason, studies evaluating therapies without randomization must be seen as describing associations and not reflecting true effect. Several examples exist in which the findings from observational data were not confirmed in randomized controlled trials, the most notable of which is the effect of estrogen replacement therapy on cardiovascular outcomes.
Assess Loss to Follow-Up

After randomization is determined, the reader must focus on accounting for the patients in the trial. In accordance with the CONSORT guidelines for reporting randomized controlled trials, many trials now provide a diagram showing the flow of all patients in a clinical trial. This helps the reader quickly determine the dropout rate and follow-up of the study. If 500 patients are randomized to a particular interventional device and only 400 are seen in follow-up, then a potential for an unmeasured effect of the therapy exists. While no loss to follow-up would be ideal in preserving the benefits of randomization, this is seldom the case. Sackett et al\textsuperscript{6} have proposed a 5-and-20 rule of thumb, whereby <5\% loss to follow-up leads to little bias and >20\% loss to follow-up poses a serious threat to validity of the results. In trials where a considerable number of patients (~20\%) are lost to follow-up, significant caution must be used in interpreting the results. Even if the patients are not able to undergo all follow-up exams and procedures, the investigators must be able to report the outcome of these patients. If these data are not available, one way to assess whether the loss to follow-up can affect a trial’s results is to assume the worst-case scenario for the missing patients and to see how that would affect the results presented.

Step 2

Look for Blinding

The second step in evaluating the validity of clinical trial design in testing a therapy is in determining blinding. The goal of blinding is to ensure that once randomized, patients get care that is similar outside of the studied or control therapy. Blinding has numerous potential benefits depending on the trial design and individuals or groups that have been blinded. Blinding may reduce biased psychological responses to interventions and increase rates of complying with trial regimen among patients; reduce differential withdrawal, dose adjustment, or interventions by trial investigators; and most importantly, reduce information bias while analysis of the data is performed.\textsuperscript{15}

Blinding should be applied to as many potential parties as possible. In the case of pharmacologic therapies, the medical staff providing care, the patients, and the outcomes assessors can and should all be blinded. This
becomes more difficult in trials evaluating devices in interventional cardiology. It may not be feasible to blind the operator to the type of stent or the use of an atherectomy device. However, the patients, the other medical staff, the clinicians who see the patients in follow-up, the interventionalists who perform repeat angiograms, and the outcomes assessors can all be blinded to the therapy.

In the example cases, the investigators in the REPLACE-2 trial went to great lengths to retain blinding. Prior to randomization, the interventionalist specified a preference for abciximab or eptifibatide as the GPI of choice for the intervention. Each patient then received 3 infusions. In 1 treatment arm, patients received bivalirudin, heparin placebo, and GPI placebo, and in the other treatment arm, patients received bivalirudin placebo, active heparin, and active GPI. A blinded activated clotting time (ACT) was then performed, and active drug was given if the ACT was less than 225 seconds. Finally, if the interventionalist determined that provisional GPI was required, the active bivalirudin arm received active GPI, while the heparin and GPI arm received placebo GPI. In this fashion, blinding of the patients and medical staff was retained, which helped ensure patients in both arms of the trial received similar care during the procedure and afterward. On the other hand, the EUROMAX trial was an open-label trial—both the investigators and the patients were aware of which treatment was being administered. To minimize reporting bias that may be associated with open-label design of trials, the EUROMAX trial had an independent clinical events committee to adjudicate events blindly using standardized end point definitions.

**Compare Baseline Characteristics**

The next step is to determine if the patients were similar at the start of the trial. Most clinical trials present the baseline characteristics of the patients in the first table. If randomization was successful, the patients should be similar with regard to most characteristics. However, if the sample size for a randomized trial is very large, even modest differences may yield statistical significance. In such instances, the reader must be able to differentiate statistical significance from clinical relevance. As mentioned earlier, some important characteristics that affect the outcome may have been stratified, thus ensuring equal numbers of patients in each group. In smaller trials, there are often small differences in the groups. However, we would caution against
making any significant conclusions from these differences and would continue to lend weight to the process of randomization. At best, differences in the groups and direction of potential effect on the results should be noted prior to reading the results.

**Check for Intent-to-Treat Analysis**

The last part of the second step should be to determine how the patients were evaluated at the end of the trial. Specifically, was the analysis of the patients done based on the groups they were randomized to at the start of the trial, regardless of any crossover or dropout? This is defined as the *intent-to-treat principle* and is crucial in interventional clinical trials. This must be differentiated from an analysis of patients who received successful treatment. For example, if a group of patients were randomized to stent implantation or angioplasty, but the analysis for the outcome of urgent target vessel revascularization was carried out only in the group of patients who successfully underwent stent implantation, then the results would be biased toward the stent group. The stent may be difficult to deliver, and patients who were unable to undergo stent implantation may have higher rates of the desired outcome. Therefore, in both pharmacologic and device trials in interventional cardiology, the intent-to-treat principle is critical because it provides a conservative view of the benefit of a therapy, one that may be closer to actual practice.

In the Intra-aortic Balloon Counterpulsation and Infarct Size in Patients With Acute Anterior Myocardial Infarction Without Shock (CRISP AMI) trial, patients with anterior ST-segment elevation myocardial infarction without shock were randomized to receive either routine intra-aortic balloon counterpulsation (IABC) plus PCI or PCI alone. One hundred sixty-one patients were randomized to the IABC plus PCI group, while 176 were randomized to PCI alone. Of the 176 randomized to receive PCI alone, 15 patients crossed over and also received IABC therapy (5 prior to PCI and 10 after PCI). However, these patients were analyzed as part of the PCI-only group to preserve intent-to-treat analysis.

**Step 3**
Assess the Analysis Plan for Intended Comparison

The third step in determining the validity of a clinical trial is assessing the analysis plan. The analysis plan starts with the intended comparison. When the clinical trial is set up and reported, the investigators should specify the intended comparison groups clearly. In addition, when more than 1 therapy is being tested, the comparison groups must be prespecified and appropriate.

For example, the Controlled Abciximab and Device Investigation to Lower Late Angioplasty Complications (CADILLAC) trial compared angioplasty with stenting, with or without abciximab, in patients with acute MI. Patients were randomized in a 2-by-2 factorial design, meaning that patients were randomized to angioplasty or stenting and then each group was randomized again to abciximab use or not. The results are that some patients received angioplasty alone, angioplasty with abciximab, stenting alone, and stenting with abciximab. This design conserves resources and addresses 2 questions: What is the value of angioplasty or stenting, and what is the value of abciximab or not?

However, to answer these questions appropriately, the correct groups must be compared. To determine the utility of percutaneous transluminal coronary angioplasty (PTCA) versus stenting in acute MI, the comparison in the trial should be all patients who received PTCA (50% of the patients) versus stenting (50% of the patients). Likewise, when answering the question of the utility of abciximab, the comparison groups must be all patients who received abciximab, irrespective of PTCA or stent status (50% of the patients), versus all patients who did not receive abciximab (50% of the patients). When this latter comparison was carried out, the value of abciximab was found to be significant.

Note the statistical power, or ability to detect the difference between therapies for the primary analysis, that the investigators have chosen for the study. The statistical power depends on many factors, including the criterion for statistical significance that is used, magnitude of the effect that is to be observed, and the sample size of the study. The study should state and meet the minimum sample size required to adequately power the study to detect a specified difference in therapies on the primary outcome. If the minimum sample size is not met for a study, it may fail to detect a difference in treatments for the primary outcome even if one exists. For example, in the EUROMAX trial, it was determined that a sample size of 2200 patients...
would provide a power of 80% for the primary outcome, which was a composite of death from any cause or major bleeding not related to coronary artery bypass grafting (CABG) at 30 days, at a 2-sided $\alpha$ level of 0.05. The primary outcome of the EUROMAX study was originally the composite of death from any cause, reinfarction, or non-CABG major bleeding but was changed during the course of the trial to reduce the necessary sample size to obtain a power of 80%. This is in fact unusual because rarely does a trial reduce the events in the composite as that will reduce the total number of events and would not positively affect power. Reviewers should recognize and review this when seen in the description of a study.

Aside from not performing the correct comparisons, another pitfall is making multiple comparisons at the conclusion of a clinical trial. As mentioned above, the power is calculated for the primary analysis. Multiple comparisons that are performed after the completion of the trial may not have the power to detect a difference, or they may find a difference by chance. A classic example of multiple comparisons yielding a chance finding is the published report from the ISIS-2 investigators that patients with the astrologic sign Libra did not gain a benefit from the use of aspirin at the time of acute MI. This finding clearly does not have a physiologic basis, but it demonstrates the ability of multiple comparisons (12 astrologic signs) to uncover a false finding. Therefore, findings from subgroup analysis should be considered similar to observational analysis. They are hypothesis generating but do not indicate a true effect and should be viewed with caution in trials that demonstrate a consistent benefit of a therapy.

**Check Whether the Trial Assessess Superiority or Noninferiority**

After determining the comparison groups, determine whether the analysis plan is set up to assess superiority or noninferiority. A contemporary trial design in interventional cardiology to account for the rapidly changing pharmacologic and device therapies is the *noninferiority analysis plan*. To understand noninferiority, we must first review the classic superiority trial design. Traditionally, when therapy A was compared against placebo or usual care, the trial was set up to test whether the therapy improved outcome. To do this, the investigators generally postulate that therapy A will lead to a prespecified percentage improvement in the outcome; for example, 30%
improvement in the rate of restenosis. Then the power calculation is used to
determine the number of patients required to demonstrate that percentage
improvement. If the findings are statistically significant, then the therapy has
led to at least the prespecified degree of improvement, if not more. If the
results are not statistically significant, then the therapy has been found to not
improve outcomes by the prespecified amount (eg, 30% improvement in
restenosis in the previous example). The EUROMAX trial was designed to
test whether bivalirudin, initiated during transport for PCI in patients with
ST-segment elevation MIs, was superior to heparin with optional use of GPIs
in contemporary practice. The EUROMAX trial concluded that prehospital
initiation of bivalirudin was indeed superior to heparin with optional use of
GPIs and reduced the primary composite outcome of death or non-CABG
major bleeding at 30 days ($P = .001$), a finding that was driven by the
bleeding reduction. This design mixed both efficacy and safety findings and
should be evaluated as such. Although this design allows the evaluation of
potential superiority of 1 therapy, this trial design does not answer whether
the intervention arm of bivalirudin is superior for reduction in classic major
adverse cardiac events, a finding of interest with the extended infusion.

In contrast to the classic superiority clinical trial design, the noninferiority
trial design attempts to test if a new experimental therapy is not inferior to a
control therapy by retaining a prespecified percentage of the effect of the
control therapy. In the case of the REPLACE-2 trial comparing bivalirudin to
heparin and GPI, noninferiority was defined as the ability of bivalirudin to
retain 50% of the benefit of GPI therapy. Hence, based on the previous
studies, the upper confidence interval for 50% of the benefit of GPI plus
heparin versus heparin therapy was set at an odds ratio of 0.92 (Fig. 70-1). If
the effect of bivalirudin crosses this upper boundary, then the conclusion
would be that bivalirudin does not meet the prespecified noninferiority
criteria, and bivalirudin may indeed be inferior to GPI therapy. Therefore, in
a noninferiority trial, the experimental arm can be slightly worse, identical, or
slightly better in outcome compared with the control, and noninferiority can
be claimed depending on whether the outcome falls within prespecified
boundaries. The findings of the REPLACE-2 trial did find bivalirudin to not
be inferior to GPI plus heparin therapy.
It should be noted, however, that there are examples of trials that have demonstrated the superiority of a therapy, even when the initial trial design is noninferiority. A notable example in interventional cardiology includes the randomized trial of tirofiban versus abciximab in patients undergoing percutaneous revascularization. A 2-tailed analysis of the 95% confidence interval found tirofiban to have a hazard ratio of 1.01 to 1.57 compared to abciximab, demonstrating the superiority of abciximab. It should also be noted that there is no current consensus on the exact boundaries that are prespecified for noninferiority trials. The novel oral anticoagulant studies demonstrate prespecified noninferiority boundaries for warfarin comparator trials.

An important point of clarification is that equivalence does not carry the same meaning as noninferiority with regard to clinical trial design. To establish the equivalence between 2 therapies, both noninferiority and nonsuperiority must be established. This means that the effect of a new therapy and its confidence intervals on both sides must be similar to the control therapy. In fact, the effect of the new therapy could be less than or greater than the control therapy. To demonstrate this, significantly more patients are required to prove true equivalence. It is for this reason that many clinical trials comparing 2 therapies are designed as noninferiority trials, especially when 1 therapy is the standard of care.

Noninferiority trials will continue to occur in interventional cardiology as newer therapies and devices are discovered. As each new therapy is found with some specific advantage, such as cost, ease of use, or safety, trials are
required to demonstrate that the therapy is at least as effective as the prior standard of care. This was the driving force for the design for the TARGET trial, which was designed specifically to demonstrate that tirofiban was noninferior to abciximab because of its considerable cost benefit.

**Design Issues Specific to Interventional Cardiology**

Many of the validity criteria described for evaluating the methodology of therapy clinical trials thus far should be applied to all interventional cardiology trials. However, there are trial issues specific to the field of interventional cardiology that require discussion.

In addition to the noninferiority design already discussed, interventional trials require specific consideration when dealing with devices. To understand the total effect of a new device, the safety and therapeutic effect must be understood. Also, the learning curve required to be able to successfully use the experimental device must also be investigated.

Currently, a new device goes through significant study in the steps prior to the phase III pivotal efficacy and safety trial. Along the way, the device is tested in preclinical studies followed by phase I first-in-human trials, and then phase II optimal use or “dose-ranging” studies. The safety of the device can be evaluated by combining all the data. In addition, a sense of the clinical learning curve is also demonstrated.

Finally, the large phase III therapeutic efficacy trials address many of these same issues. However, as stated earlier, these trials can often not be blinded. Therefore, particular attention must be paid to postapproval surveillance. Often, rare adverse events can be detected only by this method. Unfortunately, complication rates for postapproval device therapy may be vastly underreported, making evaluation of new devices difficult. Both the US Food and Drug Administration (FDA) and industry are working hard to standardize the process for both this special type of therapy trial and postapproval monitoring.

**Step 4**

**Determine a Validity Score**

The fourth and final step in evaluating the validity of a clinical trial design is
to determine a validity score. No clinical trial design is absolutely ideal, and no clinical trial design is absolutely without merit. However, there may be some clinical trials that have fatal flaws in their design that may preclude reviewing the results. In fact, the entire exercise of determining the validity of a clinical trial design and methodology is to assess the strength with which the reader may feel the results mirror actual truth.

As a result, we have found it helpful to stop after reviewing the validity of a clinical trial design and answer 2 simple questions. The first is, “Should the results be viewed?” If the trial is set up with a fatal flaw—the therapies were not randomized or blinded, for example—then the reader should consider not reviewing the results at all. The second question is, “On a scale of 1 to 10, with 10 being the ideal clinical trial design for the specific question, how well was the trial set up?” We have found that putting a numeric value on the validity of the trial design helps in the future when weighing the results and applying them to patient care. If the readers are satisfied with the validity score they assigned to the trial, they should proceed to the interpretation of the results.

WHAT ARE THE RESULTS?

Once the reader determines that the trial was set up with suitable methodology, the results should be interpreted. In general, the results of the treatment effect are presented with regard to a prespecified primary outcome measure.

For example, the SIRIUS trial evaluated the sirolimus-eluting stent versus a standard, bare metal BX Velocity stent in 1058 patients with a newly diagnosed coronary lesion in a native coronary artery. The primary outcome was failure of the target vessel, defined as a composite of death from cardiac causes, MI, and repeated percutaneous or surgical revascularization of the target vessel. Target vessel failure occurred in 21.0% of the patients in the standard stent group and 8.6% of patients in the sirolimus-eluting stent group ($P < .001$). The investigators report that this difference was driven largely by a decrease in the need for target vessel revascularization (16.6% in the standard stent group vs 4.1% in the sirolimus-eluting stent group; $P < .001$).

When looking at the results, it is important to assess whether risk
reduction between therapies is presented as an absolute risk reduction or a relative risk reduction. For example, the above results from the SIRIUS trial are significant and may be better understood in terms of absolute risk reduction as discussed below.

**Absolute Risk Reduction**

The absolute risk reduction (ARR) is a simple calculation that can be performed for any outcome, and it can provide a sense of the overall magnitude of effect. The ARR is defined as the difference in the rates of outcomes for the tested therapy versus the control therapy. In the example of the SIRIUS trial described earlier, the ARR associated with a sirolimus-eluting stent compared to a standard stent for the outcome of target vessel failure is 21.0% – 8.6% = 12.4%. This means 12.4% fewer patients treated with sirolimus-eluting stents will have target vessel failure compared to standard stent therapy.

The ARR can be used to calculate the number needed to treat (NNT). The NNT is calculated as 1/ARR, or, in the earlier example, 1/0.124 = 8. The NNT can be used to express the results of a trial and its magnitude in terms of patients required to demonstrate the desired outcome. In our example, this would be stated as 8 patients must be treated with sirolimus-eluting stent to prevent 1 episode of target vessel failure at 9 months, the duration of follow-up in the clinical trial.

Once multiple trial results are converted to NNTs for each outcome, then it becomes easier to determine the weight of findings from each clinical trial finding. Similar to the SIRIUS trial, the results of the landmark ISIS-2 trial evaluating aspirin, streptokinase, both, or neither in patients with acute MI can also be summarized using NNT.21 The number of patients with acute MI who must be treated with 162 mg of aspirin or streptokinase compared to placebo to prevent 1 vascular death at 5 weeks is 36. In addition, 19 patients must be treated with the combination of aspirin and streptokinase to prevent 1 death within 30 days. These numbers underscore both the strength of the clinical trial findings and the synergy of the therapies when used in combination.

**Relative Risk Reduction**
In contrast to AAR, the relative risk reduction takes into account the actual rate of an outcome. Specifically, the relative risk reduction is calculated by dividing the difference between the therapies by the control event rate (Table 70-1). For example, the CAPRIE trial evaluated 75 mg of clopidogrel a day versus 325 mg of aspirin to reduce the risk of a composite outcome composed of ischemic stroke, MI, or vascular death. In total, 19,185 patients were randomized, and the event rate was 5.32% in the clopidogrel-treated patients versus 5.83% in the aspirin-treated patients. This difference was found to be statistically significant ($P = .043$).

</tr>
<tr>
<td>Number needed to treat</td>
<td>1/ARR</td>
<td>1/0.02 = 50</td>
</tr>
</tbody>
</table>

Abbreviations: ARR, absolute risk reduction; RRR, relative risk reduction.

In the CAPRIE trial, the investigators correctly report an 8.7% relative risk reduction in favor of the clopidogrel-treated patients. However, the absolute risk reduction (5.83% – 5.32%) is 0.51%. This translates to an NNT of 196. This means the clinician would have to treat 196 patients with clopidogrel instead of aspirin for at least 1 year to prevent 1 ischemic stroke,
MI, or death. Hence, this example demonstrates how the NNT and ARR may provide a better view of the overall strength of trial results compared to relative risk reduction calculations. The use of these terms may help the clinician determine whether the clinical trial findings are clinically important.

**What Are the Adverse Effects?**

The last part of evaluating the results of a clinical trial includes determining any adverse events. Most trials report the rate of adverse events with indication of whether the results are significant. For instance, in the GUSTO trial, tissue plasminogen activator (tPA) resulted in a 0.23% increase in hemorrhagic stroke compared to streptokinase. This percentage can be termed a 0.23% absolute risk increase in hemorrhagic stroke in patients treated with tPA, correlating to a number needed to harm (NNH) of 434. Restated, 434 patients with acute MI must be treated with tPA versus streptokinase to lead to 1 additional hemorrhagic stroke. In this manner, adverse effects of therapies can be put into context with the therapeutic benefits so that clinicians can weigh all the risks and benefits prior to determining clinical significance.

**Statistical Significance Versus Clinical Significance**

Statistical significance is a mathematical evaluation. Clinical trials set out to answer a question by determining the magnitude of effect that would be meaningful to practicing clinicians. They then determine the number of patients needed to adequately address the question with a specific degree of certainty, also known as the power of the trial. Finally, the results are said to meet statistical significance if the findings have less than 5% chance of representing a chance finding. It should be noted that the $P$ value of .05 is an arbitrary standard, and certainly, the level of significance for secondary analyses may require more rigorous statistical standards.\(^{25}\)

In contrast, clinical significance may vary tremendously. The trial assumptions, including the magnitude of the effect, the cost of the therapy, and the outcome tested, may all affect the individual clinician’s determination of clinical significance. The CAPRIE trial, mentioned earlier, did not lead to a change from aspirin to clopidogrel for patients with atherosclerotic disease. However, the CURE trial, which evaluated clopidogrel plus aspirin versus
aspirin alone and found a 2.1% ARR in a composite of death from cardiovascular causes, nonfatal MI, and stroke in patients with acute coronary syndromes, did lead to a change in practice.\textsuperscript{26}

Finally, clinical significance may vary depending on the location of practice, patient population, or provider outlook. The GUSTO trial demonstrated an ARR of 1% in death at 30 days for tPA with intravenous heparin, compared to streptokinase and intravenous heparin in patients with acute MI.\textsuperscript{27} This changed clinical practice in the United States but was not immediately adopted in other parts of the world.

**CONCLUSIONS**

We reviewed a method for reading clinical trials involving therapies with an emphasis on interventional cardiology. The process of determining if the trial answers your clinical question, evaluating the trials for valid methodologic design, and reviewing the results should help provide a framework for a lifelong review of the medical literature. The process of reading the medical literature ends with applying the results to the patient care.

In applying the results to patient care, special emphasis should be placed on whether relevant outcomes, both beneficial and adverse, were considered. Restenosis rates in trials with drug-eluting stents seem like reasonable outcomes. However, practicing clinicians may not routinely perform cardiac catheterizations on asymptomatic patients at 6 months, and this may indeed inflate the rate of the outcome of interest. Also, clinicians must weigh the risks and benefits of each individual therapy with patient characteristics and preferences. This is the art of medicine, and improving one’s ability to appraise the literature critically should only help with this process.

We hope that we have provided some helpful tips and warnings about pitfalls that should help with the critical appraisal of the literature. With the ever-changing face of interventional cardiology; our review of clinical trial design, including noninferiority trial design; valid trial methodology, including randomization and blinding; and assessment of trial results using ARR and NNT should provide the tools to continue to stay abreast of an ever-changing scientific field.

In my 10 years as editor-in-chief of *JACC: Cardiovascular Interventions*, we have selected about 1500 original research articles for publication. In recent years, the acceptance rate has been around 9%, so the editors have had to be very selective. Papers with high enough priority to be published in the journal have certain characteristics that I will describe in this chapter. There are, however, several other fine journals concentrating on publishing articles specific to interventional cardiology, and some of them have different interests. Also, general cardiology journals and the most selective medical journals also publish interventional cardiovascular papers. So the thought when preparing a research paper should not be, “Will it get published?” but, instead, “Which journal is best suited for my submission?” The answer to that question usually lies in the project itself. A well-planned research project will almost always result in a publishable paper. Knowledge of the type of papers published in each journal will aid in deciding where to send the paper.

When I assumed the role of editor-in-chief of *JACC: Cardiovascular Interventions* and associate editor of *JACC*, Tony DeMaria, the editor-in-chief of *JACC*, had stimulated the associate editors to reflect on how to get a paper published in a highly rated journal.\textsuperscript{1,2} I have modified those ideas over the years and will give you my advice as to what interventional cardiology journals are looking for. The first principle is the project itself. Without a well-planned research project, a publishable paper cannot be written. So what
are the fundamental characteristics of an excellent research paper?

CHARACTERISTICS OF A RESEARCH PAPER

The 3 characteristics that editors are looking for in a research paper are novelty, accuracy, and importance. This thought process of “Is it new, true, and relevant?” goes through the mind of reviewers as well. Perhaps even before these characteristics are considered, the question “Is it interesting?” is entertained. Since the job of editors and reviewers is primarily to select papers that qualify for their journal, one should not underestimate the impact of the first impression. Is it interesting or not?

Novelty

If the question being addressed has not been studied before, then it is ranked highly as novel. There are, of course, levels of novelty, and all authors attempt to justify why the project was undertaken. If the investigation has been done, then it should address what needs to be done in addition. Is it a much larger series or a comparison that confirms prior inadequately powered communications? Does it address a unique application or a unique population that has not been adequately studied? Numerous papers submitted to the journal are sometimes directed toward subsets of large pivotal trials. If these were not reported in the main paper, and especially if prespecified and addressing interesting questions, they are considered to have some novelty.

Accuracy

Is the question addressed in a way that the answers will be true? This does not mean that the findings of the investigation will reflect ultimate truth. No scientific study can claim that, but the findings must be accurate as they relate to the study. The study group characteristics and the protocol are critical components. It is not my interest here to provide a thesis on methodology for designing and performing research or on statistical methods that are valid for various investigations. However, power calculations must be considered.
Here, the input of experts in statistical methods should be encouraged. The methods must be capable of withstanding scrutiny, and they should be validated and reproducible as shown by prior work. They should be as precise as possible, and this will vary based on the data sources that are available for the work. Prospectively collected data are usually superior, but precision in the collection of those data, as well as in collecting retrospective data, is important in judging the validity of a study. Confounding variables can seldom be completely eliminated but must be considered and minimized. Randomization is assumed to remove confounding but does not always do so, and for nonrandomized comparisons, unrecognized confounders are important to consider. When results of nonrandomized comparisons seem too good to be true, the cause is commonly the presence of systematic confounders that cannot be accounted for. We may find that “The sicker patients did worse,” but we may not have identified why they were at greater risk.

**Importance**

The relevance of studies carries a lot of weight when considering publication. Importance of a study is usually viewed in a hierarchical ranking. At the top are things that have implications for patient management. When that reaches the level of potentially changing practice, the highest level of importance has been reached. Areas of relevant importance include when studies establish diagnoses, quantify severity or risk, or define mechanisms by which outcomes are determined. Even when the study is not adequate to establish any of these but generates a novel hypothesis, the paper may be of interest. However, it is true that the statement “This paper is only hypothesis generating” is frequently part of the review of a rejected paper. If the study fails to provide more than a hypothesis for further study, that should be indicated rather than insinuating that the paper answers important questions. In that case, the importance of the hypothesis and the strength of evidence pointing to why it should be studied will be helpful. Finally, even if a study is well done, but the result is not important at all, one should wonder why it was initiated. At an editorial board meeting, when an associate editor discussing a paper says, “So what,” it is a very damaging comment. The methods may have been correct, but the finding is not important.
CONSIDERATIONS WHEN INITIATING A STUDY

I said that a well-planned project usually results in a publishable paper, and I would reemphasize that 90% of a successful paper lies with the planning and execution of the project. Before initiating a study, several questions must be considered. First, identify the question. Then, make sure it has not already been answered. Having a patient base available is not in itself a reason to initiate a project. The question should precede the resources to address it. Then a hypothesis must be generated. Consider the type of study that might address the issue. Some questions cannot be answered without a randomized comparison, while others can. Evaluate whether the resources are available to conduct the study. Is the patient base adequate at 1 institution, or are collaborations necessary? Can a database be accessed, and what is the quality of those data? Consider personnel and financial resources for the study. The final question that should be asked is: “Will the product that is produced be worth the effort that will be necessary?” This is not to say that the answers are predictable; if so, the research is not needed. However, are the question and whatever answers may be obtained interesting?

Type of Study

There is an opinion among many that randomized controlled trials always receive preferential treatment and that there is a bias toward publishing these studies. In the clinical realm, certainly randomized trials are necessary for some questions, but other questions are better answered in other ways. Studies submitted for publication are registries, meta-analyses of prior trials and outcomes research in broad populations, as well as randomized controlled trials. Preclinical studies range from bench testing of new devices or evaluation of existing devices to translational studies using animal models and human feasibility studies. Some questions are addressed with surrogate end points. Pharmacodynamic evaluation of drugs and vascular responses to interventions are examples. When studies of surrogate end points are done, one should be clear on how these surrogates may be related to clinical events, including prior correlation to clinical outcomes.
Strengths and Weaknesses of Randomized Trials

The main strength of randomized controlled trials is the elimination of significant baseline variables, whether recognized or not. It is assumed that if an adequate sample size is enrolled, then the randomization process will evenly distribute factors that are not measured. Some questions cannot be answered without randomization. Since bias on the part of the patient or healthcare team member can influence outcomes, blinding of treatment assignment is also a necessary part of some trials. However, randomized controlled trials can have downsides as well. Common errors are poor design and methods, inadequate power, and highly refined selection criteria that prevent the findings from being applied to patients of interest. On the other hand, some trials can be so broad in their selection that the subjects who do benefit from a therapy are lost in the “forest.” When these mega-trials are carried out, thoughtful consideration of subgroups should be prespecified and, if possible, adequately powered. For many questions, randomization is not possible. Some questions cannot be answered without randomized controlled trials, but some randomized controlled trials cannot answer certain questions.

Strengths and Weaknesses of Nonrandomized Trials

Broader and more inclusive populations can be studied in nonrandomized trials. It is almost always necessary to have a comparator group for nonrandomized trials. Results of registries may look impressive, but the question “Compared to what?” is a killer for publication. Always include a comparator group, and remember that the quality of such a study will depend on how comparable is the comparator. Well-done registries, especially prospective ones, can add validity to smaller randomized trials. The major weakness of nonrandomized comparisons is the unrecognized confounders. Data from many registries come from databases, the quality of which is essential for a believable outcome. Administrative databases are designed primarily for billing and reimbursement reasons, and the clinical data from those codes are often weak and incomplete. Nonetheless, increasing emphasize on “big data” can identify trends that can stimulate more valid investigation of subsets of interest for subsequent randomized trials and well-controlled prospective registries.
Meta-Analyses and Review Papers

Before beginning a study using meta-analytic methods or writing a review, make sure there has not been a reasonably well-done or more recently published one. Also consider the question the meta-analysis is attempting to answer. If the individual components, be they randomized trials or registries, are all in the same direction, a meta-analysis adds little. Meta-analyses are most helpful when there is conflicting information and when larger numbers enable the examination of subsets. The validity of the information gained will depend on the quality of the studies that are included and the homogeneity of the population and methods of the component trials. The best meta-analyses are those utilizing trials with common data entry. In addition, studies are valuable that pool all the baseline and outcome data from individual trials and analyze that data in a new data set. Of course, variation between trials in inclusion criteria, methods, and definitions also limits this approach. Recently, network meta-analysis has gained some acceptance as a way not only to compare treatments among trials comparing similar therapies, but also to draw conclusions from multiple comparisons when some therapies have never been tested directly against each other.

Review papers are frequently invited by journals, but some come de novo for consideration. If such a project is considered, make sure the review is needed because it has not been done recently and because there is new information. Avoid writing a piece that looks more like a book chapter than a review article. Include personal perspectives and make recommendations. Avoid simply providing a synopsis of articles on the subject. Show how the review integrates prior work.

PREPARATION OF A PAPER

The title is the first element seen and should accurately and interestingly capture what the paper is addressing without excessive length. Search engines sometimes look at the first words of a title, so put the key words first. The introduction should clearly state the background for the question (briefly), the question that is being addressed, and the population that is being studied. The methods should be described in specific detail. The validity of the methods should be supported with references. The patient acquisition should be
detailed, as should the control group if the study is nonrandomized. The results should be the easiest part. The primary end point result should be given first before presenting secondary analyses. Details of the results are usually displayed in tabular format but are best appreciated visually in graphs. In crafting the discussion, present the important results in the first paragraph, and do not merely repeat the results section but emphasize synthesis. Give a scholarly and complete review of the pertinent literature but avoid excessive length.

A FEW OTHER TIPS

Consider the length of the author list and realize that including as authors those who do not contribute to the paper is inappropriate. Ensure that the abstract reflects the full paper. Remember that editors and reviewers see the abstract first, so it should be compelling. Remember the figures. Sometimes these are an afterthought, but reviewers and readers are visual animals, and well-designed figures of results and illustrations of case examples are very powerful. All the journals have word limits; do not try to fill space by reaching this limit, and do not exceed the limit. The old adage “If I had more time, I would have written a better paper” is one to which attention should be paid. When the authors are not expert in English grammar, it is often advantageous to enlist a native English speaker to help edit a paper. Although at *JACC: Cardiovascular Interventions* we do not reject papers because of incorrect grammar, a well-written paper is much easier for reviewers to comprehend. If the paper is worth accepting, the grammar can be fixed, but a paper that does not require extensive editing is appreciated by the editors and reviewers. Of course before completing a paper, pay close attention to the instructions to authors on the website of the journal.

In an attempt to appeal to the ever-shortening attention span of readers, we have instituted an alliterative set of questions to provide the clinical perspective. Each paper ends with what’s known, what’s new, and what’s next. By doing this, we hope the reader will get a quick glimpse of which articles are of most interest to them. But in reflecting on it, these three questions should also be considered before starting any project that results in a publishable research paper.
REFERENCES

MULTIPLE CHOICE QUESTIONS

1. Which of the following papers likely receive the highest priority?
   A. A retrospective registry of 50,000 patients collected over 15 years.
   B. A randomized trial of 24 patients examining clinical outcomes.
   C. A pooled analysis of four moderate-sized trials using patient specific data.

2. Randomized trials are best suited to:
   A. Provide accurate results.
   B. Eliminate confounders.
   C. Change practice

3. The most important studies are those that:
   A. Quantify risk.
   B. Establish a diagnosis.
   C. Influence practice.

4. Confounding variables in large databases can be eliminated by propensity matching.
   A. Yes
   B. No

Cost-Effectiveness in Interventional Cardiology

Quality Assurance and Quality Improvement in Interventional Cardiology
INTRODUCTION

The management of cardiovascular diseases, especially coronary artery disease, has been revolutionized after Dr. Mason Sones performed the first coronary angiography in 1960 and Dr. Andreas Gruentzig pioneered percutaneous coronary intervention in 1977. Since 1977, percutaneous techniques for coronary angioplasty have significantly evolved. Interventional cardiology has emerged as a subspecialty of cardiology with tremendous potential of impacting patient outcomes in a broad spectrum of cardiovascular diseases including, but not limited to, acute coronary syndromes, stable coronary artery disease, heart failure syndromes, and valvular heart diseases. From the development of ever-improving coronary interventional equipments and techniques to facilitate treatment of the most complex coronary disease to the introduction of catheter-based therapy for nonoperable aortic stenosis, interventional cardiology has seen a major transformation in therapeutic possibilities over the last decade, and the continuously expanding horizon of interventional cardiology well demonstrates its potential beyond just coronary intervention as first witnessed in 1977. Nonetheless, selecting a specific therapy and offering it to the right
patient become challenging in our society of limited resources. Careful evaluation of available evidence becomes vital in determining the appropriateness of a specific intervention, considering both clinical efficacy and cost-effectiveness. Cost-effectiveness of the most significant therapeutic developments in interventional cardiology over the last 2 decades is reviewed in this chapter. A basic approach in cost-effectiveness analysis is briefly reviewed here.

**BASIC APPROACHES AND METHODS OF COST-EFFECTIVENESS ANALYSIS**

**Incremental Cost-Effectiveness Ratio (ICER)**

ICER is a widely utilized and accepted standard to evaluate cost-effectiveness of a particular intervention, and the majority of the studies that are discussed in this chapter have used an ICER as the fundamental metric. The ICER is defined as the incremental cost of providing a specific intervention or therapy divided by the incremental gain in the health benefit.

Thus, any new intervention will be compared to a previous type of care, often the current standard of care. Often the ICER is compared to a standard willingness-to-pay threshold, eg, $50,000 per life-year gained. Values of the ICER below the threshold, also known as the ceiling ratio, would be considered a socially acceptable healthcare expenditure to gain 1 year of life. Thus, in principal, any service that falls below the threshold would be considered cost effective. However, there is no socially acceptable threshold, there are uncertainties in the measurement of cost and efficacy, and society will often spend more than the threshold for patients in acute settings (rule of rescue). This has limited the use of cost-effectiveness analysis for determining policy. However, cost-effectiveness can expose the assumptions underlying our decisions, which can add setting policy.

**Utility Assessment**

Utility is a measure of overall health and functioning, generally scaled from 0 to 1. Thus, for a patient with coronary artery disease suffering from angina, a
utility of 0 would be death and 1 would be perfect health and functioning without chest pain. Utility integrates multiple measures of health status (eg, functional status, symptoms) into a single number (utility or quality of one’s life). However, utility is difficult to measure. It may be estimated from cumbersome trade-off methods such as standard gamble or time trade-off, but survey methods such as the health utility index or EQ-5D tend to be more universally used although less exact.

**Quality-Adjusted Life-Years (QALY)**

Survival time alone, in general, is not considered a satisfactory measure of an outcome in a patient with a utility of <1. Utility may be combined with survival to give QALY, an overall measure that incorporates survival and health status. Utility assessment provides the strongest base to estimate quality-adjusted survival. Incremental gain in QALYs is often used as the measure of overall health benefit, describing not just survival but also quality of that survival, and is often used as a more salient denominator in willingness-to-pay thresholds. Estimation of QALY can be explained with an example of severe angina. Let us consider that living 5 years of life with severe angina is equivalent to 4 years spent in good health. Here the quality adjustment would be 0.8 (4 years in good health/5 years with severe angina); 1 year with severe angina would be 0.8 QALY. Using this equation, 10 years of life with severe angina would be equivalent to 8 QALYs free from angina.

**Life Expectancy**

Time plays an important role in cost-effectiveness analysis. The time horizon of the analysis (determined by the analyst) is the time frame over which the effect of an intervention on cost and health is evaluated. Ideally, time horizon should cover the entire period over which the intervention may have an effect. Such time periods often span across a patient’s lifetime where the intervention affects mortality. Therefore, the selection between lifetime horizon and time horizon based on study follow-up significantly affects the analysis. Life expectancy over a fixed time horizon is similar to the area under the survival curve. For a specific group of patients, for example, surgery may reduce mortality from 3% to 1%, with additional perioperative mortality of 3%. On the other hand, medical therapy for the same group of
patients may reduce mortality from 3% to only 2% with no upfront added mortality. Here estimation of life expectancy, with either medical or surgical therapy, as a function of time horizon (lifetime vs specific cutoff used in the study) would reveal that medical therapy is superior in short-term (in trial) follow-up, but surgical therapy provides a long-term survival benefit.  

**Costing**

Selection of the “perspective” is crucial in cost-effectiveness analysis because societal, payer, and patient perspectives affect specific costs and effects included in the analysis. Societal perspective is the most commonly utilized perspective in cost-effective analysis (CEA). Societal CEAs are often more comprehensive than those performed based on patient or payer perspectives. From a societal perspective, cost is not the same as price; cost is the value of the next best use of the resource. In determining costing, the societal perspective incorporates all resource costs associated with the use of an intervention including physician time, other healthcare resources, and the use of nonhealthcare resources such as caregiver time. Costing methodology also often involves indirect costs, future costs, and the valuation of costs. Indirect costs distinguishes “direct healthcare costs” from “direct nonhealthcare costs” (such as child care costs for a parent undergoing treatment, costs of transportation, and cost of the time a family member spends caring for a disabled relative).

**Modeling With Markov Analysis Versus CEA Alongside Clinical Trials**

QALYs, cost, and the ICER are considered vital measures for CEA. The duration of many clinical trials is usually not long enough for an accurate estimation of the long-term course of a clinical disease. This limits the accurate estimation of the changes in life-years and QALYs with a specific therapy and thus incremental gain in life-years or QALYs. CEA based on in-trial data, in terms of cost per life-year or QALY gained, has limited utility for economic decision making due to short-term follow-up in clinical trials. Therefore, long-term projections of short-term results are often required to estimate cost per life-year or QALY gained. This can be done by developing
a model based on short-term event rates for projecting an average life expectancy and lifetime cost of therapies to derive lifetime ICER or lifetime cost per QALY gained. This can be done by utilizing a Markov decision analytic model. The Markov model is particularly utilized when the disease process involves risk that is continuous over time, when the timing of the event is important, and when the important events (such as myocardial infarction [MI]) occur repeatedly over time. A Markov model is defined by a set of mutually exclusive and exhaustive health states. At any point in time, a person can reside in only 1 health state and for fixed increments of time (known as Markov cycle length). People are assumed to transition from one health state to another depending on a set of transition probabilities. Values are assigned to individual health states, which represent the cost and utility of spending 1 Markov cycle length in that health state. Such values, when combined with time spent in individual health states, help derive estimates of average cost and effect to calculate long-term (beyond trial period) cost-effectiveness of different treatments. A comprehensive review of Markov modeling is beyond the scope of this chapter. However, it can be simplified by CEA of the PLATO (Platelet Inhibition and Patient Outcomes) trial.

The PLATO trial compared ticagrelor and clopidogrel for prevention of cardiovascular events in 18,624 patients presenting with acute coronary syndrome over 12 months. The composite of death from vascular cause, MI, or stroke occurred significantly less frequently in patients receiving ticagrelor compared to clopidogrel (9.8% vs 11.7%, \( P < .0001 \)). Ticagrelor was also associated with significant reduction in MI alone (5.8% vs 6.9%, \( P = .005 \)) and death from any cause (4.5% vs 5.9%, \( P < .001 \)). Rate of major bleeding was comparable between the ticagrelor and clopidogrel groups (11.6% vs 11.2%, \( P = .43 \)). CEA was performed using PLATO data in the Swedish health setting. CEA based on in-trial data, performed over a 12-month period, demonstrated that the total cost was €96 higher in the ticagrelor group than the clopidogrel group. QALYs, estimated based on EQ-5D, were 0.0006 higher in ticagrelor-treated patients compared to clopidogrel-treated patients. For the in-trial period of 12 months, ICER was €160,000/QALY gained with ticagrelor (much higher than the willingness-to-pay threshold of €20,000/QALY gained). Lifetime estimates of CEA, QALY, and cost were created using a Markov model based on the 1-year decision tree from PLATO. The initial start state in the long-term Markov
extrapolation model was either “post MI,” “post stroke,” “no event,” or “dead” (based on the prespecified end point in PLATO). For patients with “no event” in the 12-month period, the annual risk of mortality was estimated based on the age-specific mortality rates from Swedish life tables, and the annual risk of nonfatal MI and nonfatal stroke was estimated based on the observed hazard function of clopidogrel-treated patients. Survival after nonfatal events was modeled by estimating the hazard ratio considering the increased hazard for death after MI or stroke relative to the standard risk of death from life tables. Annual costs associated with the “no event” state and costs after “nonfatal events” were estimated in the Markov model. Cumulative long-term cost was estimated based on the cost in each state of the Markov model. Long-term QALYs were estimated based on age adjustment and by applying decrements with each nonfatal MI and stroke. Lifetime CEA for acute coronary syndrome patients based on Markov model demonstrated an ICER of €2372/life-year gained and €2753/QALY gained, both well within the willingness-to-pay threshold. Therefore, this lifetime CEA demonstrates the limitation of the cost analysis based on in-trial data due to the trial’s short-term follow-up.

**Cost-Effectiveness Plane**

The cost-effectiveness plane is a 2-dimensional display of incremental effectiveness versus incremental cost. Thus, points on the plane represent a graphical display of the ICER. As described in Figure 72-1, it is divided into 4 quadrants. Quadrant B is the most cost effective since it introduces more effective newer treatment strategies at less cost than control treatment option. Conversely in quadrant D, the new therapy is less effective and costs more; it does not make sense from societal perspective to adopt treatment with an ICER in quadrant D. Quadrants A and C both introduce subjectivity in the interpretation of ICER, as the new therapy offers increased effectiveness at increased cost (or decreased effectiveness at lower cost).
FIGURE 72-1 Cost-effectiveness plane. Quadrant B demonstrates that the new treatment is dominant and should be accepted. In quadrant D, new treatment is dominated by control and should not be adopted. In quadrants A and C, adoption of new treatment is reasonable. Incremental cost-effectiveness ratio (ICER) for new therapy should be interpreted against socially acceptable threshold. Occasionally, ICER of new therapy may appear attractive for certain subgroup of population. CER, cost-effectiveness ratio.

**Statistical Approaches in CEA**

**Bootstrap Analysis and the Cost-Effectiveness Plane**

There is uncertainty in the estimation of both effectiveness and cost. CEA must take this into account. Where patient level data from clinical trials are available, the error in calculation of the ICER due to the play of chance (stochastic error) can be evaluated. Thus, using available patient-level data from clinical trials, the 95% confidence intervals (CIs) of both cost and effectiveness can be estimated. The most often used methodology is bootstrap analysis where an empiric estimate of a sampling distribution is made by drawing a large number of samples with replacements from the original data. The bootstrap approach has been considered the most appropriate general method for comparing treatment costs, since it does not make any distributional assumptions in comparing differences in costs and QALYs (or other outcome measures) between the 2 treatment groups. Each estimate of cost and effectiveness derived from the dual bootstrap may then be used to
form an estimation of the ICER.

**Graphical Display of the Distribution of the ICER**

The points from the conjoint bootstrap analysis may then be displayed in the cost-effectiveness plane, offering a graphical representation of the distribution of the ICER.\(^\text{18,19}\) Alternatively, uncertainty due to the play of chance may also be displayed as a cost-effectiveness acceptability curve, where for any willingness-to-pay threshold the probability of the new therapy being cost effective is plotted.\(^\text{3}\) The x-axis is the willingness-to-pay threshold, and the y-axis is the probability of being cost effective. The points on the curve represent the fraction of the ICERs below any threshold. The cost-effectiveness acceptability curve and the display of the distribution of the ICERs in the cost-effectiveness plane are complementary representations of the same data. The ICER distribution on the cost-effectiveness acceptability curve for ticagrelor in acute coronary syndrome (ACS) from the PLATO trial is demonstrated in *Figure 72-2*. The probability of ICER for ticagrelor compared to clopidogrel being \(<20,000/QALY\) gained approached 100% for a wide range of ACS presentations, making ticagrelor a dominant strategy compared with clopidogrel.\(^\text{15}\)
FIGURE 72-2 Cost-effectiveness acceptability curves for ticagrelor in acute coronary syndrome (ACS; based on PLATO trial data). Cost-effectiveness acceptability curve for ticagrelor compared to clopidogrel in PLATO trial demonstrated ticagrelor to be a dominant antiplatelet agent with a high probability for incremental cost-effectiveness ratio (ICER) well under the willingness to pay threshold in a wide spectrum of patients with ACS. NSTEMI, non–ST-segment elevation myocardial infarction; STEMI, ST-segment elevation myocardial infarction; QALY, quality-adjusted life-years. (Reproduced from Nikolic E, Janzon M, Hauch O, Wallentin L, Henriksson M. Cost-effectiveness of treating acute coronary syndrome patients with ticagrelor for 12 months: results from the PLATO study. Eur Heart J. 2013;34(3):220-228, by permission from Oxford University Press.)

Sensitivity Analysis

Bootstrap analysis, however, will only assess uncertainty due to the play of chance. There may also be bias, where variables used to determine the ICER have additional uncertainty. This may be assessed by sensitivity analysis in addition to the bootstrap analysis. When patient-level data are not available, such as in Markov model simulations, then sensitivity analysis is the only method available to consider the distribution of the ICER. Parameters used in estimating both effectiveness and cost may be varied within limits, often
established from the literature. The validity of assumptions from which parameters for CEA are derived is very important. Sensitivity analysis is performed using different assumptions (reasonable variations in the parameters used in CEA) to derive cost-effectiveness estimates. If these estimates are not significantly different, it underscores the validity of CEA.  

This concept can be further understood with an example of the CEA in the PLATO trial. In the analysis discussed earlier, cost of ticagrelor was considered to be €2.21 per patient per day (as reimbursed in Sweden). The lifetime CEA, based on Markov model, demonstrated ICER of €2372/life-year gained and €2753/QALY gained. If the cost of ticagrelor is considered €3.00 per patient per day, ICER per QALY gained was €4874 (still well below the willingness-to-pay threshold). If the cost and QALY estimates are considered equal for clopidogrel- and ticagrelor-treated groups, cost per QALY was €5204. Here the cost-effectiveness results are only driven by the differences in the clinical events, as demonstrated in the PLATO trial. Similar results were observed with variations in the parameters used for the long-term Markov model and different subgroups such as patients with ST-segment elevation MI (STEMI), non–ST-segment elevation MI (NSTEMI), unstable angina (UA), and diabetes. Thus, the sensitivity analysis demonstrates validity of various assumptions used in the CEA by consistently demonstrating ticagrelor to be a dominant strategy compared to clopidogrel for patients presenting with ACS.

**Interpretation and Projections From Randomized Clinical Trials**

Short-term trial data are often extrapolated to lifetime estimates to arrive at cost per life-year gained or cost per QALY gained. These lifetime estimates for new treatment are often compared against other conventionally accepted treatment strategies. Such lifetime estimates have important implications on policy setting. Interpretation and generalization from clinical trials with few years of follow-up to lifetime outcomes should be done with caution. Survival, utility, cost structure, practice patterns, and resource utilization can have a wide range of variations, with uncertainty becoming greater the more that short-term data are extrapolated.
Primary Percutaneous Coronary Intervention Versus Thrombolysis in Acute Myocardial Infarction

Primary percutaneous coronary intervention (PCI) is widely accepted as the preferred treatment modality for patients presenting with acute MI, with intravenous thrombolysis reserved for patients who cannot be transferred to a PCI-capable hospital within 60 minutes from presentation. Compared to thrombolytics, primary angioplasty has demonstrated less in-hospital mortality, lower in-hospital and 6-month rates of reinfarction, and less death. Further, primary angioplasty is associated with lower rates of fatal bleeding complications, including intracranial hemorrhage. The cost of either approach depends on initial hospitalization, initial cost of revascularization, subsequent readmission, subsequent investigations and interventions, adjuvant use of antiplatelet and anticoagulant agents, outpatient care, and work loss.

Five-year comparative effectiveness of angioplasty versus thrombolytic therapy was evaluated in a cohort of 395 patients enrolled between 1990 and 1993. All-cause mortality was significantly lower in the angioplasty group compared to the streptokinase group during the first 30 days (1% vs 7%, \( P = .01 \)) and during 5-year follow up (13% vs 24%, \( P = .01 \)). The streptokinase group required significantly higher revascularization procedures during the 5-year follow-up period. This study demonstrated that per patient, total medical charges at the end of the follow-up period were lower in the primary angioplasty group compared to the streptokinase group ($16,090 vs $16,813, \( P = .05 \)). Total charges per patient for those who were alive at the end of follow-up trended toward being lower in the angioplasty group ($18,664 vs $21,772, \( P = .08 \)). This medical cost consisted of days spent in the hospital, diagnostic and therapeutic procedures, and medications used during the follow-up period calculated as per-hospital charges in 1992.

In a substudy of the CAPTIM trial (Comparison of Angioplasty and Prehospital Thrombolysis in Acute Myocardial Infarction), the cost efficacy of primary PCI was compared against alteplase, a more potent thrombolytic
agent than streptokinase.\textsuperscript{23} In the overall study (randomized multicenter trial of 840 patients), investigators compared primary PCI to prehospital thrombolysis for patients presenting with STEMI. All prehospital thrombolysis patients were transferred to a PCI center for further management and rescue angioplasty. The trial showed that primary angioplasty was not better (for death, nonfatal MI, and stroke) than prehospital thrombolysis with rescue PCI at 30 days, but the primary PCI group had a significantly lower composite of death, nonfatal MI, stroke, revascularization, and major bleeding (34\% vs 61\%, \(P = .0001\)). In the cost-efficacy substudy, 299 patients were enrolled at 3 participating sites between 1997 and 2000. Cost data were prospectively collected during initial hospitalization and during 1-year follow-up. The primary PCI group had significantly lower cost of hospitalization by $883 compared to the thrombolysis group.\textsuperscript{23} Longer length of hospitalization and cost of thrombolytic agents offset the initial higher cost of angioplasty. This difference in cost persisted at 1 year ($1224 lower in the angioplasty group than the prethrombolysis group, \(P < .04\)).\textsuperscript{23}

Cost and health outcomes comparing primary PCI and thrombolysis in patients presenting with STEMI have been more comprehensively evaluated in the SWEDES trial.\textsuperscript{24} The trial compared strategies of primary PCI with enoxaparin and abciximab versus thrombolysis with enoxaparin. Antiplatelet regimens were similar. In-hospital and 1-year clinical outcomes (death, nonfatal MI, stroke) were similar between the 2 groups.\textsuperscript{24} Quality-adjusted weight was obtained using EQ-5D questionnaire to calculate quality-adjusted survival. At 1 year, cost of intervention per patient in the PCI group was higher than the thrombolysis group ($4602 vs $3807, \(P = .047\)). The cost of antiplatelet agents was also higher in the PCI group ($1309 vs $1202, \(P = .001\)). The cost of hospitalization was higher in the thrombolysis group ($9278 vs $7244, \(P = .02\)). Combined cost of care per patient at 1 year was not significantly different between the 2 groups ($25,315 in PCI group vs $27,819 in thrombolysis group). Quality-adjusted survival remained marginally higher in the PCI group compared to the thrombolysis group (0.759 vs 0.728). In cost utility analysis, there was a trend toward $2504 less annual cost per patient and a 0.031 gain in quality-adjusted survival in the PCI group compared to the thrombolysis group. This trend, although statistical nonsignificant, appeared to be driven by less repeat hospitalizations in the PCI group. As depicted in Figure 72-3, PCI remained a cost-effective
strategy in 88% and 89% of bootstrap replications when using threshold values of $50,000 and $100,000/QALY gained, respectively.

**FIGURE 72-3** Primary percutaneous coronary intervention (PCI) is more cost effective than thrombolysis in patients presenting with ST-segment elevation myocardial infarction (STEMI) at 1 year follow-up (SWEDES trial). Graphical distribution of the incremental cost and quality-adjusted survival with primary PCI in STEMI patients compared to thrombolysis, based on 5000 bootstrap replications. Primary PCI is a favorable strategy since majority of the bootstrap replications are in right lower quadrant of cost-effectiveness plane and below the socially accepted threshold of $50,000/QALY gained. QALY, quality-adjusted life-year; USD, US dollars. (Reproduced from Aasa M, Henriksson M, Dellborg M, et al. Cost and health outcome of primary percutaneous coronary intervention versus thrombolysis in acute ST-segment elevation myocardial infarction-Results of the Swedish Early Decision reperfusion Study (SWEDES) trial. *Am Heart J*. 2010;160:322-328, Copyright © 2010, with permission from Elsevier.)

In summary, primary PCI, as a first-line therapy in the management of patients with STEMI, is cost effective up to 5 years, primarily due to reduced rates of repeat hospitalization in the follow-up period.22–24

*Early Invasive Versus Conservative Management of Patients Presenting With UA/NSTEMI*
Clinical outcomes with an early invasive strategy are superior compared to the conservative management for patients presenting with UA or NSTEMI. Both strategies affect cost of care at several levels including hospitalization, emergency room visits, diagnostics and interventions, cardiac medications, rehabilitation and nursing home stay, and outpatient physician follow-up.

The TACTICS-TIMI-18 trial (Treat Angina With Aggrastat and Determine Cost of Therapy With an Invasive Versus Conservative Strategy–Thrombolysis in Myocardial Infarction-18) demonstrated that the composite of death, MI, or rehospitalization for ACS at 6 months was significantly lower in the early invasive group (within 48 hours) compared to the conservative group (16% vs 21%, \(P = .03\)). The treatment strategy in TACTICS-TIMI-18 was contemporary and inclusive of both coronary stenting and use of glycoprotein IIb/IIIa inhibition, favoring generalizability of clinical and economic findings to current clinical practice. Average initial cost of hospitalization appeared higher with an early invasive therapy compared to the conservative approach ($15,714 vs $14,047). As expected, initial rates of hospitalization and revascularization procedures (PCI and coronary artery bypass grafting [CABG]) were higher with an early invasive approach despite the significantly shorter length of stay especially in the high-risk populations (older, diabetic, and ischemic electrocardiogram [ECG] changes). This early increase in cost, however, was offset by lower 6-month follow-up costs for the early invasive arm, primarily due to reduced rates of rehospitalization. Total 6-month cost, therefore, remained comparable between the 2 treatment strategies. The ICER for death or MI prevented was $25,478 with an early invasive approach. Considering the time horizon of 6 months and CEA based on in-trial data, QALY and health utility status remained unchanged between the 2 groups.

However, applying life expectancy data from both these methods to the entire TACTICS-TIMI-18 study population demonstrated a significant advantage to the early invasive approach. The Framingham Heart Study and PURSUIT/Duke trial projections were used to estimate lifetime cost-effectiveness. Specifically, this analysis revealed that ICER with an early invasive approach for NSTEMI/UA patients is within society’s willingness-to-pay threshold (ICER of $16,272/life-year gained using Framingham Heart Study and ICER of $22,538/life-year gained based on the PURSUIT trial).

Economic benefits of the early invasive approach as observed in
TACTICS-TIMI-18 remained unchanged when subsequent developments in medical therapy and revascularization approaches were considered (eg, drug-eluting stents [DES]). The RITA-3 trial (Randomized Intervention Trial of Unstable Angina-3) demonstrated that high-risk patients (older, diabetic, positive biomarkers, and ST-segment changes on ECG) had the highest economic benefit of the early invasive approach at 5-year follow-up. The TACTICS-TIMI-18 trial provided insight into this observation, but RITA-3 (larger sample and longer follow-up) conceptualized it more definitively. Further, clinical efficacy of the early invasive approach was demonstrated in a United Kingdom–based population at 5-year follow-up compared to the conservative therapy in a randomized multicenter comparison of 1810 patients presenting with NSTEMI (composite of death and nonfatal MI: 16.6% vs 20%, \( P = .04 \)). The ICER with either strategy among low-, intermediate-, and high-risk patients was compared to societal threshold of £20,000 to £30,000 per QALY gained. A Markov model was constructed to evaluate lifetime cost-effectiveness beyond the 5-year trial follow-up. This multivariate model created low-, intermediate-, and high-risk groups based on 5-year prediction of death or MI. The ICER was approximately £55,000, £22,000 and £12,000 per QALY gained for the low-, intermediate-, and high-risk groups, respectively.

It appears that the early invasive approach compared to conservative management for patients presenting with UA/NSTEMI is cost effective, especially for the high-risk patient population,  

**Optimal Medical Therapy (OMT) Versus Initial Revascularization in Stable Coronary Artery Disease (CAD)**

The COURAGE trial (Clinical Outcomes Utilizing Revascularization and Aggressive Drug Evaluation) provides the most comprehensive long-term outcomes data of stable CAD patients managed with OMT compared to PCI plus OMT in 2287 patients with 4.6-year follow-up. There was no difference in the primary end point of death or MI between groups; however, the PCI group had more angina relief and improved quality of life. Index resource utilization was significantly higher in the PCI group compared to the OMT group ($12,162 vs $752), but subsequent resource utilization was comparable
($22,681 vs $23,996, respectively). The higher in-trial cost was driven by higher initial cost of PCI. CEA of COURAGE trial demonstrated that addition of PCI as an initial management strategy for symptomatic chronic stable angina patients results in an ICER between $168,000 and $300,000 per life-year or QALY gained. Life expectancy beyond the trial period was estimated by Framingham survival data. In-trial and lifetime cost estimates for the PCI group remained significantly higher than the medical therapy group ($11,410 and $9451, respectively). The ICER/QALY gained for PCI was $206,229 for the trial period and $168,019 for lifetime. Therefore, medical therapy appeared to be dominant (better outcome at lower cost) (Fig. 72-4A). The cost-effectiveness acceptability curve demonstrated that at the $50,000 ICER/QALY gained threshold, PCI was rarely cost effective for the in-trial period, and there was only a 25% probability for lifetime. At the $100,000 threshold, the probability of ICER/QALY gained with PCI was <25% for the in-trial period and 41% for lifetime (Fig. 72-4B). This raised a question of which patients with chronic angina may derive cost-effective benefit from PCI as an initial management approach. In another cost-effectiveness substudy of the COURAGE trial, the ICER for PCI was evaluated in 3 quartiles of patients with chronic angina. These quartiles were defined by identifying health status among 3 domains of Seattle Angina Questionnaire (physical limitation, angina frequency, and quality of life). The ICER for PCI ranged from $80,000 to $330,000 for patients with intermediate to severe angina (lowest and middle quartile), whereas it ranged from $520,000 to $3 million in mild (upper quartile) angina. Therefore, at any level of angina severity, PCI as an initial strategy did not appear to be cost effective at socially acceptable cost thresholds.

Percutaneous coronary intervention (PCI) was dominated by medical therapy at an ICER threshold of $50,000/QALY and $100,000/QALY gained. B. CE acceptability curve shows that PCI was cost effective <25% of the time for the ICER threshold of $50,000/QALY and 41% of the time for the ICER threshold of $100,000/QALY on lifetime horizon, making medical therapy a dominant initial strategy for stable coronary artery disease. CE, cost-effectiveness; ICER, incremental cost-effectiveness ratio; QALY, quality-adjusted life-years. (Reproduced from Weintraub WS, Boden WE, Zhang Z, et al. Cost-effectiveness of percutaneous coronary intervention in optimally treated stable coronary patients. Circ Cardiovasc Qual Outcomes. 2008;1(1):12-20.)

The BARI-2D trial (Bypass Angioplasty Revascularization Investigation-2 Diabetes) randomly compared revascularization plus OMT (1176 patients; 378 with CABG and 798 with PCI) versus OMT alone (1192 patients) in a total of 2368 patients with type 2 diabetes mellitus and CAD over a 5-year follow-up and demonstrated comparable all-cause mortality as well as combined death/MI/cerebrovascular accident between the 2 groups. Four-year cost analysis showed that prompt revascularization (either catheter based or surgery based) was not favorable compared to OMT for in-trial or lifetime cost estimates. In the PCI stratum, medical therapy yielded slightly higher QALY compared to PCI (3.25 vs 3.22) at significantly lower cost ($67,800 vs $73,400, P = .02) for the in-trial period, making it the dominant strategy (quadrant B in the cost-effectiveness plan). Prompt revascularization with CABG was more costly and less effective at 4 years compared to medical therapy. However, lifetime estimates showed that CABG compared to medical therapy increased survival from 12.9 to 13.42 years at only marginally higher cost ($235,500 vs $210,900), yielding an ICER of $47,000/life-year gained. Therefore, prompt revascularization with PCI did not appear to be cost effective compared to medical therapy. However, revascularization with CABG may be cost effective for lifetime estimates.

Methods of Revascularization for Left Main or Multivessel Coronary Artery Disease

Although CABG is still considered the revascularization method of choice for multivessel or left main coronary disease, PCI has become an increasingly utilized revascularization method for certain multivessel and left main CADs,
largely due to the advent and evolution of DES. Long-term follow-up data from randomized clinical trials comparing CABG and PCI for multivessel coronary disease have suggested that both groups are comparable in death and nonfatal MI. However, the PCI group has significantly increased rates of repeat revascularization procedures during 8 to 12 years of reported follow-up.\textsuperscript{31,32}

Initial cost comparison data between CABG and PCI comes from EAST (Emory Angioplasty Versus Surgery Trial). Total costs of CABG and PCI were comparable during the 8-year follow-up period ($46,548 vs $44,491).\textsuperscript{31} However, initial observations in EAST demonstrated higher revascularization costs with PCI, which were confirmed in subsequent economic and quality-of-life data analyses in the BARI trial (Bypass Angioplasty Revascularization Investigation). CEA of the BARI trial over a 12-year follow-up period suggested that the initial higher medical cost of bypass surgery was offset by lower subsequent revascularization procedures and hospitalizations during follow-up compared to PCI ($123,000 for CABG vs $120,750 for PCI, $P = \cdot .55).\textsuperscript{32} Initial cost of CABG was 54\% higher than PCI, but the ICER for CABG at 12 years compared to PCI was $14,300/life-year gained for the in- trial period and $13,300/life-year gained for lifetime.\textsuperscript{32} Using the Duke Activity Status Index and RAND Mental Health Inventory V, the QALYs were 6.45 years for PCI and 6.58 years for CABG, yielding an ICER of $11,300/QALY gained for CABG.\textsuperscript{32} Despite the use of balloon angioplasty as the percutaneous revascularization method in EAST and BARI, increased rates of revascularization and the associated cost persisted with the use of BMS. For instance, the ARTS trial (Arterial Revascularization Therapy Study) demonstrated comparable death and MI at 3 years between CABG and PCI, but significantly increased rates of repeat revascularization in the PCI arm. The ICER for CABG per event-free patient (death, MI, or cerebrovascular accident [CVA]) was €10,492 at 3 years (well below the ICER threshold of €20,000-30,000/QALY or life-year gained).\textsuperscript{33}

Early studies that demonstrated higher rates of repeat revascularization in patients with multivessel CAD, especially with diabetes, attributed these findings largely to the use of balloon angioplasty or BMS for revascularization in the PCI group, which are known to perform less well than DES.\textsuperscript{32,33} The FREEDOM trial (Future Revascularization Evaluation in Patients With Diabetes Mellitus: Optimal Management of Multivessel
Disease) compared the outcomes of multivessel coronary disease with either PCI using DES or CABG in patients with diabetes. At 5 years of follow-up, the primary composite of death, nonfatal MI, and CVA was significantly higher in the PCI group compared to CABG (26.6 vs 18.7, \( P = .005 \)), again demonstrating that CABG as a revascularization strategy outperformed PCI in this population, despite the use of the most contemporary and best-performing percutaneous material.\(^{34}\) Index hospitalization cost was higher in the CABG group compared to DES-PCI by $8622. Five-year cumulative cost was also slightly higher in the CABG group by $3641.\(^{34}\) However, CABG was associated with a gain in life expectancy of 0.794 years and an overall quality-adjusted life expectancy of 0.663 QALY.\(^{34}\) Therefore, economic analysis demonstrated robust cost-effectiveness for CABG over DES-PCI, with lifetime estimated ICER of $8132/QALY gained (99.2\% of bootstrap replications < $50,000/QALY gained) and $6791/life-year gained, and persisted across a wide range of subgroups (based on SYNTAX score, age, hemoglobin A1C, and number of vessels involved).\(^{34}\)

The consideration for angiographic complexity in 3-vessel or left main CAD and their variable impact on clinical and economic outcomes when DES-PCI is compared with CABG was evaluated in the SYNTAX trial (Synergy Between PCI With TAXUS and Cardiac Surgery). One-year results from the SYNTAX showed a significantly higher composite of major adverse cardiac and cerebrovascular events (MACCE) in the PCI group compared to CABG, primarily driven by increased rates of repeat revascularization.\(^{35}\) However, when the clinical outcomes were compared based on the complexity of coronary anatomy, only a high SYNTAX score (≥33) was associated with higher events in the PCI group.\(^{35}\) The ICER for CABG compared to PCI based on interaction between SYNTAX score and QALY demonstrated PCI to be a dominant strategy in 3-vessel CAD with low (<23) and intermediate (23-32) SYNTAX scores as well as for isolated left main disease at 1 year.\(^{35}\) However, the ICER for 3-vessel disease with high SYNTAX score was favorable for CABG at $43,486/QALY.\(^{35}\) Again, the 5-year clinical outcomes of SYNTAX demonstrated that the composite of MACCE was significantly lower in the CABG group compared to DES-PCI (26.9\% vs 37.3\%, \( P < .0001 \)).\(^{36}\) Rates of MI and repeat revascularization were significantly higher in PCI with comparable death and stroke. MACCEs for CABG were comparable with DES-PCI for low SYNTAX score and for left
main coronary disease.\textsuperscript{36} For intermediate and high SYNTAX score, DES-PCI had significantly higher MACCEs at 5 years.\textsuperscript{36} Five-year economic data from SYNTAX are currently ongoing. Initial economic data for 5-year follow-up presented at the Transcatheter Cardiovascular Therapeutics Conference in 2013 demonstrated that the cost of initial hospitalization remained higher with CABG (by $10,036) compared to DES-PCI.\textsuperscript{37} In-trial cost remained $5619 higher in the CABG group at 5 years with 0.1 QALY gained. Lifetime estimates suggested 0.412 QALY gained for CABG, yielding an ICER of $16,537/QALY gained.\textsuperscript{37} Cost-effectiveness of CABG versus PCI based on SYNTAX score showed CABG as a dominant strategy for high SYNTAX score (>32) with an ICER of $8219/QALY gained.\textsuperscript{37} For low SYNTAX score (<23), PCI remained a dominant strategy, including for left main disease.\textsuperscript{37} For intermediate SYNTAX score (23-32), the ICER for CABG was $36,790/QALY gained, making CABG a reasonably cost-effective strategy.\textsuperscript{37}

In summary, cost-effectiveness of CABG versus PCI for multivessel and left main CAD depends largely on the presence of diabetes and SYNTAX score. For patients with diabetes and high SYNTAX score (>32), CABG appears to be cost effective compared to PCI. For low SYNTAX score (<23), PCI appears to be dominant. For intermediate SYNTAX score (23-32), CABG appears to be cost effective in the long term.\textsuperscript{31–37}

\textit{Ischemia-Driven Revascularization}

The FAME trial (Fractional Flow Reserve Versus Angiography for Guiding Percutaneous Coronary Intervention) demonstrated that ischemia-driven revascularization by fractional flow reserve (FFR) compared to angiography-guided revascularization resulted in an improved composite of death, nonfatal MI, and repeat revascularization at 1 year.\textsuperscript{38} FFR is defined as the ratio of maximum blood flow in the distal coronary artery in the presence of a significant stenosis to maximum blood flow in a normal vessel.\textsuperscript{39} It is calculated by simultaneous pressure measurement in the aorta and distal coronary artery beyond the stenosis of interest after achieving maximum hyperemia with pharmacologic vasodilatation. An FFR value of <0.75, and more recently ≤0.80, has been demonstrated to reliably identify significant coronary stenosis.\textsuperscript{39} The FAME trial randomly compared angiography-
guided PCI to FFR (≤0.8)-guided PCI in a total of 1005 patients for the primary composite end point of death, nonfatal MI, and repeat revascularization at 1 year. The 1-year event rate was significantly lower in the FFR-guided PCI group compared to the angiography-guided PCI group (13.2% vs 18.3%, \( P = .02 \)). Freedom from angina was comparable between the 2 groups at 1 year. The FAME-2 trial subsequently compared outcomes (primary composite end point of death, MI, and urgent revascularization) of initial PCI for ischemic coronary stenosis (FFR <0.8) with medical therapy in a total of 1220 patients. The primary end point was significantly lower in the PCI group (4.3% vs 12.7%, \( P < .001 \)), primarily driven by lower rates of urgent revascularization at 7-month follow-up.\(^40\) The trial results were consistent with the COURAGE trial, meaning PCI was more effective in relieving angina and improving quality of life. However, the COURAGE trial demonstrated that initial PCI was not a cost-effective strategy in the management of stable CAD.\(^20\) It becomes important to investigate whether initial PCI becomes more cost effective in the management of ischemia-only (FFR <0.8) stable coronary stenosis. Cost-effectiveness data from the FAME-2 trial demonstrated that cumulative cost at 1 year was higher in the PCI group compared to the medical therapy group ($12,646 vs $9763, \( P < .001 \)),\(^40\) but that PCI was associated with a significant increase in patient utility from baseline as estimated by EQ-5D (0.054 vs 0.0001). Assuming that utility of PCI linearly declines over 3 years with unchanged cost difference between the 2 strategies, ICER for PCI remained at $36,000/QALY gained.\(^40\) The ICER for PCI increases more than the $50,000 threshold if utility of PCI declines at 2 years or utility of medical therapy increases at 3 years. Further, the ICER for PCI as estimated based on angina severity at baseline revealed that PCI may remain cost effective for Canadian Cardiovascular Society (CCS) class 2 to 4 angina ($27,000/QALY) but not for CCS class 0 to 1 angina ($102,000/QALY).\(^40\)

In summary, limited cost-effectiveness data suggest that PCI compared to medical therapy may be a cost-effective strategy for the initial management of stable CAD with demonstrated ischemia (FFR ≤0.8), especially for angina severity of CCS class 2 and greater.\(^40\) Additional clinical trial data in patients with more severe levels of ischemia are needed to resolve this issue.
COST-EFFECTIVENESS OF CORONARY STENTS

Balloon Angioplasty Versus Coronary Stenting in Acute Myocardial Infarction

Although balloon angioplasty (percutaneous transluminal coronary angioplasty [PTCA]) compared to coronary stenting is somewhat antiquated and minimally used for the management of acute MI, the Stent-PAMI trial and its CEA have provided a cost-efficacy comparison between the 2 strategies for patients presenting with acute MI. The Stent-PAMI trial, a multicenter randomized comparison of PTCA with stenting or PTCA alone, included 900 patients and demonstrated that the combined end point of death, reinfarction, stroke, and ischemia-driven target vessel revascularization was significantly lower in the stent group over 6 months of follow-up.\(^{41}\) This difference was primarily driven by an increased rate of ischemia-driven target vessel interventions in the PTCA group due to a significantly increased rate of vessel restenosis at 6 months.\(^ {41}\) Cost utility analysis comparing QALYs between the 2 groups was performed at 1 month, 6 months, and 1 year.\(^ {42}\) Mean hospital cost was $1900 higher in the stent group, and 1-year follow-up cost was $1000 lower in the stent group. The aggregate 1-year medical care costs were $976 higher in the stent group compared to the PTCA group (\(P = .02\)). After several cost assumptions in 2001, the overall 1-year cost of stenting was only $343 more than the PTCA group (\(P = .21\)).\(^ {42}\) Base-case cost utility analysis for the in-trial period with utilities assessed by EQ-5D showed an ICER for the stent group at $65,066/QALY gained at 1 year.\(^ {42}\) However, the ICER improved to $22,067/QALY gained with cost assumptions in 2001 compared to in-trial costs. These cost improvements were largely attributed to the technical improvements in coronary stents, stent delivery systems, and price competition, making ICER more favorable for stent use in acute MI.\(^ {42}\) Therefore, primary PCI with coronary stenting has been established as a more effective economic strategy compared to balloon angioplasty for over a decade now.

First-Generation Drug-Eluting Stents Versus Bare Metal
**Stents**

Bare metal stents (BMS) have provided a significant advantage over balloon angioplasty for the treatment of coronary disease. However, BMS usage was plagued with a tendency toward scar tissue formation within the stent during its healing process that resulted in significant restenosis. The first-generation Cypher sirolimus-eluting stent (SES) and the soon-to-follow Taxus paclitaxel-eluting stent (PES) were the first DES approved by the US Food and Drug Administration (FDA). Their development revolutionized percutaneous intervention, as the elution of antiproliferative drugs significantly reduced rates of in-stent restenosis. The SIRIUS (Sirolimus-Eluting Balloon Expandable Stent in the Treatment of Patients with De Novo Native Coronary Artery Lesions) and TAXUS IV trials demonstrated that the SES and PES, respectively, when compared to BMS, significantly reduced the rates of repeat revascularization in patients undergoing coronary stenting by way of this process.\(^{43,44}\) CEA of SIRIUS and TAXUS trials also demonstrated robust cost reduction with DES for de novo native severe coronary disease.\(^{43,44}\) For these reasons, DES is widely accepted over BMS whenever feasible and has become the standard of care.

**Second- Versus First-Generation Drug-Eluting Stents**

The zotarolimus-eluting stent (ZES) and everolimus-eluting stent (EES) constitute second-generation DES. Several studies have evaluated safety, efficacy, and cost-effectiveness between second-generation and first-generation DES. Three-year clinical outcomes of Endeavor ZES compared to Cypher SES, as studied in the ENDEAVOR III trial, demonstrated that ZES use significantly decreased rates of MI and composite of death or MI compared to SES.\(^{45}\) The ICER was $57,002/QALY gained, with 41% of bootstrap replicates showing an ICER <$50,000/QALY.\(^{45}\) The ENDEAVOR IV trial compared 2-year clinical efficacy, safety, and economic outcomes between Endeavor ZES and Taxus PES stents for single de novo CAD in 1548 patients and demonstrated that target lesion failure (TLF; composite of cardiac death, MI, and target vessel revascularization) and target lesion revascularization (TLR) were comparable between Endeavor and Taxus DES.\(^{46}\) CEA demonstrated that ZES and PES were comparable with respect to quality-adjusted survival (1.58 vs 1.57 years, \(P = .83\)) and cumulative cost
at 2 years ($19,621 vs $20,029, \( P = .44 \)).\(^4\) The SPIRIT IV trial with 3687 patients provided the largest randomized comparison between Taxus PES and Xience V EES.\(^4\) SPIRIT IV provided a real-world comparison between alternate DES platforms since it included multivessel and multilesion intervention without protocol-driven angiographic follow-up. TLF at 2 years was significantly reduced in the EES arm compared to PES (6.9% vs 9.9%, \( P = .003 \)).\(^4\) MI, ischemic-driven TLR, and stent thrombosis were also significantly reduced with Xience V EES with a nonsignificant difference in all-cause and cardiac mortality.\(^4\) Resource utilization data analysis suggested comparable index procedural cost for EES and PES. Total target vessel revascularization–related costs were $661 lower per patient at 2 years in the EES group compared to the PES group (\( P = .013 \)).\(^4\) However, the cost of non–target vessel revascularization was higher in the EES group by $441 per patient, making total cardiovascular-related cost at 2-year follow-up comparable between the EES and PES groups ($22,061 vs $22,355 per patient). The EES group had $272 lower cost at 2 years per patient with 0.0064 QALY gained compared to PES.\(^4\) CEA (Fig. 72-5) demonstrated that EES was economically attractive, with 64% bootstrap replicates falling in the right lower quadrant of the cost-effectiveness plane (dominant) indicating ICER <$50,000/QALY.\(^4\)

![Figure 72-5](image.png)

**FIGURE 72-5** Joint distribution of cost and effectiveness differences in cost-effectiveness plane (SPIRIT IV trial). A. Joint distribution of the cost and efficacy (for target vessel revascularization) differences at 2 years for the everolimus-eluting stent (EES) versus paclitaxel-eluting stent (PES) demonstrated EES to be a dominant strategy with $273 lower cost and 0.0064 higher quality-adjusted life-years with an ICER below $50,000/QALY (solid circle), with 64.8% of bootstrap replicates falling in the lower right-hand quadrant. B. Cost-effectiveness acceptability curve indicated the
probability (85.7%) that the EES is economically attractive compared to the PES.

ICER, incremental cost-effectiveness ratio; QALY, quality-adjusted life-year.

**Economics of Drug-Eluting Stents Beyond Randomized Trials**

DES have emerged as a cost-effective strategy (especially second-generation DES) compared to BMS, primarily by decreasing the cost of repeat revascularization and MI after the index procedure. However, it is important to evaluate this cost saving strategy in real-world situations where cost-effectiveness is affected for a variety of reasons, such as off-label use and absence of protocol-driven resource utilization.

With safety concerns due to DES-related stent thrombosis, in January 2007, the FDA issued an advisory to restrict the use of DES for unapproved or untested indications. In response to this, the use of DES fell substantially, likely due to limited use of DES for a more select group of patients (eg, diabetes, long segment stenosis, small vessel) compared to their previous unrestricted use. The strategy of unrestricted versus selective use of DES was evaluated at the population level in the EVENT registry (Evaluation of Drug-Eluting Stents and Ischemic Events). Clinical outcomes and cardiovascular cost in 10,144 patients were evaluated between 2 time periods (2004-2006: unrestricted use era; and in 2007: selective use era). Ninety-two percent of patients undergoing PCI during the unrestricted era received at least 1 DES, while only 68% of patients in the selective use era received DES. One-year rates of death and MI were comparable between the 2 eras; however, TLR was slightly increased during the selective use era (4.1 vs 5.1, \( P = .03 \)). Total cardiovascular care cost per patient was lower during the selective use era ($401 per patient with 95% CI, $131-$671, \( P = .004 \)), with an increased initial hospitalization cost in the unrestricted DES use (due to more number of DES placed) not offset by lower rates of TLR. Risk-adjusted ICER for unrestricted versus selective use of DES was $16,000 per TLR avoided, $27,000 per any repeat revascularization, and $433,000 per QALY gained. The probability of an ICER <$10,000 per TLR avoided was
Selective use of DES, therefore, appears more cost effective.

COST-EFFECTIVENESS OF ADJUVANT MEDICAL THERAPY WITH PCI

Antiplatelet Agents

Glycoprotein IIb/IIIa Inhibitors

Initial studies have demonstrated that the use of glycoprotein IIb/IIIa inhibitors (GPIs) has reduced 30-day composite of death, MI and repeat revascularization after angioplasty (36% relative risk reduction at 2 days) in patients presenting with ACS compared with patients who did not receive a GPI. Early benefits of GPIs appeared more pronounced in high-risk patients and persisted with coronary stenting. CEA of the RESTORE trial (Randomized Efficacy Study of Tirofiban for Outcomes and Restenosis) demonstrated that the early clinical benefit after high-risk angioplasty with tirofiban could be achieved at an insignificant incremental cost for the initial hospitalization and at 30 days compared to the placebo. However, patient risk was noted to play heavily into the cost breakdown. Among patients undergoing PCI at low (<5%) probability of events (in-hospital death, MI, or emergent additional revascularization), the ICER for GPI use was unfavorable (>50,000/event averted). At intermediate probability of events (5%-7%), the ICER was marginally cost effective (<50,000/event averted at $750 cost of therapy and >$50,000/event averted at $1000 cost of therapy). At high probability of events (>7%), GPI use was highly cost effective, with the ICER ranging from approximately $25,000 to $36,000 per event averted.

Clopidogrel

The addition of clopidogrel to aspirin alone for medically treated NSTEMI patients provided robust clinical benefit for secondary prevention (20% relative risk reduction in composite of cardiovascular mortality, nonfatal MI,
and stroke), as demonstrated in the CURE trial. The total cost of care was $442 higher in the clopidogrel arm compared to placebo for the trial period (cost difference primarily driven by cost of clopidogrel). The ICER for clopidogrel was $6318/life-year gained with 94% bootstrap-derived ICER estimates <$50,000/life-year gained for the in-trial period. Lifetime estimates, projected based on the Framingham study, showed that the ICER for clopidogrel was $9820/life-year gained. Superior clinical efficacy and cost-effectiveness of clopidogrel plus aspirin compared to aspirin alone was also demonstrated in NSTEMI patients undergoing PCI up to 1 year (PCI-CURE). Total cost per patient in the entire follow-up period (inclusive of initial and subsequent hospitalization along with cost of clopidogrel) was $423 higher in the clopidogrel group in which PCI was performed during either the initial or subsequent hospitalization, whereas it was $90 higher for the clopidogrel group undergoing early PCI during only the initial hospitalization. The ICER for clopidogrel was $4775/life-year gained among all patients and was $935/life-year gained among the early PCI group. The COMMIT trial (randomized comparison of a total 45,852 STEMI patients receiving clopidogrel plus aspirin vs aspirin plus placebo) demonstrated that adding clopidogrel to aspirin for STEMI patients for an average of 2 weeks provided a 9% relative risk reduction in death, reinfarction, or stroke at 4 weeks. For STEMI patients, using CURE data to model events between 28 days and 1 year and assuming treatment with clopidogrel for 1 year, lifetime CEA demonstrated that the ICER for clopidogrel was $10,691/life-year gained. The strategy of using clopidogrel plus aspirin compared to aspirin alone for up to 1 year appears to be dominant for patients presenting with ACS.

**Prasugrel**

The conventional antiplatelet regimen of aspirin plus clopidogrel has been substantially improved with the advent of newer thienopyridine (prasugrel) and nonthienopyridine (ticagrelor) agents. Safety and efficacy of prasugrel (60-mg loading dose followed by 10 mg daily maintenance) versus clopidogrel (300-mg loading dose followed by 75 mg daily maintenance) for intermediate- to high-risk NSTEMI patients undergoing planned PCI was evaluated over 6 to 15 months in a total of 13,608 patients in the multicenter,
randomized TRITON-TIMI-38 trial.\textsuperscript{55} The original trial and the economic substudy both demonstrated a reduction in the composite of cardiovascular death, MI, or stroke.\textsuperscript{55} TIMI major bleeding episodes not related to CABG were higher in the prasugrel arm. Initial hospitalization costs (inclusive of periprocedural bleeding and MI) were similar between the 2 groups.\textsuperscript{55} Excluding the cost of study drug, total (initial and follow-up) hospitalization costs were $517 lower in the prasugrel group, with the majority of the cost offsets being due to reduced rates of repeat hospitalization involving PCI.\textsuperscript{55} However, the mean cost of study drug was $308 higher for the prasugrel group compared to the clopidogrel group. Therefore, the cumulative medical care cost (study drug, initial and subsequent hospitalization) was $221 less per patient with prasugrel. Treatment with prasugrel compared to clopidogrel (for 14.6 months) increased life expectancy by 0.102 years and QALYs by 0.095, making it a dominant strategy (ICER < $50,000/life-year gained in 99.8\% bootstrap replicates).\textsuperscript{55} The ICER for prasugrel remained favorable ($9727/life-year gained) when the generic cost of clopidogrel was considered at $1 per day. The ICER for prasugrel remained at $20,714/life-year gained in 84\% of bootstrap estimates when the most conservative cost model was created, including cost of life expectancy lost due to increased bleeding, generic cost of clopidogrel, and cost of care due to life-years gained with prasugrel.\textsuperscript{55}

### Ticagrelor

The addition of ticagrelor to aspirin significantly reduced the composite of vascular death, MI, or stroke without increasing the bleeding complications compared to clopidogrel in the PLATO trial for ACS patients with and without ST-segment elevation.\textsuperscript{15} As described earlier, long-term cost-effectiveness of this strategy has been evaluated from a healthcare perspective in Euros (€) using short-term base-case analysis from trial data and long-term analysis beyond the trial period using a Markov extrapolation model (data extrapolated primarily from the PLATO outcomes).\textsuperscript{15} The ICER for ticagrelor was €2752/QALY gained (incremental cost of ticagrelor to be €362 with QALY gained of 0.13).\textsuperscript{15} The ICER for ticagrelor remained favorable in a variety of ACS and patient subgroups, as displayed in the cost-effectiveness acceptability curve in Figure 72-2.
In summary, use of clopidogrel along with aspirin demonstrates robust cost-effectiveness for the secondary prevention of patients presenting with ACS. Use of ticagrelor as a second antiplatelet agent is cost saving across a broad spectrum of ACS patients. For patients presenting with ACS and undergoing PCI, use of prasugrel appears to be cost effective compared to clopidogrel.

**Anticoagulants**

**Bivalirudin**

Advances in anticoagulation strategies during PCI have warranted a reevaluation of their cost-effectiveness in the modern era. The ACUITY trial (Acute Catheterization and Urgent Intervention Triage Strategy) established that a GPI plus heparin-based antithrombotic strategy increased rates of bleeding with comparable ischemic events (death, MI, and ischemia-driven revascularization) when compared to bivalirudin alone for patients with intermediate- to high-risk ACS at 30 days managed with an early invasive approach. Similarly, patients undergoing primary PCI for STEMI in the HORIZONS-AMI trial had a significantly lower rate of net adverse clinical events with bivalirudin compared to GPI plus unfractionated heparin at 30 days (9.2% vs 12.1%; response rate [RR], 0.76; 95% CI, 0.63-0.92; \( P = .005 \)). This was due to a lower rate of major bleeding (4.9% vs 8.3%; RR, 0.60; 95% CI, 0.46-0.77; \( P <.001 \)) with similar MACE (composite of death, MI, stroke, and target vessel revascularization: 5.4% and 5.5%; \( P = .95 \)).

Economic analysis of the ACUITY trial showed that the cost of anticoagulation in US hospitals differed significantly based on the regimen chosen. During the initial hospital stay, bivalirudin monotherapy resulted in a $600 net cost savings per patient compared to heparin plus GPI and $200 net cost savings per patient compared to heparin plus provisional GPI therapy. The initial cost savings with bivalirudin monotherapy persisted at 30 days compared to any GPI-based regimen. Attributed cost calculations suggested that both major and minor bleeding episodes were independent drivers of increased in-hospital cost in the heparin plus GPI group. Cost-effectiveness of bivalirudin over heparin plus GPI was also demonstrated for STEMI patients undergoing primary PCI. A UK health service–based economic
analysis of HORIZONS-AMI was performed with a lifelong time horizon combining a decision analytic model and a Markov model to derive lifetime estimates. A bivalirudin-alone strategy was dominant (in 99% of replicates in a probabilistic sensitivity analysis with the ICER <€20,000/QALY gained) over heparin plus GPI with per-patient lifetime savings of €267 and an incremental gain of QALY of 0.09 years. The above data support the notion that bivalirudin is cost effective, as a treatment for both STEMI and ACS. However, current practice often utilizes GPIs only as bailout and not as protocol-based therapy. In light of this, the recent HEAT trial (How Effective Are Antithrombotic Therapies in Primary PCI) compared the strategy of bivalirudin monotherapy with bailout GPI versus unfractionated heparin monotherapy plus bailout GPI in patients undergoing primary PCI for STEMI. In this single-center, randomized trial involving over 1800 patients, the primary end point (composite of all-cause mortality, stroke, reinfarction, or unplanned revascularization) occurred more frequently in the bivalirudin group versus the heparin group (8.7% vs 5.7%, \( P = .01 \)) at 28 days. Use of bailout GPI and major bleeding episodes were comparable between the 2 groups. The HEAT trial, therefore, questions the cost-effectiveness demonstrated in the HORIZONS-AMI trial with bivalirudin. Although demonstrated in a single-center experience, it appears that heparin is superior compared to bivalirudin when used with bailout-only GPI, likely due to the significant cost savings associated with heparin use. This initial observation warrants further investigation in determining the optimal medical and cost-effective anticoagulation strategy during primary PCI for STEMI.

**Enoxaparin**

When compared to heparin, enoxaparin has the ability to achieve more consistent anticoagulation without the need for effect monitoring. In light of this, the ExTRACT-TIMI 25 trial compared enoxaparin with heparin when used as the anticoagulant for STEMI management. Enoxaparin was found to be superior to unfractionated heparin in patients presenting with STEMI undergoing thrombolysis with a 2.1% absolute reduction in death or MI and significantly reduced rates of nonfatal major bleeding, nonfatal disabling stroke, and nonfatal intracranial hemorrhage at 30 days. Total cost (hospitalization and follow-up) at 30 days was $102 higher with enoxaparin compared to unfractionated heparin. Further, estimated lifetime cost beyond
the trial period was $1105 higher in the enoxaparin group. The ICER of enoxaparin compared to unfractionated heparin was $880/life-year gained at 30 days (99.9% bootstrap replicates < $50,000/life-year gained), $5700/life-year gained for lifetime beyond the trial period (99.9% estimates < $50,000/life-year gained), and $4700/QALY gained, making the use of enoxaparin a cost-effective strategy.  

COST-EFFECTIVENESS OF TRANSCATHETER AORTIC VALVE REPLACEMENT FOR AORTIC STENOSIS

Transcatheter aortic valve replacement (TAVR) is a landmark development in interventional cardiology and underscores the potential of transcatheter therapies for advanced and life-threatening cardiovascular diseases such as severe aortic stenosis. During TAVR, diseased native aortic valve is displaced and is functionally replaced with a bioprosthetic valve delivered on a catheter either retrograde through the femoral artery (known as transfemoral TAVR [TF-TAVR]) or antegrade through the left ventricular apex (known as transapical TAVR [TA-TAVR]). Long-term management options are limited for patients with severe aortic stenosis who have prohibitive operative mortality (inoperable) or high operative risk. Such patients utilize a significant amount of medical resources. Analysis of clinical and economic outcomes of medically managed patients with severe aortic stenosis from a Medicare database demonstrated 88% mortality over 5 years with 1.8 years of mean survival. During a 5-year follow-up period, the average patient experienced 4 to 5 hospitalizations, mainly heart failure related, with total 5-year healthcare cost of $63,844 per patient and annual follow-up cost of $29,278 per year alive. This cost was composed of initial and subsequent hospitalizations, requirement of skilled nursing, and physician reimbursements. A substantial number of severe aortic stenosis patients are medically managed and do not undergo surgical aortic valve replacement because of inoperable status or high surgical risk. The estimated cost of providing care to medically managed patients with severe aortic stenosis...
among the entire Medicare population approaches $1.3 billion/year. TAVR has emerged as an attractive strategy for such patients. Cost-effectiveness of TAVR has been performed for the Edwards SAPIEN valve system (Edwards Lifesciences, Irvine, CA).

**TAVR for Patients With Prohibitive Risk for Surgical Aortic Valve Replacement (Inoperable)**

Efficacy and safety of TAVR were compared to standard therapy for patients who were considered inoperable due to prohibitively higher operative mortality in the PARTNER trial (cohort B), which was a multicenter randomized trial including a total of 358 patients between 2007 and 2009. Compared to standard therapy, TAVR resulted in a 20% reduction in mortality, improved functional status, and reduced hospitalization rates at 1 year. The mean cost of the TAVR procedure was $42,806, and the mean cost of the initial TAVR hospitalization was $78,542. Mean cost of follow-up hospital care was significantly lower in the TAVR group compared to the standard therapy, primarily driven by reduced rates of cardiovascular hospitalization ($18,074 vs $44,099, \( P < .001 \)). Total cost of care at 12 months (initial procedure and follow-up) was $52,455 higher in the TAVR group compared to medical therapy, driven by cost of the initial procedure and longer length of rehabilitation and skilled nursing. Health utilities were statistically higher for the TAVR group compared to the control group at 12 months, estimated by EQ-5D (0.72 vs 0.62, \( P < .05 \)). The lifetime ICER for TAVR was $50,212 compared to standard therapy with a gain in life expectancy of 1.6 years (Fig. 72-6). QALY gain with TAVR was not as robust as life-years gained, resulting in a slightly higher ICER/QALY gained of $61,889 with the majority of bootstrap iterations falling between ICER/QALY thresholds of $40,000 to $60,000 (Fig. 72-7). The ICER/QALY gained or ICER/life-year gained for TAVR, compared to medical therapy, was slightly higher than the conventionally considered willingness-to-pay threshold of $50,000. However, it is either comparable or favorable to the ICER of most advanced cardiovascular procedures such as use of defibrillators in the primary prevention of sudden cardiac death, initial PCI for stable angina, atrial fibrillation ablation, hemodialysis, and destination left ventricular assist devices. Similar CEAs from the UK
National Health Services perspective demonstrate that TAVR for inoperable patients is cost effective compared to medical therapy over a 10-year time horizon with an ICER/QALY gained of £16,100 (societal cost-effectiveness threshold considered below £20,000/QALY gained).\textsuperscript{64}

**FIGURE 72-6** Cost-effectiveness plane for transcatheter aortic valve replacement (TAVR) in inoperable patients compared to standard therapy in the PARTNER trial (cohort B). The cost-effectiveness plane with the joint distribution of projected lifetime mean incremental costs and life expectancy of TAVR versus medical therapy indicated the difference between 2 groups for life-years gained (1.6 years) on the x-axis and the cost ($79,837) on the y-axis (dark dot) with surrounding lifetime incremental cost-effectiveness ratio point estimates derived from 5000 bootstrap replications of the study sample (white dots). LE, life expectancy; LYG, life-years gained. (Reproduced from Reynolds MR, Magnuson E, Wang K, et al. Cost-effectiveness of transcatheter aortic valve replacement compared with standard care among inoperable patients with severe aortic stenosis: results from the placement of aortic transcatheter valves (PARTNER) trial (Cohort B). Circulation. 2012;125(9):1102-1109.)
FIGURE 72-7 Cost-effectiveness acceptability curve for transcatheter aortic valve replacement (TAVR) in inoperable patients with severe aortic stenosis compared to standard therapy in PARTNER trial (cohort B). Cost-effectiveness acceptability curve of TAVR versus medical therapy. The plot of the probability of cost-effectiveness, calculated as the proportion of bootstrap iterations falling below a given cost-effectiveness threshold, against a wide range of incremental cost-effectiveness ratio (ICER) thresholds demonstrated that nearly all iterations of the study sample resulted in ICER ratios between $40,000 and $60,000 per life-year gained. (Reproduced from Reynolds MR, Magnuson E, Wang K, et al. Cost-effectiveness of transcatheter aortic valve replacement compared with standard care among inoperable patients with severe aortic stenosis: results from the placement of aortic transcatheter valves (PARTNER) trial (Cohort B). Circulation. 2012;125(9):1102-1109.)

The recently published US trial comparing the self-expanding Medtronic CoreValve (Medtronic, Minneapolis, MN) to standard therapy for inoperable patients with severe aortic stenosis has demonstrated a 1-year survival benefit of CoreValve over medical therapy and has planned a prespecified economic analysis that would give further insight into cost-effectiveness of TAVR in this patient population.65

**TAVR for Patients With High Risk for Surgical Aortic Valve Replacement**
TAVR in patients considered high, but not prohibitive, risk for perioperative mortality was compared with surgical aortic valve replacement (SAVR) in cohort A of the PARTNER trial. Initial trial outcomes at 1 year and subsequently reported outcomes at 2 years demonstrated comparable rates of mortality and stroke. Quality of life with TAVR was not significantly different than SAVR at 1 year. Economic analysis has been separately performed for TF-TAVR (assumed to be performed in the catheterization laboratory) and TA-TAVR (assumed to be performed in the operating room) compared to SAVR due to fundamental differences in both techniques. The acquisition cost of the Edwards SAPIEN valve was $30,000 versus $5277 for a standard bioprosthetic aortic valve. For TF-TAVR patients, initial procedural cost was significantly higher for TAVR compared to SAVR ($36,652 vs $14,475), but overall initial hospitalization costs appeared comparable to SAVR due to reduced intensive care unit stay and reduced length of hospitalization ($72,219 vs $76,067). For TA-TAVR, both procedural and overall initial hospitalization costs were significantly higher than for SAVR. Resource utilization between initial hospital discharge and 12-month follow-up appeared comparable between TAVR (TF-TAVR and TA-TAVR) and SAVR with fewer rehabilitation and skilled nursing requirements in the TAVR group. For the overall 12-month study period, the TF-TAVR cohort had marginally lower ($1250) cost of care compared to SAVR, and the TA-TAVR cohort had a $9906 higher cost of care compared to SAVR. The pooled analysis demonstrated a slightly higher 12-month cost for TAVR as a whole compared with SAVR ($100,504 vs $98,434), with an ICER for TAVR of $76,877/QALY gained. However, there were significant variations in the bootstrap replications of ICER, primarily due to significant cost differences in the TAVR group depending on access site. Specifically, TF-TAVR was an economically attractive strategy with ICER <$50,000/QALY gained for the trial period in 71% bootstrap replications compared to SAVR (Fig. 72-8A). TA-TAVR remained dominated by SAVR in 86% of bootstrap replicates, making it economically an unattractive strategy at 12 months compared to SAVR for high-risk severe aortic stenosis patients who do not have favorable femoral vessel anatomy for TF-TAVR (Fig. 72-8B).
FIGURE 72-8 Cost-effectiveness plane for high-risk severe aortic stenosis undergoing transcatheter aortic valve replacement (TAVR) compared to surgical aortic valve replacement (AVR) in the PARTNER trial (cohort A). The ICER/QALY gained for (A) transfemoral (TF) and (B) transapical (TA) TAVR as a function of joint distribution of cost (TAVR – AVR) and gain of QALY (TAVR – AVR) at 12-months.
The solid circles represent base-case estimates, and the surrounding open circles represent ICER estimates for 1000 bootstrap replications of the study sample. The dashed lines represent a willingness-to-pay threshold of $50,000/QALY gained. TAVR appeared to be a dominant strategy for the TF cohort but was dominated by AVR for the TA cohort. ICER, incremental cost-effectiveness ratio; QALY, quality-adjusted life-year. (Reproduced from Reynolds MR, Magnuson E a, Lei Y, et al. Cost-effectiveness of transcatheter aortic valve replacement compared with surgical aortic valve replacement in high-risk patients with severe aortic stenosis: results of the PARTNER (Placement of Aortic Transcatheter Valves) trial (Cohort A). J Am Coll Cardiol. 2012;60(25):2683-92, Copyright © 2012, with permission from Elsevier.)

**TAVR for Patients With Intermediate Risk for SAVR**

Limited data exist regarding safety and efficacy of TAVR for patients with intermediate operative risk, and several multicenter, randomized clinical trials are currently under way to evaluate TAVR compared with SAVR for this patient group. The SURTAVI trial is evaluating the self-expanding Medtronic CoreValve versus SAVR for patients with severe symptomatic aortic stenosis with intermediate surgical risk (Society of Thoracic Surgeons [STS] score–predicted perioperative mortality of 4%-10%; ClinicalTrials.gov identifier: NCT01586910). At the time of publication of this chapter, the PARTNER II trial is ongoing and evaluating the second-generation SAPIEN XT and third-generation SAPIEN 3 heart valve systems for a wide range of symptomatic severe aortic stenosis patients including inoperable, intermediate-risk (STS-predicted surgical mortality of 4%-8%), and high-risk (STS-predicted surgical mortality of >8%) patients (ClinicalTrials.gov identifier: NCT01314313). Trial results from a single-center, prospective study evaluating patients with intermediate-risk severe aortic stenosis do exist. This study from the Netherlands used propensity matching in 84 patients undergoing placement of TF-TAVR with the third-generation CoreValve (€17,590 per valve) versus SAVR with the bioprosthetic Carpentier-Edwards PERIMOUNT magna valves (Edwards Lifesciences; €2700).\(^{67}\) In-hospital and 1-year mortality were comparable between TAVR and SAVR.\(^{67}\) As expected, initial hospitalization cost was higher with TAVR compared to SAVR (€40,802 vs €33,354).\(^{67}\) The lack of a significant cost difference between groups during follow-up did not offset the initial higher cost with TAVR (1-year total cost: €46,217 vs €35,511, \(P < .009\)). However, the small number of patients, nonrandomized trial design, and cost analysis
without ICER limit generalizability of results.

In summary, for patients with severe aortic stenosis, TAVR appears to be cost effective for inoperable patients compared to medical therapy.\textsuperscript{63,64} For high-risk patients, TAVR performed via transfemoral access, as opposed to transapical access, is an economically attractive strategy compared to SAVR.\textsuperscript{66} Insufficient evidence exists for cost-effectiveness comparisons between TAVR and SAVR for intermediate-risk patients.

**COST-EFFECTIVENESS OF RADIAL VERSUS FEMORAL APPROACH FOR PERCUTANEOUS CORONARY INTERVENTION**

Although recognized early on as an alternate access site, radial artery access has gained momentum in recent years and is being embraced among interventionalists in the United States and worldwide. Several favorable aspects of transradial intervention include increased patient comfort, reduced bleeding complications, and lower mortality compared to the femoral approach among STEMI patients.\textsuperscript{68,69} Along with clinical benefit, transradial intervention is also cost saving, as demonstrated by cost comparisons between transradial (TRI) and transfemoral (TFI) intervention at 5 high-volume centers (total 7121 PCIs; 17% radial and the rest femoral) in the United States using a retrospective dataset obtained from the National Cardiovascular Data Registry–CathPCI database.\textsuperscript{69} Patients undergoing radial intervention were younger, less likely to undergo primary PCI for STEMI, and had fewer risk factors. Bivalirudin was less frequently used in TRI.\textsuperscript{69} Cost data were obtained from each hospital’s accounting unit, tallied from the day of PCI through discharge. TRI had lower rates of bleeding and reduced unadjusted in-hospital mortality compared to TFI.\textsuperscript{69} Adjusted cost of TRI was $830 lower compared to TFI.\textsuperscript{69} This cost reduction was mainly driven by reduced postprocedural cost with TRI, partly as a result of reduced bleeding but primarily as a result of length of hospital stay. Cost savings of TRI compared to TFI were incremental as the risk of bleeding increased
($642 for low risk, $706 for intermediate risk, and $1621 for high risk). The major cost-saving strategy with TRI in this study due to reduced length of stay was consistent with a previous cost analysis from the EASY trial. The EASY trial (single-center, randomized trial of 1005 patients) demonstrated clinical noninferiority out to 30 days of bolus-only GPI and same-day discharge compared to standard GPI infusion for 12 hours and an overnight stay after an uncomplicated TRI. Since patients were randomized after PCI, cost of hospitalization excluding PCI, subsequent urgent revascularization, and hospitalization or emergency room visits for any reason up to 30 days were included in the economic analysis. Thirty-day cost analysis demonstrated a higher cost in the inpatient group compared to the outpatient group, driven by the initial extra night spent in the hospital without significant difference in resource utilization between discharge and 30 days (mean cost difference of $1141 per patient). There are several limitations in extrapolating these findings to the US health care system. First, safety of same-day discharge after uncomplicated PCI should be established in a large, multicenter randomized trial. Second, there is a potential disincentive from a hospital perspective due to the US reimbursement system where reimbursement for inpatient PCI is significantly higher than outpatient PCI. Overall, however, TRI is considered a cost-effective strategy.

COST-EFFECTIVENESS OF VASCULAR CLOSURE DEVICES AFTER PERCUTANEOUS CORONARY INTERVENTION

Closure devices are routinely used for femoral access site hemostasis. Cost-effectiveness data for vascular closure devices are limited and are primarily represented by Angio-seal (St. Jude Medical, Saint Paul, MN). The equivalent safety and efficacy of the Angio-seal collagen-based closure device compared to manual compression have been established in multiple randomized trials. Cost efficacy of Angio-seal was demonstrated in a single-center economic analysis involving 3943 patients undergoing PCI. Pooled analysis of the randomized trial data was used to predict vascular
complication rates among those undergoing hemostasis via Angio-seal versus manual compression, and direct cost related to the vascular complications was obtained from hospital-level billing data.\textsuperscript{71} Cost attributed to a vascular complication was derived with a case-control analysis between patients with and without vascular complication in each group. A base-case decision analytic model demonstrated net cost savings of $44 per case for patients treated with the Angio-seal closure device compared to manual compression, making it a cost-effective strategy.\textsuperscript{71}

**MULTIPLE CHOICE QUESTIONS**

1. What is the most common method used for cost-effectiveness analysis?
   - A. Sensitivity analysis
   - B. Incremental cost-effectiveness ratio
   - C. Bootstrap analysis
   - D. Markov analysis
   - E. Health utility assessment

2. What quadrant of cost-effectiveness plane is considered most cost effective?
   - A. Upper right
   - B. Upper left
   - C. Lower right
   - D. Lower left

3. What is the concept used in Markov decision-analytic model?
   - A. Projection of cost per life-year or quality-adjusted life-year (QALY) gained based on short-term results
   - B. Projection of 10-year cost per QALY gained based on 2-year results
C. Projection of health utility changes after short-term intervention
D. Projection of long-term survival based on short-term results

4. Which antiplatelet agent, when used in combination with aspirin, has been demonstrated to be cost effective across a wide spectrum of patients with acute coronary syndrome (ACS) for secondary prevention?
   A. Clopidogrel
   B. Prasugrel
   C. Ticagrelor
   D. Ticlopidine
   E. Cilostazol

5. Which access route is shown to be the least cost effective in patients undergoing transcatheter aortic valve replacement (TAVR)?
   A. Transfemoral
   B. Transapical
   C. Transcaval
   D. Transaortic

ANSWERS

1. B
Incremental cost-effectiveness ratio (ICER) is the most widely used and accepted method to evaluate cost-effectiveness of a particular intervention. Authors have found that ICER has been used in the majority of studies as a fundamental metric evaluating cost-effectiveness of a new therapy. The ICER is defined as the incremental cost of providing a specific intervention or therapy divided by the incremental gain in the health benefit. ICER is usually compared to a standard willingness-to-pay threshold, eg, $50,000/life-year gained.

2. C
The cost-effectiveness plane (CEP) is a 2-dimensional display of incremental effectiveness versus incremental cost where the x-axis represents incremental cost of a new therapy compared to the conventional therapy and the y-axis
represents incremental effectiveness of the new therapy compared to the standard treatment. Thus, points on the plane represent a graphical display of the ICER. The CEP is divided into 4 quadrants. The lower right quadrant is the most cost effective since it introduces more effective newer treatment strategies at a lower cost than the standard treatment option. Such newer therapies are known as “dominant” therapies over standard treatment.

3. A

The duration of many clinical trials is usually not long enough for an accurate estimation of the long-term course of a clinical disease. This limits the accurate estimation of the changes in life-years and QALYs with a newer therapy and thus incremental gain in life-years or QALYs over standard therapy. Therefore, the cost-effectiveness analysis based on the data collected during the clinical trial follow-up period has a limited utility for economic decision making. Long-term projections based on short-term results are required to estimate cost per life-year or QALY gained. Markov analysis allows modeling for average life expectancy and lifetime cost of therapies to derive lifetime ICER or lifetime cost per QALY gained based on short-term event rates and cost data collected during the in-trial period.

4. C

As a second antiplatelet agent along with aspirin, ticagrelor has been demonstrated to be cost effective compared to clopidogrel in reducing the composite of vascular death, myocardial infarction, or stroke without increasing the bleeding complications for ACS patients with and without ST-segment elevation (PLATO trial). Prasugrel has been shown to be cost effective compared to clopidogrel only for patients presenting with ACS and undergoing percutaneous coronary intervention (TRITON-TIMI-38 trial).

5. B

The cost-effectiveness analysis of the PARTNER cohort A trial, comparing TAVR versus surgical aortic valve replacement (SAVR) for patients with severe aortic stenosis and high surgical risk, demonstrated significant variations in the distribution of ICER depending on the access route for TAVR. The 12-month overall cost of care was lower with transfemoral TAVR (TF-TAVR) compared to SAVR, whereas it was significantly higher
with transapical TAVR (TA-TAVR) compared to SAVR. This cost difference was primarily driven by higher cost of initial hospitalization with TA-TAVR.
Interventional cardiology consists of several related procedures that are performed in the coronary, peripheral, and cerebral vascular systems, as well as the central aorta, the cardiac valves, and the structural units (parenchyma) of the heart itself. Almost all of the procedures are performed under radiographic fluoroscopic guidance in a cardiac catheterization laboratory (cath lab), or sometimes a “hybrid” laboratory that can also function as a surgical operating room. Often the fluoroscopic imaging is complemented with intravascular ultrasound, transthoracic or intracardiac echocardiography, and rotational computed tomographic angiography (CTA). Thus, the modern cath lab is a complex, highly technologically sophisticated facility where both patients with chronic, stable conditions as well as patients with life-threatening illnesses are evaluated and treated. Therefore, it is essential to have an active quality assurance and improvement (QA/QI) program in place. This program will need to consider all aspects of the risks encountered by patients undergoing procedures in the cath lab, as well as by staff working there. This will of course include radiation risk and methodologies for reducing it. However, radiation risk is an extensive subject on its own and will not be covered in this chapter.
GENERAL COMPLICATIONS FROM INVASIVE CARDIOVASCULAR PROCEDURES

With the tremendous growth and increased experience of invasive cardiovascular training programs, paralleling the general overall growth in cardiac catheterization as a common diagnostic procedure, there has been a decline in the risks of undergoing an invasive procedure. Complication rates with general diagnostic catheterization and angiography are quite low. Major adverse cardiovascular events (MACE) such as death, stroke, myocardial infarction (MI), and emergency surgery typically occur in <0.1% of diagnostic procedures.\(^1\) However, for cardiovascular procedures where therapeutic intervention is attempted, the story is very different (Tables 73-1 and 73-2). Complication rates may be much higher and may be widely different between institutions.

Table 73-2 In-Hospital and Short-Term Complications Following Percutaneous Coronary Intervention for ST-Segment Elevation Myocardial Infarction in the Stent Era
In addition to the MACE events listed in Tables 73-1 and 73-2, there are several other serious events that are of clinical importance and typically are incorporated into the QA/QI program. The foremost of these are acute kidney injury (AKI), bleeding, and blood transfusions. The reasons for this are illustrative of many of the larger quality issues in general.

**Acute Kidney Injury (AKI)**

A large-scale analysis of almost 1 million percutaneous coronary intervention (PCI) patients from >1200 hospitals revealed that AKI occurred in approximately 7.1% of the patients, and 0.3% (3000 patients) had a new requirement for dialysis. A number of factors were found to be independently associated with developing AKI, and these could help serve as clinical predictors of the event (Fig. 73-1). The occurrence of AKI was quite serious, inasmuch as rates of death, bleeding, and MI were all significantly increased when AKI occurred (Fig. 73-2).
**FIGURE 73-1** Independent predictors of acute kidney injury (AKI) or dialysis. A. Independent predictors of any AKI (including dialysis). B. Independent predictors of dialysis only. (Reproduced from Tsai TT, Patel UD, Chang TI, et al. Contemporary

**Bleeding and Transfusion**

Invasive cardiovascular procedures can be accompanied by unwanted and unexpected bleeding. While it might be thought that blood transfusion is simple and effective for treating blood loss when necessary, many studies have shown that both bleeding and blood transfusions are serious clinical events in themselves and are harbingers of worsened outcomes. In a large analysis of >1 million PCI procedures at >1100 hospitals, major bleeding within 72 hours of the procedure was found in 5.8% of patients (60,000 cases), which is a very substantial number.\(^3\) Periprocedural bleeding has been found to be related to increased mortality by almost double over the subsequent year at least (Table 73-3 and Fig. 73-3).\(^4,5\) Furthermore, analyses of blood transfusion events in PCI patients, even when adjusted for coexistent anemia and blood loss, have found transfusion to be related to long-term mortality (Fig. 73-4).\(^6\)

**FIGURE 73-3** Association between bleeding and/or transfusion in percutaneous coronary intervention (PCI) and 1-year mortality. TIMI, Thrombolysis in Myocardial

To help identify ahead of time and possibly prevent bleeding in PCI, several bleeding risk models have been developed, one of which is shown in Table 73-4. This model is based on a risk scoring system and uses 10 clinical variables available at the bedside. Points are given for each level of the variables, and the summed points can be used to classify patients into low-, medium-, and high-risk groups for bleeding. The model has been found to be useful in identifying PCI patients at higher risk for bleeding events (Fig. 73-4).

FIGURE 73-5 Risk of post–percutaneous coronary intervention bleeding based on the National Cardiovascular Data Registry CathPCI bleeding risk score. Scores of <25 are low risk, scores of 25 to 65 are medium risk, and scores >65 are high risk. (Reproduced from Rao SV, McCoy LA, Spertus JA, et al. An updated bleeding model to predict the risk of post-procedure bleeding among patients undergoing percutaneous coronary intervention. JACC Cardiovasc Interv. 2013;6:897-904.)

Risk models such as these for AKI and bleeding, as well as others for risk-adjusted mortality, often are the primary focuses of a QA/QI program. This may especially be true in the early stages of a new QA/QI program that has just been initiated.

VARIATIONS AND QUALITY

The quality imperative throughout medicine and cardiology, but particularly in procedure-based interventional cardiology, specifies that regular, comprehensive, and detailed analyses of (1) patient selection, (2) processes of care, and (3) outcomes will lead to reductions in adverse events and thereby to improvements in safety and quality of care. It is for these reasons that QA/QI programs in interventional cardiology have come into existence. One of the major focus areas for these programs is the variations in practices.
between operators and between institutions, and the possible relationships between such variations and adverse events. Variations therefore have become a major subject area for review. Examining variations is one way to begin to understand processes that may be at work and how they might relate to outcomes, both good and bad. Several examples can be given for illustration.

**Detection of Coronary Artery Disease (CAD)**

An analysis of >560,000 patients with no history of prior MI or revascularization, undergoing elective diagnostic catheterization at 691 hospitals found there was wide variation between hospitals in detecting obstructive CAD, even when allowances were made for the amount of obstructive disease that might be considered significant (Fig. 73-6). Variations in clinical practice patterns that determine suitability of patients for diagnostic angiography presumably underlie these variations.

![Hospital variability in detection of coronary artery disease. Curves represent the distribution based on various definitions of coronary artery disease by degrees of stenosis severity.](image)

**FIGURE 73-6** Hospital variability in detection of coronary artery disease. Curves represent the distribution based on various definitions of coronary artery disease by degrees of stenosis severity. (Reproduced from Douglas PS, Pate MR, Bailey SR, et al. Hospital variability in the rate of finding obstructive coronary artery disease at elective, diagnostic coronary angiography. *J Am Coll Cardiol.* 2011;58:801-809.)

**Treatment of CAD**

In a survey of >5000 patients with angiographically proven significant coronary disease at 130 hospitals in Europe, the proportions of patients
treated with medications, PCI, or bypass surgery varied widely across the hospitals (Fig. 73-7). Patient and physician preference, clinical characteristics of the patients, and local customs may all have influenced the decision making. But this illustrates that even once CAD is detected its management may differ markedly from one region to another. The Dartmouth Atlas of Cardiovascular Health Care had indicated the same was true in the United States.

Patients with atrial fibrillation (AF) often receive oral anticoagulation, and while this decreases risk for stroke, it increases bleeding risks. In AF patients who develop ST-segment elevation MI (STEMI) and undergo primary PCI, the choice of a drug-eluting stent (DES) or bare metal stent may have serious implications, since DES may necessitate prolonged poststent therapy with dual antiplatelet agents. In an analysis of >14,000 AF patients undergoing primary PCI for STEMI at several hundred hospitals, the variation across hospitals in the proportion of patients treated with DES varied from none to

**Procedural Success**

In an analysis of >19,000 carotid artery stent (CAS) procedures at 188 hospitals, the risk-adjusted rates of stroke or death varied 4-fold across the hospitals, ranging from 1.2% up to 4.7% (Fig. 73-9).11 A study of >22,000 PCI attempts on chronic total occlusions (CTO) at >1000 sites by 60 operators over a 4-year period found that procedural success rates varied across the operators (Fig. 73-10).12 Success rates were higher with greater operator experience. A review of almost 15,000 Medicare fee-for-service beneficiaries ≥65 years of age who underwent transcutaneous aortic valve replacement (TAVR) at 417 hospitals in a 3-year interval examined short- and long-term outcomes.13 There were 2-fold or greater differences in 30-day and 1-year risk-standardized mortality rates after TAVR across the hospitals, ranging from 3.8% to 10.2% (at 30 days) and 11.8% to 25.6% (at 1 year).

Mortality and 1-Year Costs

Value in interventional cardiology focuses on measuring quality of outcomes achieved relative to costs for a cycle of care. This is difficult to study in a uniform manner unless there are data from a single integrated organization. The US Veterans Health Administration (VA) comes very close to this. In a study of >19,000 patients undergoing PCI at 60 VA hospitals, risk-adjusted and risk-standardized mortality was examined, as well as the 1-year costs of care for the patients. The standardized mortality was noted to vary across the hospitals, but only within a narrow band. However, the 1-year standardized costs varied much more broadly (Fig. 73-11). Actual costs varied almost 5-fold, ranging from approximately $20,000 up to $100,000.

Summary

These few examples mentioned here serve to illustrate the phenomenon of variability that occurs virtually everywhere. The sources of all these variations are not known, and certainly variations in themselves do not necessarily imply poor quality or poor practices. In fact, sometimes an analysis of variations helps identify “good practices” that can lead to better outcomes. But either way, variations in practices and outcomes are often the starting point for examination of the deeper issues at work.

DOMAINS OF QUALITY ASSURANCE/QUALITY IMPROVEMENT PROGRAMS

There are 3 basic topic areas or domains into which QA/QI programs may be divided (Table 73-5). The general elements are: (1) structure and organization; (2) processes of care; and (3) outcomes. Each of these domains has several subsidiary topics within it. The American College of Cardiology (ACC) and the Society for Cardiovascular Angiography and Interventions (SCAI) have published an expert consensus document on cardiac catheterization laboratory standards.¹ This expert consensus document specifies that a robust QA/QI program containing these and other elements is an essential feature for all cath labs (Table 73-6).

committee
  • Periodic reports on weekly, monthly, or quarterly schedule

Process of Care
  • Angiographic quality review
  • Completion of reports review
  • Standardized order sets
  • Preprocedure checklists
  • Guidelines and appropriateness review
  • Handling of emergencies
  • Staffing and personnel
  • Ancillary services

Outcomes
  • Mortality: actual and risk-adjusted
  • Adverse events: acute kidney injury, bleeding, transfusion, stroke, cardiac arrest, need for emergency surgery, others
  • Radiation exposure: patients and staff
  • Radiographic contrast dose
  • Infection

  • Committee with chairman and staff coordinator
  • Database and data collection
  • Data analysis, interpretation, and feedback
  • QA/QI implementation
  • Goals outlined to eliminate outliers, reduce variation, and enhance performance
  • Tools available to accomplish data collection and analysis
  • Feedback mechanisms in place
Educational provisions for staff and operators
• Incorporation of practice standardization/guidelines
• Professional interaction and expectation
• Incentives for high-quality metrics
• Adequate financial support for QI personnel
• Administrative oversight and action plans
• Thresholds for intervention
• Appropriate use assessment

**Structure and Organization**

Structure and organization usually encompass the managerial aspects of a QA/QI program within the institution. The exact arrangements will vary from one hospital to another. The QA/QI program may be independent of the general hospital-wide quality improvement program, or it may be a component of it. There should be a committee with a chair that meets regularly. The program should be a peer-review process and meant to be constructive and not punitive. Credentialing and recredentialing for specific procedures should be within the purview of this committee.

**Processes of Care**

The majority of the work of the QA/QI program will be process reviews. All of the patient care processes must be considered for review from time to time and whenever appropriate. It is generally known that deficiencies can arise and quality can be compromised whenever clinical workflow surrounding a process of care occurs capriciously (ie, haphazardly) and is not managed carefully. Correcting significant errors, improving quality of care for patients, and improving clinical outcomes often can all be achieved by carefully analyzing processes of care and their associated workflow patterns. At times, a single adverse event, such as an unexpected death, a cardiac arrest, or a major bleeding event, will trigger an immediate review of the causes and
consequences, along with an examination of the responses by staff members. Often it is just these single events that initiate the study of workflow patterns with an idea toward improving them. These are learning opportunities that the QA/QI program must utilize and build upon in constructive and creative ways. The QA/QI program must not be seen only as a punitive exercise, or else support and participation will not be forthcoming.

**Outcomes**

The only way to study outcomes is by collecting and analyzing data. Therefore, it is necessary for the cath lab to have a vigorous data collection system in place. The national registries (National Cardiovascular Data Registry [NCDR]) operated by the ACC were started as quality improvement activities, with the goal of standardizing data collection and providing comparative analyses of outcomes to participating institutions. These were seen as complementing or supplementing the work that institutions were already engaged in. Approximately 90% or more of all cath labs in US hospitals now participate in the CathPCI module of the NCDR. These participating cath labs receive regular reports detailing their specific outcomes metrics for a number of outcomes, along with comparisons to similar hospitals and to national averages (Fig. 73-12). Hospitals of course can and do analyze their own data in conjunction with these reports, examining other measures that may be of interest to them individually (local demographics, length of stay, costs, etc). The essential, critical element underlying all such activity is accurate data.
### Executive Summary

ACCREDITATION

One way to approach QA/QI in the cath lab is through professional society accreditation. There is an organization for this, the Accreditation for Cardiovascular Excellence (ACE). ACE operates a rigorous cath lab evaluation and accreditation program that provides on-site reviews and written assessments of the cath lab along with suggestions for improvement. Not all cath labs that apply will receive accreditation upon first review. Once accreditation is received, it is time limited, so that reaccreditation can be obtained and is encouraged. The entire program is viewed as an iterative method to review operational details and outcomes and remedy any deficiencies that may be noted. The ACE program has 12 basic topic areas that are initially reviewed as part of the overall schematic plan, as shown in Table 73-7 (available at: www.cvexcel.org). In 2017 the ACC began offering cath lab and other accreditation services, based on the national NCDR registries. (available at: www.accreditation.acc.org).

- Quality assurance
- Radiation safety

RESULTS

Establishing a QA/QI program can be a frustrating and time-consuming activity. While it is often relatively easy to tabulate adverse outcomes and identify quality gaps, formulating effective strategies to deal with these problems can be challenging. Furthermore, when there are several adverse outcomes or quality gaps that have been identified, prioritizing them in some logical and meaningful order can be difficult. Every institution will be different and take a different approach. Changes will not occur quickly nor will results be observed immediately. Patience and persistence are required. An example of a successful quality improvement initiative, a multicenter one, comes from the Northern New England Cardiovascular Study Group. This consortium of 10 hospitals chose to tackle the problem of contrast-induced AKI, which, as described earlier, is an unwelcome adverse event in cardiovascular procedures. The hospitals were divided into an intervention group, a control group, and a benchmark group. The intervention hospitals agreed to form multidisciplinary teams, participate in monthly conference calls, participate in a process of identifying best practices, implement changes in patient care, and report on their individual strategies, achievements, and problems. The structures and features of these multidisciplinary teams that were formed at the intervention hospitals almost exactly match the design features described earlier for an effective QA/QI program. The results of the effort are exceptionally encouraging (Fig. 73-13). The multicenter initiative was able to significantly reduce the rates of AKI by 21% at intervention hospitals, while no changes in AKI were observed at benchmark or control hospitals. It is important to keep in mind that it required more than a year to effectively demonstrate improvements.

CONCLUSIONS

Increasing attention is being focused on QA/QI throughout interventional cardiology. We are called upon both as individual operators as well as hospital systems to demonstrate that adverse events are being minimized, while outcomes are being improved. As new technologies emerge and new procedures are developed, we must show that these can permit safer and more successful approaches to existing clinical problems and/or permit more difficult problems to be treated that might have gone untreated before. In addition, we are called upon to demonstrate that not only are individual procedures safe and effective in their immediate outcomes, but also they have value to patients over longer periods of time when compared to alternative treatments that can be employed. Only by establishing robust QA/QI
programs will these efforts be able to succeed.

REFERENCES

**MULTIPLE CHOICE QUESTIONS**

1. What are the 3 basic topic domains in a quality assurance/quality improvement (QA/QI) program?
   A. Variability; mortality; adverse events
   B. Meetings; publications; adverse events
   C. Structure; processes; outcomes
   D. Peer review; work flow; outcomes

2. True or false? The major adverse event rates associated with general diagnostic cardiac catheterization procedures have declined over the past 2 decades.

3. Risk-adjustment models have been developed for all of the following adverse events with percutaneous coronary intervention (PCI) EXCEPT:
   A. Bleeding
   B. Acute kidney injury (AKI)
   C. Mortality
   D. Stroke
4. A catheterization laboratory QA/QI program should have all of the following features EXCEPT:
   A. Committee with chair
   B. Regular meetings
   C. Written process for credentialing
   D. Regular periodic reports
   E. Punitive disciplinary actions

5. True or false? Variations in physician practices, hospital processes of care, and clinical outcomes are part of the nature of medicine, are expected and natural, and should not be subject to examination in a catheterization laboratory QA/QI program.

ANSWERS

1. C

A robust and comprehensive QA/QI program can generally be described as having 3 features or aspects: *structure*, which refers generally to the managerial organization of the QA/QI program; *processes*, which refers to the arrangement of medical care activities; and *outcomes*, which refers to the types of events that are examined. Within this broad tripartite layout, there are many subsidiary topics.

2. True

One of the more gratifying findings that has been noted over 30 years of documentation of general diagnostic catheterization laboratory procedures is that adverse events like death, myocardial infarction, stroke, and emergency surgery have declined. In modern studies, these adverse events occur in fewer than 1% of cases and, generally, in 0.1%. The same has not been true overall for interventional procedures, although for some interventional procedures and some adverse outcomes, event rates have declined. The risk-treatment paradox for interventional procedures likely plays a role in this; as experience with a procedure grows, such that adverse event rates in “simple” cases decline, that procedure is then performed in more higher risk cases. This can lead to a non-zero “plateau” in overall adverse event rates with intervention.
3. D

The National Cardiovascular Data Registries (NCDR) of the American College of Cardiology (ACC) have developed and validated a number of risk-adjustment models for certain procedures. This permits a more fair and balanced comparison of different institutions, which may have populations that vary in their procedural risks. For PCI, risk-adjustment models exist for death, bleeding, AKI, new need for dialysis, and 30-day readmission. As yet, there are no validated models for stroke with PCI.

4. E

The focus of a catheterization laboratory QA/QI program must be on identifying, documenting, analyzing, and understanding features that impact quality of care and outcomes. This generally means examining patient selection, processes of care, and adverse events. These activities must involve all levels of personnel working in the catheterization laboratory and its affiliated units: physicians, nurses, technicians, assistants, and clerical staff. The environment must be engaging, thoughtful, inquisitive, and, above all, fair. It is exceedingly rare for deliberate, single-individual actions to cause an adverse event. Much more commonly, there are chains of actions that lead to adverse events. It is these action chains that need to be identified and altered or corrected. Then the corrective action must be followed and observed to document that it worked. This requires the active engagement and willing participation of everyone involved. Hostile, punitive, and blame-finding activities discourage participation and poison the system, ultimately undermining it.

5. False

Variations are a fact in every aspect of medicine and life itself. Observing variations can be a rewarding and fruitful way of examining system behavior. Attempting to link variations to adverse events and outcomes can be tedious and unproductive. Much of the time, no association can be found where one was thought to exist. However, patient and persistent observation, documentation, and analysis are required. Occasionally, 1 or more observed variations will be able to be linked to an adverse event or outcome, and the insights gained will lead to improvements in patient care. This makes the examination of variations a necessary and vital part of a catheterization
laboratory QA/QI program.
Part IX  Principles of Innovation

74  Innovation and Interventional Cardiology: Looking Back, Thinking Ahead
75  Principles of Innovation: Transforming Clinical Needs into Viable Inventions
76  Web-Based Learning
77  Medical Simulation in Interventional Cardiology
The field of interventional cardiology has been driven by technical innovation. In a remarkable progression of needs identification, invention, testing, and refinement, innovators have developed nonsurgical techniques to see into the heart, diagnose a wide array of conditions, and deliver potent therapies. The pathways to innovation were not always simple or straightforward. Many of these inventors persevered despite being told by peers that what they were trying to do was infeasible and foolhardy. Some of most momentous contributions came from innovators who recognized the significance of a serendipitous event, applied newly available technologies to a longstanding clinical need, maximized the value of a previous discovery by casting it in a different light, or refined nascent tools and techniques to make them safer and more effective. Collectively, the efforts of these creative, determined individuals laid the foundations of a dynamic field that integrates diagnostics with the minimally invasive treatment of ischemic heart disease and other cardiac conditions.

BACKGROUND OF INNOVATION
The Pioneers

One of the earliest pioneers of cardiac catheterization, Werner Forssmann, was a German surgical resident who saw the need for a safer, more direct way to deliver drugs to the heart for cardiac resuscitation. He was interested in accessing the right heart via the venous system, but was not permitted to conduct a study because of the prevailing certainty that any foreign penetration of the heart would be instantaneously fatal. However, Forssmann was familiar with previous catheter experiments on animals, as well as accounts of accidental incursions in which the patients had survived.\(^1\) In 1929, he threaded a urethral catheter into his own right atrium via his left antecubital vein and documented the catheter position by x-ray. Although the significance of his achievement was recognized by some, its merit was overshadowed by the consensus that his work was unacceptably dangerous. While Forssmann initially persisted in his research, the condemnation of his peers and loss of several academic positions caused him to abandon cardiology.\(^2\)\(^3\)

Years later, building on Forssmann’s work, André Cournand and Dickinson Richards went on to routinely catheterize both the right heart and the pulmonary artery, establishing the safety of the procedure in association with their groundbreaking research into cardiopulmonary physiology. By analyzing blood taken from the heart via a catheter, Cournand and Richards were able to detect hemodynamic abnormalities characteristic of congenital heart disease and pulmonary heart disease, measure the actions of cardiac drugs, perform studies of traumatic shock, and explore the physiology of heart failure.\(^4\) For this research, they were awarded the Nobel Prize in 1956, which they shared with Forssmann.\(^3\) Notably, while Forssmann was reportedly trying to develop a therapeutic technique, the essential advancements in the understanding of right heart physiology and pulmonary blood flow that followed came from innovators who focused on catheterization as a diagnostic tool.

Serendipity, and the genius to recognize its potential, has also played an important role in the history of interventional cardiology. F. Mason Sones, Jr., a pediatric cardiologist, was interested in improving the ability to visualize the coronary arteries. He conducted numerous animal experiments in which he placed an aortic catheter close to the coronary ostia for the delivery of contrast dye, but experienced little success.\(^1\) In 1958, while
performing an aortogram on a patient for an unrelated purpose, the catheter slipped out of position and contrast dye was injected directly into one of the patient’s coronary arteries. Although this caused asystole, Sones was able to resuscitate the patient and recognized in the process that the near-fatal slip had allowed him to clearly visualize the small coronary vessels for the first time. Sones went on to pioneer a technique that used specially shaped catheters to safely produce selective, high-quality images. Although the new imaging technique was initially met with skepticism, the ability to accurately diagnose blockages in the coronary arteries opened the door for the development of tools and techniques for revascularization.\textsuperscript{1,5}

Up to that point, advances in catheterization had made dramatic contributions to the understanding of human circulation and the ability to diagnose arterial stenoses. However, it took another unexpected event to make the transition to therapeutic intervention. In 1963, Charles Dotter, a vascular radiologist in Portland, Oregon, unintentionally recanalized a patient’s iliac artery by passing a catheter through an occlusion in the attempt to perform an abdominal aortogram.\textsuperscript{1} In retrospect, this was the first time a condition that was normally treated with major surgery was approached with a minimally invasive, catheter-based technique.\textsuperscript{6} Dotter’s intervention marked the beginning of endovascular therapeutic techniques. He and his then-fellow, Melvin P. Judkins, went on to develop a technique for percutaneous transluminal dilation of peripheral arteries using a series of sequentially larger, rigid catheters (the “Dotter procedure”).\textsuperscript{7,8}

Around the same time, Thomas Fogarty, a surgical resident working with Dotter, identified the need for a safer, less traumatic way to remove vascular thrombus than through open surgery. He designed a novel, balloon-tipped catheter that could be inserted through a small incision in the vessel wall and passed through the thrombus. The balloon was then inflated with saline and pulled back so that the balloon dragged the thrombus out with it. Fogarty’s simple, elegant embolectomy technique went on to replace open surgical thrombectomy as the method of choice.\textsuperscript{9} (See text box on Tom Fogarty.) Subsequently, Fogarty and Dotter worked together on a catheter to treat arterial stenoses that used a balloon to increase the lumen diameter. However, their progress was ultimately limited by the fact that the available latex balloon material was too compliant to exert sufficient force on the lesions.\textsuperscript{1}
The Modern Era

In Europe, where Dotter’s catheter-based angioplasty technique was received with more interest than in the United States, a young German physician, Andreas Gruentzig, learned the method from a mentor. After relocating from Germany to Zurich, Switzerland, in 1970, Gruentzig used the technique to perform peripheral and renal artery recanalizations. Recognizing that Dotter’s approach could only enlarge the lumen to the size of the catheter, he sought to improve the balloon concept by working with a polymer chemist to develop a balloon made of a tougher material that could exert more force on the plaque. Gruentzig launched the modern field of interventional cardiology when he performed the first coronary balloon angioplasty in 1977.¹

Tom Fogarty, MD

While an operating room scrub technician in the late 1950s, a young Tom Fogarty removed the finger from a surgical glove and, using fly-fishing techniques, tied it to the end of a urethral catheter. With this crude bit of engineering, Fogarty invented the first balloon catheter for the vascular system. The resulting device, the Fogarty embolectomy catheter (Fig. 74-1), eventually became the standard of care for surgical embolectomy. Since then, Dr. Fogarty has received more than 70 patents for a range of surgical and interventional products, including balloons used for laparoscopic hernia repair, a device for minimally invasive breast cancer diagnosis and therapy, and a self-expanding stent graft for percutaneous abdominal aortic aneurysm repair. In his distinguished career, Dr. Fogarty has founded or co-founded more than 30 medical technology companies and serves as a scientific advisor to numerous others.
Many of the early practitioners of angioplasty were inspired by Gruentzig to be inventive and entrepreneurial. In the years that followed the initial
procedure, the innovations conceptualized by these clinicians propelled the field forward. Milestone technologies include John Simpson’s over-the-wire method for the delivery of angioplasty catheters, and his atherectomy device for plaque removal (see text box on John Simpson). Ulrich Sigwart and Julio Palmaz (see text box on Julio Palmaz) addressed problems of arterial recoil and restenosis through the development of coronary stents. Patient outcomes were further improved through numerous refinements to the stent design, as well as successive generations of drug-eluting stents and adjunct protective devices.

Gruentzig’s contribution to the culture of innovation in interventional cardiology was nearly as defining as his balloon catheter. A dynamic, free-spirited physician, Gruentzig was known for his charismatic and enthusiastic style as a clinician and teacher. He pioneered the live-demonstration course, which has become the signature educational and cultural event in the field, and serves as a showcase for new technologies. Gruentzig also provided a role model for much of what was to occur at the interface of innovation, entrepreneurship, and practice in interventional cardiology. He was a principal figure in the company that produced his balloon catheter, and for a while, even personally decided which physicians could purchase the devices.

Similarly, the innovators of the interventional tools that followed also helped found and grow start-up companies that competed to develop the best new technologies. As the industry expanded rapidly, the unusually close interaction between physicians and companies was reinforced by clinical and financial success. Young interventionalists learned from their mentors how to interface with companies and became the next generation of innovators. Other physicians became involved in device testing via preclinical and clinical trials. These individuals and the culture they created propelled interventional cardiology to a unique position at the epicenter of technical innovation and entrepreneurship in the early part of the 21st century. As 1 measure of the rate of technology innovation, cardiovascular devices account for more than half of all devices receiving premarket approval (original and supplements) from the US Food and Drug Administration (FDA)\textsuperscript{10} (Fig. 74-4).
John Simpson, MD, PhD

John Simpson began his career as a physician innovator by inventing the over-the-wire angioplasty catheter, a device that formed the basis for Advanced Cardiovascular Systems (ACS, now Guidant). Later, Dr. Simpson invented the Simpson AtheroCath, the first catheter for directional atherectomy (Fig. 74-2). Since then, Dr. Simpson has helped found numerous other companies in interventional cardiology, including Perclose, LuMend Inc., Fox Hollow Technologies, and Avinger, Inc.

FIGURE 74-2 The Fox Hollow Technologies atherectomy device.

Notable inventions:
• Over-the-wire angioplasty catheter
• Suture-based interventional closure device
• Simpson AtheroCath (directional atherectomy)
• Avinger catheter systems (image-guided atherectomy)

Selected roles as founder/director:
• Advanced Cardiovascular Systems (ACS)
• Devices for Vascular Intervention (DVI)
• Perclose
• LuMend
• Fox Hollow Technologies
• De Novo Ventures
• Avinger, Inc.

**Julio Palmaz, MD**

After attending a lecture by Andreas Gruentzig on the advantages and limitations of balloon angioplasty in 1978, Julio Palmaz invented the idea of the balloon-expandable stent *(Fig. 74-3)*. Although his path was not easy, Dr. Palmaz eventually convinced Johnson & Johnson to acquire his technology, which formed the basis for the Johnson & Johnson Interventional Systems division. A key inventor of the endovascular stent graft for treatment of abdominal aortic aneurysms, Dr. Palmaz has also worked to improve the materials used for stenting and has been an active proponent of implantable nanodevices for in vivo diagnostics.
FIGURE 74-3 An early Palmaz-Schatz stent before and after balloon deployment.

Notable inventions:
• Balloon-expandable vascular stent
• Endovascular abdominal aortic aneurysm stent graft

Selected roles as founder/director:
• Advanced BioProsthetic Surfaces
• Palmaz Scientific
• Palmaz Vineyards

The climate for technology innovation in the United States and abroad, however, is undergoing a historic change. Today’s value-oriented healthcare environment in major developed markets means that new technologies must also represent cost-effective solutions. To maximize their chances for reimbursement and adoption, innovators must demonstrate value by comparing a new therapy to the current standard of care in terms of clinical effectiveness, relevant outcomes such as survival and quality of life, and cost reduction.

In addition, heightened regulatory scrutiny in both the United States and Europe has substantially increased the amount of money and time required to
bring a new device to market. The protracted timeline has added significantly to the risk profile for investors, reducing traditional venture investment in device technology. Against this backdrop, US innovators are pursuing new pathways such as nontraditional funding sources or moving clinical trials and/or entire companies overseas. Perhaps most importantly, the types of innovations most likely to get funding in this environment will be therapies with the potential to make a major difference in the quality of care, patient satisfaction, or cost reduction, rather than those technologies that offer only an incremental improvement over the existing standard of care.

Coupled with these new forces of value-based innovation and tightened regulatory oversight, the culture of entrepreneurship for physicians has changed dramatically, particularly in the United States. Compared to the early days of angioplasty, there is much stronger attention to potential financial conflicts of interest for physicians who invent and/or test new technologies. In the current climate, transparency of financial involvement with companies is mandated by federal (“sunshine”) laws, and in general, physicians with financial interests in a company or product are strongly discouraged or prohibited from participating in human trials of the technology. Even as these and other market realities have added additional layers of complexity to the innovation process, new opportunities are emerging. Advanced developing markets such as China and India offer vast patient populations that are increasingly suffering chronic conditions such as heart disease, diabetes, and hypertension. In these countries, the rapidly growing middle class is demanding improved healthcare services, medical technologies, and related interventions, factors that in turn are stimulating improvements in healthcare infrastructure and expanded insurance coverage. However, innovators must approach these markets strategically, since they tend to be highly price sensitive, with unique challenges based on cultural differences and local conditions that must be carefully considered.

In this chapter, we explore the landscape of innovation in our field by examining the common characteristics of successful innovators, describing some of the essential tools required for developing and assessing new cardiovascular technologies, and looking ahead to some of the most significant challenges facing the next generation of innovators.

COMMON QUALITIES OF
SUCCESSFUL INNOVATORS

Careful examination of the lives and careers of several well-known physician entrepreneurs reveals a number of shared characteristics and traits that contributed to their success. Interestingly, many of these qualities contradict commonly held ideas about the interests and innate skills one would expect to find in an innovator. In this section, we outline some of the key factors that lead to important innovations and, in the process, highlight some potential misconceptions and myths about the development of new technologies.

Focus on the Patient

**Myth:** Medical technology innovators are innate tinkerers; success requires a mechanical mind.

**Fact:** Successful medical innovators identify important clinical problems and seek to solve them; success requires focus on the patient.

The familiar image of a great inventor is someone with extraordinary technical curiosity and expertise—the type of person who spent his or her childhood taking apart household appliances or building machines in the garage. Indeed, many technology inventors are inveterate tinkerers. In order to apply their analytic minds to the solution of everyday problems, these individuals often choose engineering or another technical profession. However, the inventor of medical devices and products does not necessarily fit this mold. The defining characteristic of the medical innovator is not mechanical aptitude, but the ability to recognize critical shortcomings in current medical practice.

John Simpson exemplifies this kind of innovator; one who identified problems and devised solutions without a “how it works” background. He spent much of his youth on a farm and never developed an interest in electronics, taking things apart, or any of the other childhood activities often associated with inventors. During his education, Simpson pursued a PhD in immunology along with his medical training, but stayed away from engineering and technological fields. As a physician-innovator, Simpson developed the original over-the-wire angioplasty system, directional atherectomy, and numerous other innovations. For each of these technologies
and the companies he ultimately built around them, Simpson was deeply involved on the clinical side, but he left the engineering and manufacturing to other, more capable hands. “I know my limits,” Simpson emphasized. “I didn’t even try to interfere with the engineers.” Instead, he stayed focused on the ultimate goal. “You fix the patient and you win,” he summarized succinctly.\textsuperscript{11}

Along the same lines, another common misconception about physician-innovators is that in order to be successful, they must also be shrewd businessmen. Julio Palmaz cites his own experience as a counterexample, noting that he was unable to convince his university that his invention of the stent was worth patenting and that he struggled unsuccessfully to attract financial backing until he partnered with Richard Schatz.\textsuperscript{12} Tom Fogarty, who has started more than 30 companies, describes himself an “idea generator” and “enabler” but not someone who can run a company. His goal has always been to turn fledgling medical device companies over to experienced managers as soon as possible.\textsuperscript{13}

In short, the key aspect of medical technology innovations is that they solve an important problem in clinical practice. Innovators have to “…keep the patient in front of the vision,” emphasized Simpson.\textsuperscript{11} Unquestionably, the innovation process involves many other complex elements, all of which must be addressed to bring an idea from concept to commercialization. However, it is the identification of an acute clinical need that forms the foundation of a successful business opportunity. The fundamental intellectual discipline is needs finding.

\textbf{Relationships}

\textbf{Myth:} Successful physician-innovators are lone geniuses who single-handedly bring a concept to life.

\textbf{Fact:} Successful physician-innovators recognize their own limitations and surround themselves with a team of talented individuals to bring their ideas to fruition.

As with any other professional undertaking, relationships are essential to the success of the physician-innovator. For the young innovator, the most important early relationship is with a mentor. Successful device entrepreneurs can all point to mentors whose influence, support, and enthusiasm were
instrumental to their success. Andreas Gruentzig was training in peripheral vascular disease at the Ratchow Clinic in Darmstadt, Germany, when he first heard Dr. Eberhart Zeitler speak about Charles Dotter’s early work with peripheral recanalization. Gruentzig was intrigued by the concept, but his chief at the time abhorred the idea of forcing a catheter into a narrowed artery, and vowed that such treatments would not be performed in his hospital.\(^8\) As a result, Gruentzig moved on to University Hospital in Zurich, where he was able to find several mentors who were more open-minded and supportive. Among these were the chief of medicine, Dr. Walter Siegenthaler, and the head of cardiology, Dr. Wilhelm Rutishauser. Dr. Rutishauser assisted Gruentzig in his critical move from the department of radiology into cardiology, which was a political and practical necessity for him to initiate his research program in angioplasty.\(^{14}\)

While some universities now offer formal programs that teach the process of innovation, there is no substitute for hands-on mentoring. Tom Fogarty, who credits an early surgeon mentor with helping him get into the cadaver lab to test his balloon catheter, tutoring him on appropriate bench models, and ultimately being the first surgeon willing to use his device, noted that, “Being in the environment promotes [innovation]; it’s more of a mentoring issue than it is reading a book on how to innovate.” Carrying that tradition forward, he explained that when working with students, he makes sure that they have experienced the surgical environment and have personally observed any clinical problem they are trying to address. “Before they start doing anything, I get them to understand how the problem is currently handled, not only in the operating room but also so that they have some insight into what is involved in the postoperative care, how long it takes, and what some of the follow-up issues are.”\(^{13}\)

As a need is identified and a project begins to take shape, different relationships—partnering with experts in other areas—become a critical component of success. Even the most iconic medical innovators are quick to acknowledge scores of colleagues who brought key abilities to their fledgling companies. Success comes from identifying and acknowledging areas of personal limitation and enlisting the aid of those who can be most helpful. As Simpson explained, “It’s always a team effort. The whole concept that there’s some special visionary out there who does all this stuff by his or herself is flawed as far as I’m concerned. It’s about putting together a group of individuals that each make a real, genuine contribution and can work together
to develop something that is really special.”¹¹ For a medical technology venture, success requires people with expertise in medicine, engineering, manufacturing, regulatory affairs, reimbursement, fundraising, finance, management, marketing, and sales, among other areas.

The story of Gruentzig’s development of the first coronary balloon exemplifies the need to partner for key expertise. During the early development of angioplasty balloons, Gruentzig experimented with a number of materials, all of which proved to be too compliant to be effective in dilating arterial stenoses. The breakthrough came when he approached a professor emeritus of chemistry, Dr. Andreas Hopf, who introduced Gruentzig to polyvinylchloride. Using this material, Gruentzig was able to make the thin-walled noncompliant balloons necessary for angioplasty. As innovator-entrepreneurs progress in their careers, they typically develop significant networks of individuals with diverse areas of expertise. These networks can be enormously helpful to the aspiring inventor in the process of building a comprehensive team. Fogarty summarized this concept as follows: “Value creation in developing new devices comes from multiple sources. If you think just because you had the idea you brought all the value, you’re not going to get there because somebody has to implement that idea and one individual can’t do it.”¹³

**Independent Thinking**

**Myth:** Successful physician-innovators pursue a concept only after building consensus approval from colleagues in their field.

**Fact:** Successful physician-innovators often need to push through major skepticism and discouragement from their colleagues and the medical establishment.

The typical physician is not especially adept at identifying which promising medical technologies will ultimately be successful. This phenomenon is not unique to medicine—many design and consulting firms exist on the principle that innovation is best done using the unique perspective of an outsider. Experience teaches people to view their profession only as it exists today without questioning its foundations in any meaningful way. A classic example is telegraph operators, who notoriously failed to appreciate the changes in behavior that would result from voice
Physicians are particularly susceptible to this professional conservatism because the format of medical school tends to discourage the inquisitiveness required of an innovator. Fogarty observed, “You do no harm by doing what you’ve always done before, and … in the field of medicine, I think the way we’re taught certainly deters innovation.” Much of medical training is devoted to learning the current standard of care in terms of symptoms and treatment guidelines. Because of the volume of information to be learned, little time remains to question the status quo.

The medical culture also affects the would-be innovator in the early stages of testing and promoting an idea. Most successful innovators have numerous stories of the initial disbelief and discouragement that they encountered from their peers. Fogarty invented his thrombectomy balloon during a time when it was widely believed that any manipulation of the intima would cause additional thrombosis. The balloon, designed to rub across the intima in order to remove clot, was therefore considered to be unsafe. More specifically, as Fogarty recalls, the surgeons who saw his first prototype told him that his idea was “crazy, inappropriate and dangerous.” However, Fogarty noted that at the time, he was only in his first year of medical school. He explained, “I didn’t know enough about medicine to know if it would work or not—and that’s probably one of the best attributes of not knowing something. You’re not deterred because you don’t know, and I think that’s often how a lot of new approaches are tried.”

Ultimately, even after collecting clinical data to support his claims, Fogarty was unable to publish his work; 3 journals rejected his manuscript for publication because his results defied conventional wisdom. Eventually, the volume of data that Fogarty and others generated in support of the thrombectomy balloon forced a change in thinking, and the technique became accepted.

The lesson, clearly, is that the physician-innovator must be willing to buck professional conservatism in order to be successful. Innovation occurs when an individual champions a new technique, despite initial unpopularity, until sufficient data exist to convince the medical community of its merit. For this reason, the typical inventor needs to be an independent thinker with both the skills to identify promising new technologies and the conviction to pursue them.
Perseverance

**Myth:** The best innovators succeed because they do not allow failures to occur.

**Fact:** Successful innovators accept that major setbacks occur and are driven to persevere because of a strong belief in the clinical need and their solution to it.

Disparagement from the medical community is only 1 of the hardships that the typical medical technology venture may face. Setbacks can occur at any step along the way, from fundraising through design development, clinical trials, and commercialization. The successful entrepreneur accepts this uncertainty and presses forward, motivated by conviction in the clinical need and the benefits his or her solution will offer. Fogarty, in fact, calls failure “a preamble to success.” He related, “When something doesn’t work, the information obtained about what not to do often that leads you down the path of what you should do. If there’s a need, there’s a need, and just because what you try to do to address it doesn’t work the first time, doesn’t mean the need goes away.”

Julio Palmaz’s experience with the coronary stent offers a telling example of persevering despite encountering significant obstacles on multiple fronts. At the time of his invention, implantation of metallic structures into arteries was so novel that most physicians could not believe that it might be successful. They understood the potential structural benefits of a stent, but were certain that any foreign structure placed within the artery would thrombose. In fact, when early human trials showed a high rate of thrombosis, many physicians believed that their fears had been affirmed. Undeterred, Palmaz revised the implantation technique to include anticoagulation, and other investigators (notably Antonio Colombo) modified the implantation technique so that thrombosis became a manageable issue.

Due in part to these clinical issues, Palmaz also encountered difficulties obtaining funding. “There were so many other techniques that were being evaluated at the time that stents had to wait their turn,” he recalled. Alternatives to angioplasty from atherectomy to brachytherapy had the attention of funding agencies, leaving Palmaz unable to obtain grant support or private funding.

In the course of pursuing an innovation, setbacks naturally occur. One
approach for managing this is, simply, persistence. When Palmaz and his associates approached established vascular device companies with his initial stent results, the response was uniformly negative. None of these companies were willing to shoulder the significant risk that remained in getting the stent to market. After months of trying, the stent team finally found a backer in Johnson & Johnson, which was just trying to enter the catheterization market at the time. The support of this company was sufficient to bring the product to market, and all of the rejections leading up to that point became an instructive footnote.

While persistence is essential, it is also important to point out that every major development program experiences 1 or more significant changes in direction, some of which can be drastic. Entrepreneurs should avoid becoming so enamored of their invention in its original form that they are unwilling to evolve or modify their concept in response to new information.

**PREPARING FOR A FUTURE IN INNOVATION**

With these qualities of successful physician-innovators in mind, what should a physician entering the specialty of interventional cardiology do to prepare to become a part of the culture of innovation? To answer this question, we interviewed a number of interventional cardiologists who have made names for themselves as successful innovators. While some of their insights and recommendations were unique to their own experience, a number of suggestions that emerged were consistent from one physician to the next. Often, these insights reinforced the importance of the character traits mentioned previously. In this section, we explore their insights and provide concrete advice for those wishing to join this innovative culture. (See Table 74-1.)

Table 74-1 *Anticipating the Future*
New Technology: The Next 10 Years

The older age and desire of people to remain active and healthy will be an important force for technologies that improve quality of life. These may range from smart surgical or interventional techniques to artificial audio and visual replacement, e.g., cochlear and retina implants. The challenge is to make good technology for a price affordable to a large part of the world’s population. In that respect, I have become much more optimistic than five years ago. If we can make a mobile telephone for five euros, smart medical devices should also be affordable.

—Nico Rijp

The imaging revolution changing everything. Our ability to non-invasively image, to detect disease before or soon after it becomes clinically manifest, to visualize actual disease processes (not just structure), and to be able to respond, appropriately, therapeutically, based on what imaging reveals is radically transforming the practice of medicine and will continue to do so the next ten years, especially with advances in molecular imaging and target therapeutics.

—Gregg W. Stone

Global Markets

In countries like India, physicians are very cost sensitive, patient centric and socially sensitive. The price of imported technology is a major concern and there is limited capital for high risk ideas with a developing regulatory environment. Because of this frugal mindset, the innovations championed here are essentially low cost and without frills. However, if their quality is ensured, these innovations will change the way procedures are done, not only in India but will be relevant to the rest of the world.

—Balbham Bhargava, Professor of Cardiology, All India Institute of Medical Sciences; director, Stanford India Bioscience

Atherosclerosis

We are entering into an era of what has been termed vascular reparative or restorative therapy. This means that we will no longer implant permanent devices, but rather will implant temporary solutions that do their job and then disappear. One example of this is the use of bioresorbable coronary artery scaffolds, which serve the purpose of a metal stent-plaque stent for one to two years, and then will fully resorb, restoring the coronary artery as close as possible to its native, pristine state, with normal dimensions and vasomotor responses. Such a therapy may also facilitate prophylactic treatment of vulnerable plaque, thereby preventing heart attack and sudden death. This is a dream which may be realized within ten years.

—Jeffrey W. Moses

Congestive Heart Failure

Witness the advent of bi-ventricular pacemakers and defibrillators in that population as evidence of what fairly simple device development in that area can do to affect a huge cohort of patients. Futuristic therapies—cell therapy and other pro-remodeling therapies of one kind or another—have incredible potential markets, therefore are incredible potential areas for device development.

—Campbell Rogers, Chief Medical Officer, HeartWare

Valvular Disease

I see little reason to doubt that within ten to fifteen years, most valves will be treated percutaneously, either through ways to dacilitate them, or ways to repair them, or ways to replace them. All of these technologies are existent today that make sense and have shown reasonable feasibility, I think that will only get better.

—Stephen O’Rourke

There are several significant challenges around the percutaneous treatment of valvular disease. From the patient’s perspective, the biggest challenge is availability, because most of the minimally invasive treatments are approved only for high risk patients who cannot tolerate a surgical procedure. From a provider’s perspective, the biggest challenge is that the approved devices are always one or two generations behind, and although they work well, they are often bulky, difficult to use, and at times associated with significant morbidity. The latest generation devices, which feature significant enhancements in profile and other characteristics that improve the precision of implantation, remain in very long term clinical trials in the US And from an economic perspective, because the regulatory pathway makes it so difficult to get to commercialization, instead of three or four approved values competing for market share, every three to four years, there is one new value. So there is no free market pressure on cost.

—Maurice Buchbinder

Peripheral Vascular Disease

Outside the US, there seems to be a strong sentiment towards the concept of "have nothing behind." The idea that implantation of a permanent metallic prosthesis should be avoided if at all possible. Peripheral artery disease is a chronic and relentless disease process and vascular specialists should avoid therapies that could complicate future interventions if they fail.

—John R. Laird, Professor of Medicine and Medical Director, UC Davis Vascular Center

We face enormous challenges when it comes to achieving ideal results ... in terms of optimizing angiographic and clinical outcomes, as well as improving patients’ quality of life and longevity. As compared to the coronary arteries, the peripheral arteries have more extensive, lengthy blockages and we haven’t only digested but we have developed different strategies and treatments based on what works best. Moreover, because there are multiple specialties treating this disease, figuring out more specifically what constitutes a good outcome will require more collaboration and cooperation amongst all the stakeholders—in both our patients. I personally think that outcomes need to be measured not just by patency of an artery or the distance a patient can walk, but also the patients’ perceptions, by their functional status, and by economics—and what did we achieve, how much did it cost to get them, and was it of value to the patient? This is the concept of value-driven health care. Again, we need good clean data to assess this properly.

—Kenneth Rosenfeld

The real game changer in the next ten years will be much of the guess work in cardiovascular diagnostics and treatments. New technologies may be based on the use of nanoparticles and artificial intelligence. One example of this is the development of disease state. These modeling technologies have the potential to reduce the number of unnecessary procedures while focusing resources on those patients with the greatest needs.

—Fred St. Goar, Interventional Cardiologist, El Camino Hospital and Fogarty Institute for Innovation

The field of percutaneous intravascular replacement will have a huge impact on how we treat patients with mitral regurgitation and advanced cardiac disease. Mitral regurgitation is four to five times more prevalent than aortic valve disease, affects patients across many decades of life, and often involves significant co-morbidities. To date, medical therapy has been the treatment of choice because surgery is often contraindicated given the significant morbidity and poor ventricular function associated with this condition. Moreover, these catheter-based intravascular therapies, which are already on the near horizon, will drive advancements in the ancillary devices needed to make the procedures successful such as enhancements in imaging modalities like 3D or 4D transesophageal echocardiography to guide the procedures, and innovative new approaches for non-invasive vascular access and closure.

—Maurice Buchbinder

The process and maturity of medical device innovation has rapidly traversed borders in the past half a dozen years. From joint ventures in China to cost basis implementations in India, device development has taken on a global role and partnerships in those market-expanding countries are essential for success. Geographic markets can provide isolated values and then be leveraged to other regions of the world.

—Peter Fitzgerald, Professor of Medicine and Director, Center for Research in Cardiovascular Interventions, Stanford Medical Center
Training for Innovation

As discussed in the previous section, the most important characteristic of the successful physician innovator is a primary focus on the needs of the patient. Our interviewees echoed this sentiment, reinforcing the need for would-be physician-innovators to be actively involved in patient care. As Jay Yadav, founder and chief executive officer (CEO) of CardioMEMS, Inc., explained, “If you just try to stay in an ivory tower and are not hands-on, chances are you’re not going to find the right problems and acceptable solutions. There are a lot of solutions that sound great on paper, but are not really implementable in a clinical setting.”

In order to be innovative, an individual must often synthesize knowledge over more than 1 discipline in order to solve a clinical problem in a new way. Early innovations in interventional cardiology were technologically straightforward, so physicians with little additional training were able to make those leaps single-handedly. As the field continues to mature, the physicians we interviewed envision that the technical and scientific knowledge required for successful innovations will steadily increase.

Several interviewees felt particularly strongly that basic science will play a significant role in future innovations and should be emphasized in training. Nicolas Chronos, chief medical officer at Endotronix, Inc., and CEO at Cardiology Care Clinics, encouraged future inventors to understand the biology as much as they can, and then seek out people who have the expertise needed in other areas, for example, in inflammation. “I don’t think that people like ourselves are ever going to become experts in inflammation, but at least [we can understand] the implications for other biological processes,” he said. Similarly, Nico Pijls, Professor of Cardiology at Catharina Hospital in Eindhoven, the Netherlands, suggested that training in physiology and at all of the basic sciences should be in-depth. “There should be a sound interest and desire to know what is the basis of things, what is the task of every part of the body, why is a particular process in physiology going on,” he stated. “Through sound physiologic thinking … the need for new inventions will be uncovered.”

Although a solid foundation in basic science was perceived as critical to the future of innovation in the field, the interviewees were less eager to recommend lengthy engineering training for physicians. There was a perception that while physicians should gain some familiarity with these
technologies, overall their time is better spent outside an engineering classroom. Stephen Oesterle, senior vice president of medicine and technology at Medtronic, Inc., observed that many of the technologies that are finding application in medical devices come from the information technology (IT), communications, data analytics, MEMS (micro-electromechanical systems), and low-power microelectronic industries. He suggested that, while it would be challenging for practicing physicians to take engineering courses in each of these disciplines, there are several comprehensive trade journals that frequently report on the early stages of companies pursuing these technologies. “I have also found willing mentors in several of the leading technical universities who can serve as ‘translators’ as I seek deeper understanding,” Oesterle added. Yadav agreed, emphasizing the need to focus on solving clinical problems, rather than learning engineering. “It’s not so much if you’re an engineer or not … really the key thing is to look with a questioning mind. Don’t assume that the way something is being done right now is the optimal way of doing it. Chances are it’s not. It can be improved on.”

In addition to scientific skills, several of the successful entrepreneurs recommended business training for the aspiring physician-innovator. None recommended a formal business degree, instead believing that the necessary skills could be learned through a short course or on the job. “I think most interventional cardiologists can learn business if they have an interest and an aptitude for it. I think that’s much more learnable, in some ways, than some of the engineering and physics involved in innovation,” said Tim Fischell, CEO at Ablative Solutions, Inc. Oesterle agreed that going to business school was not necessary for most physician entrepreneurs, but felt that some basic financial competence was necessary. “A rudimentary knowledge of how to read an operating statement and evaluate a balance sheet is essential,” he said. “The cost of raising capital through venture sourcing, convertible loans and other debt vehicles should be understood. The more one can understand about the dynamics of venture funding, the better.” Oesterle noted that many business schools offer short modules that cover the basics of finance, and suggested that books on the topic can also suffice, “unless one plans to be the chief executive through the later stages of a start up.”

Thus, innovative physicians should focus on being physicians first, emphasizing good patient care and thorough knowledge of the underlying
science. While basic financial competence is important, the interviewees felt that deeper expertise in key areas could be acquired most effectively by reaching out to specialists as needed.

The Changing Landscape

The experts also commented on changes that they perceive are occurring in the field of medical-technology entrepreneurship. Broadly, there is a perception that true innovation is becoming more difficult because of changes in the nature of technologies themselves, the restrictive regulatory environment, the reduced availability of traditional funding, and challenges around reimbursement. Reflecting back on the development of his balloon embolectomy catheter, Fogarty estimated that it cost between $12,000 and $15,000 to get the device into commercial use, and noted that, at the time, the regulatory path consisted of peer scrutiny and informed consent from the patient. “There are just a lot more things that you have to deal with now, versus what you could do then,” he said.

According to Gregg W. Stone, Professor of Medicine at Columbia University and Director of Cardiovascular Research and Education at Center for Interventional Vascular Therapy at Columbia University Medical Center, one outcome of the difficult regulatory environment in the United States is that, while many medical device ideas still originate in the United States, a significant portion of product development has moved overseas. Initial destinations include “think tank” geographies such as Israel, with the likelihood that more innovation and development will move east as countries such as China and India continue to gain economic strength. He added, “A worrisome trend is that some start-up and mature companies are actually no longer developing products for the US market because of the time and expense to get devices approved here.”

With regard to possible future changes in the regulatory environment, the predictions were varied. Stone suggested that, in many respects, the US FDA may get somewhat easier to navigate. “Although while speculative, I believe that in the future, legislation will be passed that will provide FDA with more post-market regulatory power, which will allow them to ease up a little bit on the premarket side.” He added, “That said, though, I don’t see the FDA softening up any time soon on their relatively rigorous requirements to demonstrate safety and efficacy, usually through randomized trials for novel
technologies and therapies.”

Other interviewees warned against being too optimistic about changes in regulatory policy. “Even when the FDA commissioners come up and say, ‘We have to be kinder and gentler and we have to be more compliant,’ the FDA is the FDA, and it remains for the foreseeable future a gating mechanism,” said Maurice Buchbinder, an interventional cardiologist at Alvarado Hospital Medical Center in San Diego, California.

With regard to the reduced amount of venture funding available for medical devices, some experts see this winnowing out less valuable pursuits, rather than putting the brakes on all innovation. “It’s just going to put a priority on the types of innovations that are going to be game changers,” said Stone. “We’re not going to be able to spend hundreds of millions of dollars for incremental changes in devices and patient outcomes. There will always be room for major advances that will extend life and provide patients with a substantially better quality of life, but the onus will be on us to demonstrate that.”

In today’s cost-conscious environment, reimbursement has surpassed regulatory approval as a top concern for many device innovators. Increasingly, government entities and private insurers are basing their reimbursement decisions on whether a technology represents a good value. Accordingly, the experts agreed that successful innovators increasingly need to take cost-effectiveness into consideration early in the innovation process in order to be able to make quantitative statements about the economic value of their approach. This typically involves researching available clinical evidence, comparing the costs of the new therapy to the current standard of care, and especially for technologies with longer term effects, developing value models to project the long-term quality of life and cost benefits of treatment. Oesterle summarized the challenge as follows:

“It used to be that a medical device was approved on the basis of safety and some demonstrated efficacy. Today a much larger burden of evidence is required; particularly with regard to reimbursement. Developed markets need to reduce the amount of money spent on healthcare and are demanding technologies with manifest cost benefit. New devices must be either less costly or have demonstrated improved outcomes that can be readily translated to cost savings. Improved technology is not necessarily valued in the absence of clear value story.”
In addition to these policy changes, the interviewees each had a number of comments to make about the future of clinical practice in areas ranging from atherosclerosis to structural heart disease. The experts agreed in very broad terms about the current challenges facing cardiology, but each had a unique view of what the future holds for clinical care (see Table 74-1). Innovation by its very nature is unexpected, so it should come as no surprise that even respected authorities in the field would disagree on the devices that will be adopted into clinical practice in the future!

SUMMARY

In this chapter, we have described a number of traits held in common among the most successful physician-innovators and provided advice directly solicited from a number of contemporary inventors and entrepreneurs. The key messages are simple:

• Focus on the patient and the clinical need.
• Build a good team (around your limitations).
• Be persistent in the face of disbelief and discouragement.
• Focus on cost-effectiveness and economic value early on.

John Simpson summarized the most important components of innovation as follows, “If you’ve got people that bring commitment and willingness to persevere in adversity, then you can make special things happen, if you stay focused on doing something really clinically relevant.” As interventional cardiologists, we are in a privileged position of being in an environment of major clinical needs every day. The skills required to identify these needs and create significant new technological solutions are in fact very similar to those we have already developed in our training and practice.

ACKNOWLEDGEMENT

The authors wish to thank Stacey Paris McCutcheon for her skilled editorial work and her role in interviewing and compiling the comments of the innovators quoted in this chapter.
REFERENCES

Nowhere is the opportunity to innovate as inviting as in the field of medicine, and no specialty has been as productive in the development of new technologies as cardiology. Because heart disease remains the most common cause of death in developed economies such as the United States (and is a growing threat in middle and low-income countries around the world), new developments in cardiology can affect an especially large population and have a tremendous impact. Advances in our understanding of human physiology, genetics, and molecular biology continue to define the fundamental mechanisms responsible for disease. Through these insights, we gain new perspectives and tools with which to create novel solutions. Regardless of the specific clinical problem to be solved, a common innovation process can be applied. It is this basic approach for creating new medical technologies that we hope to convey within this chapter.

Even though there are many revisions in the latest version of this book, we kept this chapter essentially intact from the first edition. This is because the skills required to innovate are enduring. They are typically not taught in medical school, yet they have been critical to the advancement of interventional cardiology. It has been difficult for people in medicine to learn formal principles of innovation, as they are usually taught only in engineering programs. However, this trend has begun to change, and numerous medical
training programs have begun offering curricula targeted at this very issue. As history has demonstrated many times, clinicians and scientists make very good innovators. Although it is important for engineers to be skilled in the fundamental principles of innovation, clinicians and scientists have an essential role to play during the early stages of the innovation process (need finding and concept creation) and, as a result, they should learn these skills so they can participate fully in the important interdisciplinary work of creating new medical technologies.

Developing a new medical technology is a rewarding but often arduous process. The greatest success comes to those who understand the many necessary steps in the innovation process and can plan and execute a strategy to address each one efficiently and effectively.

**INNOVATION: THE BASIC STEPS**

*Innovation* is defined as the process of creating something new. As developers of a medical technology, we seek to address a real clinical need with the goal of not only creating something new, but also creating something better and/or more cost effective. The basic process of focused innovation is very simple and is summarized in Figure 75-1.
Although the innovation process is one that may be used by someone new to a field (top orange arrow), you may enter this process at any stage (orange arrows). In general, it is best to run this process rigorously from beginning to end without skipping steps to avoid the biases that come with arriving at a solution too soon. Regardless of where you enter, awareness of all steps and sensitivity to the need for iteration (blue arrows) can further improve on a good initial idea. As such, each step is briefly described below.

**Step 1: Objective Definition**

Starting with a clearly defined objective is critically important to keep you on the path to focused innovation. Being focused can prevent wasting time and
energy on creative but tangential ideas that do not meet the intended objective. A well-defined objective limits one’s focus to a reasonably sized clinical area where the application of time, research, and creative energy is likely to yield a real outcome. An objective contains the general need area being addressed plus any goals or constraints such as a time horizon or resources that will be required (eg, to enable a significant incremental advancement in mitral valve repair within a 5-year timeframe). It is a good idea to write down this goal and refer back to it occasionally as a project takes shape so that the objective becomes a mission statement for the project. In some cases, it may become clear during the development of the project that the overall goal must change.

Although focus, at any one time, on a single objective is ideal, it is also important to engage people with different backgrounds in your investigation. Medicine itself is a broad field in which an in-depth understanding of different disciplines (eg, anatomy, physiology, pathophysiology) is required to understand a problem and arrive at meaningful solutions. However, a mastery of other fields (eg, physics, electronics, engineering, mechanics) and how they may be applied to solve medical problems can yield some of the most novel inventions with greater impact. For these reasons, the ideal team is a multidisciplinary one that is diverse but remains focused on the defined objective.

Another advantage of defining an objective at the start of the innovation sequence is a practical one—in general, innovators work best within a defined area of expertise. Although there are examples of wildly creative individuals\(^1\),\(^2\) whose inventions span many disciplines and technologies, it is difficult with this type of approach to develop the depth necessary to reliably generate significant advances in medicine. More commonly, this broad style of inventorship results in patents that lie in wait for science to catch up to what has been proposed (“submarine patents”). This approach can be financially rewarding in some situations, but generally does not provide an effective pathway to technology innovation.

**Step 2: Need Finding and Identification**

Most successful medical technology inventors would say that identifying an important clinical need is the single most essential step in the innovation process. Clinical needs can be identified in many different ways. Often they
are recognized by a clinician involved in patient care when a frustrated physician wishes for a better solution to a clinical problem (eg, “if only we could have repaired this mitral valve with a less invasive approach, sparing the patient major surgery”). Needs can also be recognized by those who are not within the field of medicine, or by those who are actively seeking unmet clinical needs (eg, an entrepreneur). Such an intentional innovator must do exhaustive research and observation to evaluate a clinical problem and all existing solutions to it, carefully understanding the strengths and limitations of each. Here again, it is often helpful to involve people of different backgrounds who may not have the biases of an expert deeply entrenched in the conventions of a particular specialty. An outsider to the field is likely to question even the most basic of assumptions and may uncover a true need that is not apparent, even to the specialist (latent needs). Finding clinical needs is a fundamental skill that improves with experience. Some of the most notable innovators in cardiology have demonstrated their abilities as serial need finders (Dotter, Simpson, Fogarty; see Chapter 74).

The characteristics of a “good” need depend on personal and professional objectives. If one were to have the opportunity to choose from an array of needs, the magnitude of the potential patient outcome benefit and the size of the available market/population would certainly top the list of considerations. Although one could list many other factors, such as accessibility of the market, reimbursement, or regulatory environment, having a burning passion for the need is probably the single most important factor for success.

Once a need area has been identified, it is critically important to precisely define the need by producing a need statement. A need statement can be deceptively simple: It is a one-line description of the clinical problem, stated as clearly as possible. Each need statement must explicitly identify the problem that requires solving, the patient population that it most directly affects, and desired outcome that population wants from a new solution. Although at first it seems like an unnecessarily formal exercise to write down a need statement, it is an absolutely essential step to really understanding the need and communicating it effectively to others. Following are some examples of need statements from interventional cardiology:

- A less invasive approach to reduce mitral regurgitation in patients with congestive heart failure that enables patients who are poor surgical candidates to be eligible for the therapy.
• A better technique for directing a guide wire safely and efficiently across a chronic total occlusion that allows a single operator to access 90% of CTOs within 30 minutes.
• A minimally invasive method for restoring myocardial contractile function after myocardial infarction to prevent clinical heart failure.

It is important to differentiate carefully between needs and solutions, and focus on understanding the clinical need first. This includes paying close attention to the way in which the need and its attributes are described, as embedding a solution within the need statement can substantially narrow or bias subsequent steps in the innovation process. For example, the statement “The need for a more torqueable Teflon catheter to perform balloon angioplasty...” is heavily biased. Solutions to this need would clearly be restricted to catheter-based solutions and those using Teflon materials. More importantly, these solutions would exclude superior concepts that employ something besides a catheter. It is also a useful technique to write multiple versions of the need statement that both focus more narrowly on the central problem and/or the size of the population, as well as zoom back from them (called need scoping). The result should be a set of need statements that clearly outlines variations of the clinical problem and population, and suggest several pathways for creative improvement. An example of a narrowly focused need statement might be: “A way to prevent smooth muscle cell migration in response to stenting...”; whereas a more broadly scoped need statement may read more like: “A better way to prevent restenosis after stenting....” Finding the appropriate level of specificity of a need may take some time, and brainstorming at every level can be a very useful exercise. The most productive level of focus usually becomes clear only later, once solutions have been proposed and fertile ground for invention has been exposed.

**Step 3: Need Validation and Screening**

Once you have identified one or more unmet clinical needs, the need validation process begins. In this step, you must verify that the needs you found are indeed experienced by others. It is also important to characterize the features required of an ideal solution that would motivate key stakeholders to potentially change their behavior and adopt it. We call these
characteristics *need criteria*. There are two types of need criteria—must-haves and nice-to-haves. Both types stem from your in-depth need research and should be objectively defined based on what matters most to the affected stakeholders. This includes parameters defined by the patient (eg, risk-benefit, comfort, efficacy, fit), physician (eg, ease of use, complications), hospital (eg, cost tolerance), payer (eg, cost versus future cost savings), as well as other stakeholders. With this constellation of information, the process of needs screening may now begin. The goal of this process is to identify objectively the most optimal need to be addressed, given the criteria developed during need finding and validation. One method is to define categories such as magnitude of patient impact, efficacy (or lack thereof) of existing solutions, etc., create a ranking system, and then allow the needs under consideration to “compete” against one another. A spreadsheet or database can simplify your assessment and enable you to make rapid updates as new information becomes available. Ultimately, your goal is to choose a single need to take forward that represents the best all-around opportunity for innovation.

---

**Step 4: Concept Creation**

With need validation and screening completed, it is time to create potential solutions. This stage of the process is widely misunderstood. The popular model for the concept creation process is some mystical “aha” by the lone, brilliant inventor. In fact, brainstorming is best done with a team. Selecting the right people to brainstorm with is one of the key determinants of success. Generally, such people should be highly creative, cooperative, and experienced in the technical and/or clinical area of interest. The team members should understand that they may be helping create some new intellectual property that may ultimately be of financial value, but that the brainstorming stage is only a small part of the process of invention, which includes the substantial work of need finding, verification, and specification that occurs before it.

There are several rules for successful brainstorming.\(^4\) Perhaps most important is that the participants should create a positive session that encourages open thinking and wild ideas. Critical comments and judgment should be held back until later in the process. Participants should build on the ideas of others; the collective strength of the team carries it much further than
any individual can alone. Another important tip is to have the group focus on generating as many ideas as possible, regardless of how unrealistic they may seem; the goal at this stage is quantity over quality. A typical 60- or 90-minute brainstorming session should generate as many as a hundred or more different ideas, which may be grouped in clusters of concepts. Some groups like to use concept mapping techniques to record the branching pattern of new idea creation visually. It is certainly helpful to have a large whiteboard or other writing surface and encourage participants to draw their concepts. It may even be useful to have some materials on hand cardboard, clay, foam board to create very quick and rough conceptual prototypes.

It may often be necessary to have several brainstorming sessions on a given need. It may also be useful to have different people involved in these sessions. Remember throughout the process of inventing that it is critical to document the evolution of new ideas and their anticipated applications. Any significant writing on a whiteboard should be copied or photographed; any rough models should be saved. This helps organize and build mature ideas and enables the inventors to substantiate their rights to intellectual property.

**Step 5: Concept Evaluation and Screening**

Successful brainstorming produces a large array of potential solutions to a need. The next step is to distinguish the ideas worth pursuing from those that are not. Although the brainstorming process is unconstrained and strives for quantity of ideas, concept evaluation and screening introduces reality into the equation. The goal is to have the winning solution emerge from the list and to understand the features of that solution that need improvement in order to become successful.

The most important mechanism for the first screening should already be at hand, and it is the need criteria (see Step 3). A simple rating of how well each of the concepts will potentially address the need criteria results in an initial ranking. If an idea does not seem to have the potential to satisfy the must-have need criteria, it should be immediately set aside (or reimagined to better address the criteria). Nice-to-have criteria can be used to further move concepts up or down the list of promising solutions based on how well you think each concept will perform against them. Often, this initial screening activity permits the inventor to reevaluate the merits of each solution, suggesting modifications or improvements. From the highest-ranking ideas,
one can further screen out the best solution by imposing additional metrics. Some examples of these might include an assessment of the technical feasibility of the idea, the likelihood of adoption, potential ease-of-use, or the expected timeline of clinical trials and regulatory approval. Developing a reproducible scoring system helps keep this process objective. Some research may be necessary to support the scoring process, and often iteration of the process and idea is required.

**Step 6: Concept Development and Implementation**

Once you have selected your target concept, you can now begin the exciting journey toward making it a reality. Some important questions to pose at this stage are as follows: Is this an idea that is so significant that it could be the foundation of a company, or is it simply an incremental improvement that is better licensed to an existing manufacturer? Are the clinical and technical foundations established enough to justify bringing in investors, or is this still a research project that requires further development in an academic setting? To answer these questions, it is helpful to look at comparable companies or projects at similar stages. If you are working in a university setting, much of the work at this stage may be performed by the technology licensing office, but if you truly want to establish this invention as a reality, it is often necessary for the inventor to take a pivotal driving role. To move your idea from this point, it is now necessary to dig into your med-tech inventor’s toolkit (described next) and pull all the pieces into place.

Whatever approach the technology takes, the inventor has the opportunity to play a central role in the early development and implementation of the technology. The next section describes the essential tools to make this a productive experience.

**THE MED-TECH INVENTOR’S TOOLKIT**

*The Team*

Regardless of the fact that many famous and successful inventors like to
work alone, the benefits of working with multidisciplinary teams have been extolled in many texts. Even those who choose to invent alone realize that a team is almost always necessary to take their invention to the next level. The most important thing you can do as an innovator is understand your personal strengths and weaknesses. Assemble your team based on how the additional members complement your abilities. It is also important that your team fit the task at hand. Initially, you may not need much help, but as the project moves forward, you must bring in other people to accomplish the next set of goals. Once you lay out a plan for your business (Fig. 75-2), the evolving set of requirements logically translates into a sequence of skills necessary to move the project forward, and you then can build your team on that basis.

**FIGURE 75-2** Milestones and expertise sequence.

### Intellectual Property

#### The Basics

At the core of any great company or new product is its intellectual property. *Intellectual property (IP)* is defined as any creation of the human mind or intellect that has some value in the marketplace and that ultimately can be reduced to a tangible form. IP can be an idea, invention, expression, unique name, business method, industrial process, or even a chemical formula. IP can take on many forms. One, called the *utility patent*, is most commonly used in the medical industry. A utility patent describes a novel invention that can be used to perform a task. Typically it details a device (eg, surgical instrument) or method (eg, procedure or manufacturing process).

A patent gives its assignee the right to exclude others from practicing an
invention. In receiving that right, the assignee must permit disclosure of the invention openly to the public (hence the name *patent*, which means “to open”). In the United States and internationally, a patent term is 20 years from the *filing date* (date the patent application was filed with the US Patent and Trademark Office [USPTO]).

**The Laboratory Notebook**

A properly maintained notebook is an important tool in your toolkit. The more detailed and well maintained your notebook is, the more valuable it is in supporting your claim of invention should any IP dispute occur. Following are a few key points to remember:

- Get a bound notebook with numbered pages. Although it is allowable to paste in material on existing, bound pages, never tear out or try to add pages.
- Date and sign each page. Never ever backdate! Even if an idea occurred on a previous day, always date your notebook with the actual date matching the signature. It may be important to add an explanation for the delay in writing an entry into your notebook, but do not falsify. Dishonesty here is fraud.
- Have a non-inventor witness and date each page. Do this every few weeks; it doesn’t need to be each day. Ideally, this person would be skilled enough in the art to understand the invention.
- Sign over the edge of material that you paste or tape into the notebook, so that your signature or initials span both the bound page and the pasted-in material.
- Cross out blank spaces to ensure that no retroactive entries could be made.
- Never whiteout anything! Use a single line to strike through any errors and initial the correction.

**Inventorship and Ownership**

Legally, the definition of *inventor* is a very specific one. To be an inventor, one must have contributed (partially or totally) to the invention and participated in its reduction to practice. If you invent something on your own, then you are considered the sole inventor, as long as this work was not
performed as a “work for hire” or bound by some other contractual obligation. If someone adds to any part of a claim, then they are a joint inventor, regardless of whether their contribution was large or small. Unless bound by other contractual arrangements, rights to the patent are shared equally by all inventors. This means that each inventor can use the invention, but neither can exclude the other inventor(s). It is very important to include each inventor when filing a new patent. If inventors are not properly acknowledged, a patent may be declared invalid, rendering it of no value to any party involved.

As of 2013, the United States operates under a first-to-file patent system, which means that patent rights are granted to the first person(s) to file a patent application for protection of an invention, regardless of the date of actual invention. With this approach, the evidentiary date of first invention is less important than when the US operated under a first-to-invent patent system. However, it is still important to document and date your ideas in your laboratory notebook as soon as you have them. In the US, which is often a substantial portion of the market for medical technologies, if you compete with someone else who filed a patent at the same time, the courts will consider your notebooks to determine who had the idea first. It is the inventor who shows documented proof of earliest invention who receives patent rights. Laboratory notebooks can also play useful roles in other legal proceedings. But, as a general rule, it is essential to file your ideas with the patent office (not just document them) as soon as possible to protect your rights.

Many physicians are asked to speak publicly about their research. Public disclosure is defined as disclosure done outside the terms of a confidentiality agreement (see next section). Be aware that public disclosure has important patent consequences. If you disclose your invention prior to filing a patent application, you may be at risk of losing your rights over the invention.

Confidentiality

Inventors often must define the difficult balance between secrecy and disclosure while trying to advance their ideas. It is necessary to disclose your ideas to others to build your team and teach others in your field, but such disclosures put your ideas at risk. Confidentiality agreements can be used to discourage others from sharing or using your ideas, but often these
agreements are very difficult to enforce. In general, it is always a good practice to limit your disclosure to non-confidential matters until you have placed the receiving party under a confidentiality agreement.

How to Get Started?

Start an IP assessment by going online and searching for evidence of your idea in the literature or patent archives. The US Patent and Trademark Office (USPTO) patent database⁶ and Google Patents⁷ are two excellent sources for finding patent information. Innovators can conduct literature searches using PubMed⁸ and Google Scholar,⁹ among other sources. After searching the literature and relevant patent databases, if the idea still appears to be novel, the next step is to file either a provisional or a full utility patent application. All patents ultimately require a utility patent application for consideration, but provisional patents offer a low-cost way to protect your idea for a limited period of time. A utility patent application includes the following:

- An abstract: a brief description of the invention.
- The specification: text in which the background of the idea, the idea itself, and its various uses are described in detail. This includes drawings that are included in the application.
- The claims: a numbered list of the exact characteristics of the invention that the applicant believes are novel and for which the applicant is seeking legal rights.

Because the legal phrasing in the application is so important, it is recommended that you work with a patent lawyer to assemble the application. The cost of creating and filing a utility patent application in the United States is usually $5,000 to $15,000, most of which is the cost of legal counsel. After filing, the USPTO responds to the claims in the application, making arguments for or against rights to each of the claims individually. This process is called patent prosecution and can often be a substantial process that can last for months or years. Finally, if the patent is granted (usually in a revised form), it is called an issued patent, and you or the organization that owns the patent are designated as the assignee.

A provisional patent application (PPA) is a type of fast-track submission for inventors who want to get the earliest possible file date without having to
commit the investment necessary for a full utility patent application. The PPA can be a somewhat more informal application than the utility patent submission. As such, some inventors choose to prepare and file their own PPAs without hiring legal counsel until they file a utility patent application on the invention. Other inventors opt for professional legal counsel in creating the PPA to ensure the most robust protection early in the patenting process. The cost of filing a PPA is $100-400, and the application does not undergo any formal review or approval process by the USPTO. It merely serves to hold the filing date. As long as the inventors submit a utility patent application within one year of filing the PPA, they are granted the earlier PPA filing date for both.

One concept concerning patent rights is often misunderstood: the difference between patentability and the ability to practice. An invention is patentable if it has at least 1 claimed element that is novel. Although a patent grants permission to exclude others from practicing an invention as described in the claims, it does not necessarily provide its inventor the freedom to practice (i.e., manufacture or sell the technology or perform the procedure) the invention without infringement. To infringe a patent means that one has literally followed every step claimed by an existing patent. So, for example, if your invention incorporates another invention (in its entirety), but builds on it with a novel addition, it may be necessary for you to license rights to the other patent before practicing your invention.

For more information on the mechanics of filing patents and the legal aspects of creating new companies and technologies, there are several excellent references specifically for new inventors.\textsuperscript{10,11}

\textbf{Market Assessment}

It is best to make an early assessment of the market to determine the potential size of the opportunity in order to ensure that it warrants investing significant time and resources. The essential steps are to characterize and quantify the potential customers and understand how the demand for the new technology may evolve over time. A well-developed market analysis is an essential part of a business plan.

To properly assess the value of an idea, it is necessary to define its application in some detail. If the concept is a “disposable” or “implantable,” its use is defined by the number of procedures or patients in which it is used.
Alternatively, if it is a reusable product, the market depends on the number of hospitals or operating rooms that use it. A good starting point is to estimate from the literature the number of treatable patients within a typical year. This number multiplied by the estimated price per use serves as the total potential market per year. Demographic changes, preventive measures, access to the appropriate healthcare providers, and other factors that affect the size of the future patient population should be considered when rendering these types of estimates. Physician adoption rates vary widely between specialties, and the best estimates of these rates can be determined by examining comparable technologies. If, however, no such comparable technologies are available, a model can be derived by considering several factors: the severity of the clinical need, risk tolerance of the patient and physician population, appropriate patient inclusions/exclusions, other available competitive treatment options, and the risk-benefit profile of your technology.

When conducting market research, physician feedback can be very valuable. However, one must recognize that customers (physicians) often do not recognize their own needs, particularly considering breakthrough technologies. More often than not, they adapt to available technologies and are relatively comfortable with what is at hand. Also, one must consider physician culture; some specialties embrace new ideas (interventional cardiology is a prime example), whereas others reproach them. Although customer input is very helpful in this assessment, it is important to weigh and filter these factors carefully to differentiate between negative feedback that is fundamental and that which simply reveals resistance to change.

Clinical, Regulatory, and Reimbursement Considerations

Healthcare technologies are highly regulated, and thus, it is very important to understand the various paths to approval and reimbursement before spending significant resources to develop an idea. Although the fundamental aspects are not likely to change soon, specific regulations and reimbursement parameters can change dramatically over time and can be heavily linked to current sociopolitical issues. It is therefore essential that one consult with experienced professionals in the field before casting one’s plan into action.

In the United States, the Food and Drug Administration (FDA) oversees all commercial medical devices, biotechnology, and pharmaceutical products. In other countries, there are similar regulatory bodies, although their roles
vary widely. Although the focus of US regulators is often to prove efficacy and safety equal to or beyond that of existing technologies, the CE mark process (the approval pathway for the European Union) is more focused on safety and quality. Figure 75-3 is a chart showing a few typical paths a new medical device, biologic, or drug might take through the US FDA or European Competent Authority process. These are just a few examples; the actual process must be customized as appropriate for every individual technology.

![Figure 75-3](image)

**FIGURE 75-3** Sample processes toward approval of medical products in the United States. BLA, Biologic License Application; IDE, Investigational Device Exemption; IND, Investigational New Drug; NDA, New Drug Application; PMA, Pre-Market Approval.

The litigious nature of the US market demands a higher level of scrutiny on behalf of the FDA in comparison to the situation in Europe. Thus, quite often devices and drugs can be tested on humans and commercialized much sooner outside the US than within. There are important philosophic and ethical issues that this disparity creates. Overseas patients have access to the latest and potentially greatest medical advances much earlier; however, Americans benefit from the knowledge resulting from repeated human experience and follow-up before these new approaches are released to the US population. Until there is normalization in the way different cultures approach risk, these regulatory differences are likely to remain.

Product labeling is a significant element of the regulatory process and is
fundamentally important when formulating a clinical development strategy. The claim(s) a manufacturer makes regarding the performance of a technology is the key factor that determines how regulatory bodies determine the product must be tested. Whatever is claimed must be proven; therefore, if this proof is derivable only through extensive and expensive clinical testing, then that is dictated by the nature of the claims. Many books and websites detail these regulations and policies.\textsuperscript{12,13}

Having a reimbursement strategy for a new technology is equally as important as the regulatory issues in designing an approach to clinical trials. A clinical trial must be designed and powered to demonstrate that the new technology is worth reimbursing. If the reimbursement process has not been carefully considered early on, the costs required to commercialize the product can be grossly underestimated, and expensive clinical trials may need to be repeated.

Regulatory and reimbursement pathways that appear to be particularly difficult discourage investors or potential corporate partners. Those who understand how to navigate the process successfully can wield a significant competitive advantage. For those who do not have this experience readily at hand, there are many high-quality consulting firms that specialize in these fields, as well as recruiters available to help you add this expertise to your team.

**Ethical Considerations**

It is critically important to be aware of the potential conflicts of interest involved in bringing a new, for-profit technology forward into a healthcare setting. At every stage in the development process, you should evaluate choices against your own values. For example, when one identifies a clinical need to address, it is appropriate to ask several questions, such as:

- Should I work on this problem?
- Am I trying to increase the quality or duration of life?
- What impact would that have on the patient, caregiver, family, society, and the healthcare system?

For example, reducing mortality after major stroke seems like a noble goal, but one should consider the impact on the size and debility of the affected
patient group. Environmental issues also come into play: What are the implications of disposable versus reusable products? In manufacturing, consider the ramifications of manufacturing risk on employees (safety), the product being sold (integrity), and so on. In forming a business strategy, to what extent should consideration be given to access by people of different geographic and socioeconomic groups? Clearly, these and related questions can be difficult to answer, but it is essential to raise these issues early and reflect on the core values behind the technology that is being created.

A common ethical dilemma facing clinician inventors is the balance between financial gain from the application of a new technology and the responsibilities of ethical patient care. Many academic, hospital, and corporate organizations are wrestling with this delicate balance. Without the clinical leadership provided by physician inventors, many of our most significant technologies would not be available today. At the same time, there are clearly examples of perceived financial conflict of interest and, arguably, situations in which patients have been put at risk inappropriately. With proper oversight by independent ethical review boards and rigorous scientific peer review, it is possible to proceed wisely on a case-by-case basis. Establishing a credo is a good way to acknowledge these issues and generate the open discussion necessary to establish balance. Corporations such as Johnson & Johnson and Medtronic have integrated their credo deeply into their culture and the way they do business.\textsuperscript{14,15} Although this credo can function effectively for corporations, such a document can also provide value for organizations operating in university or not-for-profit settings.

**Communication Tools**

There are three main communication tools that are important in the successful communication of a new technology: prototypes, business plans, and presentations. Prototypes serve a multitude of early-stage functions. However, crude they may be, prototypes communicate an invention to others, help determine its feasibility, and identify challenges that may arise as it is developed further (eg, scaling it up or down, fitting it to different anatomies, manufacturing it). A tangible model is far more useful than a description or drawing of an invention. Those reviewing a technology (eg, investors, physicians) will be able to provide much better feedback with a real, three-dimensional prototype. Placing a prototype into the hands of an end-user can
also be very informative. By observing how they handle the device and what features give them the greatest satisfaction or difficulty, it is possible to learn important lessons unachievable through other means.

Business plans are another powerful communication tool. Developing and writing a plan enhances the likelihood of success of any technology development program. Although the business plan is useful to potential investors, the process of creating a plan is even more important to the innovator because it forces one to think strategically about the project that is about to be launched. A plan must tell a story. It should explain the primary motivation, the unmet clinical need, market opportunity, and the proposed business solution. Once the solution is established and clearly described, the plan should outline the development path and basics of how the company or group will bring the technology to market. Important issues should be identified and addressed, but the explanations and text should be succinct. A clear, well-organized, and concise plan communicates as much about the innovator as it does the project, and can be an important step to successful financing. An outline of a typical med-tech business plan is presented in Table 75-1.

The plan must communicate clearly why someone should be interested in
the technology and describe succinctly a compelling strategy for sustainable competitive advantage and profitability. Most audiences prefer a shorter plan (10-15 pages) than a longer one. For more detailed suggestions on how to write a winning plan, there are many sources available.16,17

The third main communication tool is the presentation, or the “pitch.” As an innovator, you must always be prepared to present your idea. Chance provides encounters with people whose feedback or support may be important. For these occasions, it is important to have a prepared, up-to-date, “30-second elevator pitch”—a rehearsed summary of the idea that communicates all its salient aspects succinctly. There should be different pitches for different anticipated audiences. Eventually, when it is time to present the concept more formally (eg, to potential investors), a polished presentation is required. Typically, these presentations are given to a wide audience including nonclinicians/nonscientists. It is important to determine in advance exactly who will be in your audience, their backgrounds, interests, and concerns, and tailor the presentation specifically to each unique audience. Detail the clinical need and the strategy for developing a sustainable competitive advantage toward profitability, and explain clearly what is being asked from the audience, as well as any returns they might gain from participating. Fundamentally, if your business plan tells a compelling story, it will be of great interest to investors.

**Financial Considerations**

Once the basic business plan is formulated, the innovator must develop a financing plan to get it off the ground. By examining the most significant value-building milestones at each stage, it is possible to determine approximately how much funding is necessary initially and how many infusions of capital may be required over the life of the business. It is rare that one is able to obtain enough capital to finance an entire venture in a single round of financing. Usually, new ventures are funded in stages, providing an opportunity to reassess the progress and value of the venture at each stage, essentially lowering the risks for investors. The chart in Figure 75-4 illustrates a few typical examples of how value roughly tracks with milestones and cash requirements.
Assessing Cash Requirements

The skill required to estimate accurately the cash required to launch a new venture can be gained only by experience. Overestimating these costs can discourage potential investors; on the other hand, underestimating costs may cause the business to fail simply because of lack of funds.

Med-tech venture start-up costs can vary significantly, depending on the size and scope of the project. For example, a simple class I surgical instrument provider may be able to start up with less than $1 million, whereas a typical medical device or biotech company often requires tens to hundreds of millions of dollars to reach profitability. Over the life of a new company, the expenses and sources of risk shift from development costs to more standard execution costs such as sales, marketing, and manufacturing. It is often the earlier, more risky expenses that are the hardest to assess, and thus, usually after all the expected expenses are tabulated, most entrepreneurs expand the amount of funding that they seek to offset the impact of the unknown.

Funding Sources and Financing Strategy
Finding resources can be the most challenging and daunting task for the innovator. Following is a list of the most common funding sources as well as their pros and cons.

**Government or Other Grants**

Government funding through small business innovation research grants (SBIRs), the advanced technology program (ATV), the National Institutes of Health (NIH), or other such grants is an excellent way to fund highly research-oriented projects. Although some grant processes can be highly political and burdened with bureaucracy, innovators rarely sacrifice any ownership or loss of control in the process.18

**Angel Investors and Self-Funding**

At the earliest stage, it is very common to draw funding from friends and family, self-funding, or “angel” investors. These resources are best applied to the initial patent and feasibility work and can often help an entrepreneur frame the opportunity better for more professional investors. If access to such resources or contacts is not immediately available, there are some well-known angel investor groups that can be approached.19 Although some of these groups have been moving into larger and later-stage financing, financing your company exclusively with angel money through several rounds can make later-stage financing more difficult when cash requirements exceed those of your angel network. Angels typically demand less of the company early on and tend to be more flexible than other investors; however, companies without professional investors risk a significant value reset later if early valuations were set outside of prevailing market conditions.

**Venture Capital**

Venture capital is the source that is usually tapped for cash-intensive opportunities that require substantial cash and time investment before returning profits. A complete list of venture groups and their interest areas can be obtained from the National Venture Capital Association (NVCA) or one of the many available handbooks on venture capital.20 Access to venture capital is rarely obtained through a “cold call” or an uninvited business plan.
The vast majority of venture groups rely on their extensive network of contacts to establish the credibility of incoming ideas and entrepreneurs. These contacts cut across academic, industry, and investment domains, and your reputation and demonstrated ability to advance such ventures can have enormous impact. It is therefore very important for the innovator to develop these relationships or find ways of accessing this network of people. Once those links are established, it is much easier to gain access to the venture capital community. Venture capitalists (VCs) add discipline and focus to a business as well as financial resources, but in return they often require substantial percentages of the company as well as other conditions that further limit their risk and increase their control. Unlike angels, who may be happy to invest in a long-standing business that throws off dividends, VCs make their returns through “exits” or liquidity events (such as acquisitions or initial public offerings [IPOs]). It is very important that the goals of the innovator align with the goals of the investors, particularly with VC investors, because most of them play an active and pivotal role in the decision making for the company.

**Banks**

Although banks are good places to get equity loans on your house, they are traditionally not good places to obtain financing for new businesses that are far from profitability. Banks have a much lower risk tolerance and do not usually place very much value on intangibles such as IP or technology.

**Vendors**

Vendors, customers, or other business partners can be very creative and strategic sources of capital. In general, these relationships are best structured once you have something to offer in return (eg, purchased services or other rights), but it is still possible to arrange preferred pricing or other cash-relief arrangements. These relationships vary widely and offer an alternative to traditional financing approaches by minimizing cash requirements.

**Corporate Partnerships**

Corporate or strategic investors can be an excellent source of capital and
other resources for a new or developing business. In general, strategic investors tend to be less price sensitive and more interested in the strategic value to their own businesses. It is usually better to bring such investors into the picture later, because the involvement of such players in a business can have a direct impact on the liquidity options later. Although each deal is different, traditionally, these partnerships can involve the corporation gaining access to equity, intellectual property, distribution, or development rights in exchange for cash or other resources. Many of the larger corporations (eg, Johnson & Johnson, Pfizer, Medtronic) have groups dedicated to partnerships that can be approached.

Public Equity

Under current market conditions, public equity accessed via an initial public offering (IPO) in the stock market or acquisition of a corporation is an option generally reserved either for biotech companies that have passed into phase III testing or medical device companies with revenue growth and profits. This threshold can change dramatically with market conditions. Several investment banks (eg, Piper Jaffray, JP Morgan, UBS Securities) have developed specialized practices focused on the med-tech space and are essential for any company contemplating this pathway. Online resources such as the Electronic Data Gathering, Analysis, and Retrieval System (EDGAR) can be used to study recent IPO activity and easily allows users to compare the fundamentals of these businesses.21

Incubators

Since the mid-1990s, multiple incubators have been formed to help early innovators bring their new concepts forward. These entities, such as ExploraMed, the Foundry, In-Cube, the Innovation Factory, and SyneCor, focus on identifying new ideas themselves or working with clinicians/scientists with ideas who do not wish to commercialize them alone. In general, incubators combine these ideas with funding, appropriate staff, and expertise in return for a significant portion of the equity of resulting companies.
KEY RESOURCES

There are many other sources to turn to for more specific information and advice. Undoubtedly, the most useful resource is one or more mentors who have succeeded in developing new technologies in a given area. There are plenty of resources even if a mentor is not available, especially with the availability of the Internet. Following are a few suggestions:

• Stanford Biodesign has published a comprehensive textbook\(^2\) that outlines the process of medical technology innovation in detail and provides references for each step in the process. An accompanying video library can be found online (www.ebiodesign.org).

• Offices of Technology Licensing: For those affiliated with an academic or government medical center, the technology licensing office can provide support in filing patents. They often finance the patent application process and explain how to license technology in order to start up a new business.

• The National Center for Biologic Information (NCBI) (www.ncbi.nlm.nih.gov): The NCBI has an extensive publicly available database that permits users to search articles, books, and other media covering almost all areas that relate to the field of medicine.

• The Food and Drug Administration (FDA) (www.fda.gov): The FDA’s website can help with regulatory and clinical trial strategy. It provides guidelines (required performance, safety, efficacy, and preclinical and clinical data) for different types of devices. The website also provides a more detailed description of the regulatory process and up-to-date information on the approval status of existing and emerging devices.

• The US Patent and Trademark Office (USPTO) (www.uspto.gov): The USPTO’s website allows users to search issued and filed patents online for free.

FINAL THOUGHTS

In this chapter, we have provided a basic primer on how to take a new technology idea to the next level. There are several excellent references cited here that are useful for those who wish to develop a deeper understanding of the issues. Just as in clinical medicine, however, the best source of expertise
is experience. Clinicians and biomedical scientists have the enormous advantage of being on the front lines of need finding, where technology opportunities present themselves. The technology innovation process does not require mystical insight—just the willingness to work hard and pay attention to some of the fundamentals we have outlined here. The biggest mistake is not taking the first step.

REFERENCES

Web-Based Learning

Lawrence W. Gimple

INTRODUCTION

Remarkable advances are regularly made in the science, clinical practice, and procedural applications of interventional cardiology, challenging the interventional cardiologist to systematically integrate new knowledge into a demanding, complex, and fast-paced environment. The rapid expansion of the evidence base for cardiovascular medicine has occurred contemporaneously with transformative changes in information technology. The Internet originated as a Department of Defense project in 1969, and the World Wide Web entered the national consciousness in 1991 with the introduction of the first graphical web browser, called Mosaic. Over the next few decades, the World Wide Web has become a ubiquitous presence in daily life that has affected all aspects of communication and social interaction. Not surprisingly, the Internet has also become a major means of distributing a broad range of educational materials. The Internet was so pervasive that in 2013, there were more than 2 trillion Google searches representing nearly 6 billion searches per day, presumably by individuals seeking information. With the rapid growth of mobile devices, people can basically access information and learn anywhere and at any time. Online learning has affected educational domains from preschool to professional education, and each area has its unique attributes and challenges. In this chapter, however, only the most important aspects of web-based learning as it pertains to the interventional cardiologist will be presented.
WEB-BASED LEARNING AND ADULT LEARNING THEORY

Adult learning strategies (called andragogy) originated in ancient times; for example, both Plato’s Academy and Aristotle’s Lyceum were focused on adult education. Although much academic work at American universities has focused on children from kindergarten through high school (known as pedagogy, or the science of teaching children), adult learning theory expanded and acquired a stronger theoretical basis with the work of Malcolm Knowles and others in the 1970s. Adult learning theory continues to evolve, and newer theories known as “transformative learning theory” are being actively explored in the academic literature. Transformative learning relates to changing one’s perspective on one’s self and one’s place in the larger social context.

Adult learning theory, according to Knowles, is based on a number of assumptions:

1. As a person matures, his or her self-concept moves from that of a dependent personality toward one of a self-directing human being.
2. Adults accumulate a growing reservoir of experience, which is a rich resource for learning.
3. The readiness of an adult to learn is closely related to the developmental tasks of his or her social role.
4. There is a change in time perspective as people mature—from future of knowledge to immediacy of application; thus, an adult is more problem-centered than subject-centered in learning.
5. Adults are mostly driven by internal motivation, rather than external motivation.
6. Adults need to know the reason for learning something.

An important assumption of adult learning relates to accumulated life experiences as a rich resource for learning. Indeed, medical residency, general cardiology fellowship, and interventional cardiology training are steeped in the ongoing experiential development of the core competencies of the Accreditation Council for Graduate Medical Education, which include medical knowledge, patient care, practice-based learning and improvement,
systems-based practice, professionalism, and interpersonal skills and communication. In each of these domains, adult learning theory can lend insight into the kinds of behaviors that are best associated with acquisition and integration of new knowledge into established practice patterns. The reduction in work hours over the past decade has additionally fragmented the time that residents and fellows spend in the hospital engaged in patient care and education. Self-directed learning, initially known as “self-teaching,” has become a critical component of physician education. “Virtual learning environments” including web-based learning may be well suited to many aspects of self-directed learning but success may vary significantly among individuals and across cultures.²

Much of the learning associated with interventional practice occurs when the interventional cardiologist confronts a new problem or a constellation of problems that are unfamiliar. Adult learners typically learn based on specific needs, and learning is reinforced when there is an immediate application of learning. Thus new patient problems often present “teachable moments” that offer unique opportunities to both learn and integrate complex new information. Adults often want to choose what they learn and how to learn it; web-based learning environments offer a broad spectrum of content, and learners can seek the kinds of learning experiences that are best suited to them as individuals. Adult learners like to know why they need to learn certain types of information; learning new information as it pertains to a specific patient or problem can fulfill this inherent need.

The arrival of enhanced social media capabilities of Web 2.0 has offered increasing opportunities for professional interactions to occur that help to establish “communities of practice” that result when interventional cardiologists interact regularly around common clinical problems or concerns. These activities had traditionally occurred during local case presentation conferences or during a cardiac catheterization laboratory conference. For cardiologists who are more separated geographically from colleagues yet still wish to interact regularly and share patient experiences or challenges, web-based learning methods may allow for the development of “virtual communities of practice” in which participants may use the powerful communication tools of the web to create shared meaning and experience, to observe more experienced operators perform common procedures, and to develop a sense of community with a group of colleagues who share their clinical interests.
In 2010, the US Department of Education\textsuperscript{3} performed a meta-analysis of more than 1000 scientific studies of online and web-based learning focusing on those reports that (1) contrasted web-based and face-to-face learning, (2) measured learner outcomes, (3) employed rigorous scientific methods, and (4) provided adequate data to calculate the magnitude of the learning effect. With respect to the evidence based on adults, the key findings of this meta-analysis included the following:

- Students in online conditions performed modestly better, on average, than those learning the same material through traditional face-to-face instruction.
- Instruction combining online and face-to-face elements had a larger advantage relative to purely face-to-face instruction than did purely online instruction.
- Effect sizes were larger for studies in which the online instruction was collaborative or instructor-directed than in those studies where online learners worked independently.
- The effectiveness of online learning approaches appears quite broad across different content and learner types.
- Effect sizes were larger for studies in which the online and face-to-face conditions varied in terms of curriculum materials and aspects of instructional approach in addition to the medium of instruction.
- Elements such as video or online quizzes do not appear to influence the amount that students learn in online classes.
- Online learning can be enhanced by giving learners control of their interactions with media and prompting learner reflection.

A large number of important unanswered questions remain with respect to web-based learning, especially related to the specific techniques in web-based instruction that make online learning most effective. Over the past few decades, numerous academic and professional organizations have developed that support the educational science underlying theories of online learning, including Merlot (Multimedia Resource for Learning and Online Teaching; \url{www.merlot.org}), Sloan-C (Sloan Consortium; \url{www.sloanconsortium.org}), and the National Science Digital Library (\url{www.nsdl.org}). Additionally, the number of academic journals publishing original research in web-based learning continues to grow.
Mobile technologies and smartphones have transformed the cultural landscape and the opportunities for information delivery. A recent survey in *Time* magazine reported that 9 of 10 Americans carry a mobile device and access it regularly. While mobile phones were nearly nonexistent a generation ago, *Time*’s poll reported that currently 25% of people check their phones every 30 minutes and 20% do so every 10 minutes. Thirty-three percent of Americans feel anxious if they are separated from their phones for even short periods of time. Seventy-five percent of Americans age 25 to 29 years sleep with their phones, and twice as many people would pick their phones over their lunch if forced to choose.4

A full discussion of “mobile learning” or “just-in-time learning” is beyond the scope of this chapter, but it is important to consider the potentially transformative implications of information delivery to learners in real time and at the point of care. Just-in-time education can potentially provide patient-specific answers to clinical questions at the moment the provider needs to know. The opportunities for clinically relevant learning at highly “teachable moments” are obvious. Text-based applications running on the web, such as UpToDate, ClinicalKey, mobile manuals, Epocrates, and many others, offer mobile access to specific clinical information on mobile devices. Increasing levels of integration with electronic medical health records for specific patient allows the possibility for both alerts and instruction relevant to specific patient care situations to be offered in real time. Such integration of electronic medical health records with just-in-time education is still in its infancy. As a particular example, the rapidly expanding fields of cardiovascular genetics and genomics are producing new knowledge at a rapid rate, and this information will not be widely familiar to many practicing physicians. Similarly, physicians will often be uncertain as to when such information is even relevant for a particular patient or disease state. Thus cardiovascular genetic data might be examples of “chunks of knowledge” that could provide “just-in-time” education to practicing cardiologists caring for patients with certain cardiomyopathies.

**Limitations**

Web-based learning is still in an early phase in subspecialty medical education, and many challenges face the organizations and groups that develop learning materials for interventional cardiologists. The rapid
expansion of learning platforms, mobile devices, and technology standards has offered both opportunities and challenges. One of the greatest challenges relates to the rapid evolution of knowledge and clinical information. Case studies, guidelines, and clinical trial results can rapidly become obsolete as new science is developed. When clinical information is embedded in enduring materials, its relevancy is quickly dated and it requires significant financial resources and effort to keep clinical information up to date, especially when it is in noneditable formats such as video or web-based packages. Clearly, the current significant use of web-based learning sites would seem to confirm that physicians desire to use online resources in education, but objective demonstration of improved physician performance or patient outcomes from these learning interactions is still lacking, especially for online educational methods that teach cognitive or procedural skills.

The quality and reliability of much educational content remains uncertain. Whereas medical journals have formal peer-review processes that have been developed over many years, online content can appear on the web from any number of sources. Much of the web-based learning in interventional cardiology comes from major cardiology societies such as the American College of Cardiology, the Society for Cardiovascular Angiography and Interventions, the American Heart Association, or the European Society of Cardiology. Much of this content undergoes a form of peer-review. Other content may come from other Accreditation Council for Continuing Medical Education–approved sites such as universities or hospital-based research foundations. However, medical educational content can also be user-generated or even crowd-sourced from comment fields, blogs, or wikis, methods where the quality and source of information may be unclear.

**Selected Glossary of E-Learning Terms**

**Apps** are small computer programs, or “applications,” that typically run on mobile devices such as smartphones or tablets (such as iPad or Google Nexus) but also on a computer or laptop. For medical uses, an app might contain mathematical formulas that allow one to calculate creatinine clearance, CHA\textsubscript{2}DS\textsubscript{2}-VASc score for atrial fibrillation stroke risk, or a Thrombolysis in Myocardial Infarction (TIMI) risk score. Other examples of apps are email, games, or mobile web browsers.
**Blended learning** refers to using web-based teaching methods together with more traditional classroom-based methods. This is sometimes referred to as hybrid learning, or “flipping the classroom,” since the latter allows lectures to be given asynchronously via the web while classroom time is reserved for higher level, integrative learning.

**Blog**, derived from the word “weblog,” is an e-learning or social media tool that allows the ongoing discussion of a particular topic or theme, often in response to a prompt. Blogs allow social interaction and engagement with a wider audience of blog readers or members. Topics are often maintained and archived in reverse chronological order for ongoing review.

**Content** is a broad term that describes the actual material to be received or learned. In the electronic world, content varies widely in complexity ranging from very small elements (eg, a phrase, image, or sound) to complex larger structures such as learning exercises, lessons, entire curricula, or even games. In some contexts, a simple piece of content might be considered a “knowledge chuck” or “learning object” that could be used as a modular building block for e-learning.

**Learning Content Management Systems (LCMS)** are required to administer all of the complex relationships that exist among pieces of content such as organization, storage, assigning meta-tags, previous uses, productions steps, relationships with other content, technical specifications, editorial review status, copyright considerations, or other management functions. Optimally content management systems would interact seamlessly with the content, with authoring tools, with production processes, with learner management systems, and with content delivery systems.

**E-learning** is a broad and evolving term that involves the use of electronic media and/or the Internet to promote education. E-learning may encompass multiple types of technology-facilitated education including multimedia, computer-based training, online education, or distance learning.

**Experience API (formerly known as “Tin Can”)** is an API (application programming interface) that has been called the “next-generation SCORM (Sharable Content Object Reference Model).” Experience API will allow data from a diverse set of educational activities to be collected and
recorded by a learning management system in a fashion that facilitates the creation of online curricula that mix online learning with traditional (real-world) educational activities.

**Learning management system (LMS)** is the software that focuses on the management of the learner, or “end-user.” An LMS typically manages the administrative aspects of educational websites including the tracking of users and membership, documentation of interactions, reporting, and other common administrative functions such as username, passwords, and e-commerce. Some systems manage certificates, transcripts of work completed, or a broader learning portfolio.

**Learning objective** is a clear, structured, and measurable statement of the behavior or performance that the learner needs to accomplish to be sure that the desired learning has actually occurred. A well-structured learning objective has 3 parts: a measureable verb, the important condition under which the performance is to occur, and the definition of acceptable performance.

**List serv** is an automated method for managing and distributing content by email to a specified recipient list. A list serv may support or replace other e-learning functions by pushing content to users who prefer to receive information by email. The resulting communications resemble a newsgroup or forum. List servs have been used by academic catheterization lab directors to facilitate educational correspondence.

**Massive open online courses**, or MOOCs, allow a single instructor to offer a course to a nearly unlimited number of learners simultaneously. Perhaps the best-known platform is Coursera, which is an online provider that partners with many of the best-known universities around the world to offer full courses for anyone with an Internet connection and at no cost. MOOCs typically offer many of the advantages of online learning including providing master instructors to teach the courses and peer assessments to review learner-generated content. Blended learning is a common aspect of MOOC courses. One MOOC instructor, Harvard’s Michael Sandel, became so famous after teaching a course called “Justice” that he achieved celebrity status in Korea, and his philosophy course has had more than 20 million views in China (with subtitles).\(^7\)

**Needs assessment** is a structured procedure that occurs prior to creating e-
learning material for identifying and prioritizing the educational needs of the community. This is accomplished by analyzing the gap between present educational state and the desired state or outcome.

**Podcasts** are electronic files, often audio and video, that are distributed over the Internet. These are typically viewed or heard on computers or mobile devices such as smartphones or personal players such as iPods.

**SCORM**, or Sharable Content Object Reference Model, allows educational content to be shared widely by differing learning management systems by specifying the standards and coding for web-based e-learning. Thus SCORM-compliant educational modules created with one product can be shared on educational sites using a different learning management system. SCORM was created as part of the Advanced Distributed Learning (ADL) Initiative from the Department of Defense.

**Social media** is often experienced as a phenomenon in mass markets but is increasingly used in professional environments including web-based interactions for physicians. Many of these sites allow the user to create a personal profile that is shared widely. Examples include Facebook, Twitter, LinkedIn, Doximity, Skype, Youtube, and many more.

**Synchronous and asynchronous e-learning**: Synchronous learning requires that both the teacher and learner be present at the same time. Common examples would include a classroom lecture or a traditional seminar in a classroom. In an e-learning environment, the interactions would require the educator and the learner to be online at the same time to allow direct interaction as in a video-conference or virtual classroom.

Asynchronous learning allows the educator and the learner to be separated by both space and time. Technologies such as email, blogs, discussion boards, social networking, and wikis support asynchronous e-learning and allow greater flexibility in the time domain. Learners may work at their own pace, review material repeatedly, and feel less time pressure when reviewing educational material or producing responses.

**Web 2.0** is a broad term given to the second generation of web methods that allowed for sharing of content among participants and for greater creation of content by users. Most Web 2.0 applications use dynamic generation of pages, typically from content held in a database, rather than
relying on static, hard-coded web pages. Wikis, video sharing, and enhanced social networking are enabled by these enhanced technologies.

**Webcast** is a transmission of audio and video over the Internet much like a television broadcast. This technology delivers prepared educational content to a learner over the Internet with limited interactivity.

**Webinar** uses more advanced Internet technologies than a webcast, allowing for audience participation and interaction with the learning activity. It may be a presentation, workshop, lecture, or seminar that is managed over the web. In a webinar, the audience can interact with the teachers and with each other in real time, and the overall educational encounter can be archived for later, asynchronous viewing.

**Wiki** is a website or related environment where the end-users themselves can create and edit content individually or by collaborating with others. Typically a wiki requires no additional software and allows for distributed or crowd-sourcing creation of content. Wikipedia is the best-known example.

## COMMON E-LEARNING FORMATS IN INTERVENTIONAL CARDIOLOGY

**Board Review Preparation and Questions**

A significant body of literature supports the use of questions with annotated responses to enhance long-term learning, rather than just “assessing knowledge.” While the actual board examination is required for credentialing, there an increasing body of evidence that assessment questions can have a significant educational effect when they are designed specifically to produce learning.\(^8-14\) Well-designed questions should not only address important medical content and knowledge, but must also be well structured to support learning. Well-constructed, relevant questions can provide learners with practice retrieving information from memory, give learners feedback about their material, focus learners’ attention on the most important learning material, and repeat core concepts for reinforcement. It has been demonstrated that these beneficial effects are apparent whether the questions...
are presented before or after the associated learning material. It has been
demonstrated that when students are tested on material and successfully recall
or recognize it, they will remember it better in the future than if they had not
been tested, a phenomenon known as the testing effect.\textsuperscript{13} Testing has been
demonstrated to provide benefits during web-based self-instruction for
professional students,\textsuperscript{10} has been shown to improve long-term retention,\textsuperscript{11}
and has been shown to improve outcomes on semester exams.\textsuperscript{12}

The American College of Cardiology’s CathSAP 4 (Cath Self-Assessment
Program) is an extensive online (or print) course in cardiac catheterization
and interventional cardiology. The course utilizes hundreds of peer-reviewed,
American Board of Internal Medicine (ABIM)–style self-assessment
questions to coordinate study and is designed to be used to prepare for initial
board certification or recertification. It contains learning chapters focused on
a broad array of clinical and scientific topics related to the cardiac
catheterization laboratory and includes self-assessments, board preparation
examinations, and interventional cardiology Maintenance of Certification
modules.\textsuperscript{15}

TCTMD Prime also includes digital slides and webcast versions of slide
presentations presented at Cardiovascular Research Foundation’s annual
Fellows Courses and the Transcatheter Cardiovascular Therapeutics (TCT)
Self-Assessment/Board Review Course.

\textbf{Live Case Demonstrations}

Patient demonstrations have been used in classic medical grand rounds and
for bedside teaching for generations. In 1846, Dr. William T. G. Morton
made history when he performed the first public surgery using anesthesia
(inhaled ether) in the Ether Dome of the Massachusetts General Hospital. In
the Internet age, “live case demonstrations” have become a common method
of web-based education with live demonstrations occurring regularly at
national meetings and broadcast from labs around the world to large
audiences at national meetings or scientific sessions. Such live case
demonstrations include cases related to coronary revascularization, structural
and valvular heart disease, and other invasive and interventional procedures
commonly performed by interventional cardiologists. Potential educational
advantages of this case format include the ability of the learner to directly
observe actual case examples of specific methods and to hear experts
Comment both broadly on medical topics and on the finer details of a specific case procedure. In many meetings, these live cases draw large physician audiences. Two-way communication between the local lab and the meeting room allows moderated discussion including multimedia presentation and playback of case images and information in real time. Case demonstrations are archived and available as web-based learning opportunities at sites such as Cardiosource (http://www.cardiosource.org/en/Lifelong-Learning-and-MOC/Education/Mt-Sinai/CCC-Live.aspx) or TCTMD Prime (http://www.tctmd.com/).

Despite the common use of this educational format, however, questions have been raised regarding the educational value, potential patient risk, ethics, use of investigational devices or off-label use of approved devices, and conflict of interest related to the marketing and use of medical equipment. In response to these concerns, the relevant medical societies representing the practice of cardiology (Society for Cardiovascular Angiography and Interventions/American College of Cardiology Foundation/Heart Rhythm Society/European Society of Cardiology/Sociedad Latinoamericana de Cardiología Intervencionista/Asian Pacific Society of Interventional Cardiology) issued a “Statement on the Use of Live Case Demonstrations at Cardiology Meetings.” This statement included discussion of the educational concerns, live versus prerecorded sessions, the use of a moderator, concerns regarding patient risk related to the overall format, patient rights and informed consent, goals for cases and patient selection, and a code of conduct for live case demonstrations with emphasis on patient safety and privacy, informed consent, conflict of interest, regulatory considerations, and educational imperatives. The writing committee concluded that data examining the educational value and patient risks associated with live case presentations are “sparse.” The writing committee was unable to determine if the educational benefits of live case demonstrations outweigh the potential negative consequences. Other professional societies, including surgical subspecialties, have also struggled with these issues.

**Case-Based Learning**

Case-based learning has long been a centerpiece of medical education, reflecting the fact that each patient and situation are unique. The case study
method was initially introduced at the Harvard Business School more than a century ago and utilized specific real-world business examples to teach business methods. Case-based learning has been the basis of many academic weekly “Cardiac Cath Conferences,” which formed the basis of learning for many cardiologists and cardiac fellows.

Case-based presentation formats in cardiovascular medicine are highly suited to web-based learning. The presentation of case information including digital video such as angiography, echocardiography, computed tomography, or cardiac magnetic resonance imaging is well suited to broadband delivery over the Internet. Case-based learning resembles the learning process that most physicians experienced during medical training. Clinical issues are discussed in the context of specific patient examples, allowing for a more sophisticated consideration of diagnostic and therapeutic options. Research has shown that active learning techniques, such as case studies, are superior to the lecture method. The relative effectiveness of the various methods for online case-based learning is not yet evidence based, although the introduction of higher-order questions and answer responses, in general, has been shown to promote longer-term learning retention. In recent years, the introduction of social media, blogging, and learner feedback has added an additional dimension to the learning experience.

*Journal Club*

Journal club has been a mainstay of the academic medical experience for generations. In a typical journal club, a recent or classic article from the medical literature is presented and discussed among a group of peers. The journal club can provide a structured format to review the background or a scientific question, the methods actually employed in research including statistical concepts, and the results. The implications of the medical literature can then be discussed and placed in a scientific, clinical, and historical context. The relationship of a scientific article to existing clinical guidelines can be reviewed and discussed.

Web-based learning is well suited to a journal club, especially in the context of the presentation of slides, digital video, and user feedback and discussion. The use of social media can promote interactivity.
Live Discussion, Interviews, Lectures, and News

As the modern information age has led to an explosion of new knowledge and technologies, the news-reporting industry has become increasingly fragmented and web-based. Many mainstream newspapers have experienced declines in print readership as online sources of information have expanded. Similarly, interest in specific medical topics in cardiovascular medicine have led to an expanded use of web-based sites that report both medical news and interventional cardiology–specific information including late-breaking information from major international meetings. Educational and informational content, including news from scientific sessions such as the Society for Cardiovascular Angiography and Interventions, American Heart Association, the American College of Cardiology, and the European Society of Cardiology, is now routinely presented and consumed online.

Educational content from these venues, and others, are routinely presented as webcasts on major channels such as Cardiosource, WebMD/Medscape/theHeart.org, or SCAI.org. Information is often presented as interviews with principal investigators or as moderated panel discussions among experts. Some of this content provides continuing medical education (CME) credit.

Traditional Journals

Most journals related to cardiovascular medicine and/or interventional cardiology are available online, and many are formatted for mobile devices such as smartphones or tablets.

TOP E-LEARNING ENVIRONMENTS FOR INTERVENTIONAL CARDIOLOGY

Creating and maintaining accurate, current, and evidence-based educational materials for e-learning for interventional cardiology require a highly committed and collaborative group of educators and clinicians working over extended periods of time. No small group of individual operators or clinicians has the breadth of experience and knowledge to run and sustain an e-learning
environment while maintaining clinical excellence over prolonged periods of time. Outstanding websites must also have adequate technology collaborations and innovation to remain compatible with evolving technical requirements. Thus the most sophisticated e-learning sites are typically coordinated by medical societies, well-funded foundations, or universities. Currently, no single site provides a truly optimized environment, which would include updated course materials, curricular organization, integration with learning objectives and competency-based models, opportunities for reflective learning, and coordination with a lifelong learning portfolio. Nevertheless, superb interventional cardiology e-learning websites provide abundant educational opportunities in important clinical areas. Many of these sites rely on their members or partners to create educational content that is frequently “repurposed” or archived from society meetings or courses for e-learning.

**Cardiosource (www.cardiosource.com)**

Cardiosource is a rich environment that integrates many of the educational resources and journals of the American College of Cardiology. It integrates learning material from its self-assessment programs (SAPs) that are updated on a regular basis, from clinical guidelines, from the Journal of the American College of Cardiology (JACC), from its educational conferences and board review courses, from unique “apps” that are customized for mobile devices, and from customized learning materials prepared for the site. The materials are searchable across multiple categories of interest and the type of credit desired. The clinical topics are broad and include acute coronary syndromes, arrhythmias and electrophysiology, congenital heart disease, heart failure and cardiomyopathies, invasive cardiovascular angiography and intervention, noninvasive imaging, pericardial diseases, prevention, pulmonary hypertension and venous thromboembolic diseases, stable ischemic heart disease, standard electrocardiography, stress testing, valvular heart disease, and vascular medicine.

Content presentation types include JACC journals (with CME credit), expert analysis, patient cases, meetings on demand, live course recommendations, courses and conferences, meeting on demand programs, self-assessment programs, and self-assessment quizzes. Live-archived interventional cases are available for both coronary and peripheral
interventions. There are materials for guideline education, journal clubs, practice management, and clinical trial reviews. Course material is typically offered with a “pretest” to assess readiness and baseline knowledge and a “posttest” to assess comprehension. Progress through the material is coordinated in a learning portfolio.

Mobile resources (for cell phones and/or tablets) include an Atherosclerotic Cardiovascular Disease (ASCVD) Risk Estimator (for compatibility with recent lipid guidelines), ACCEL, ACC Connect, AnticoagEvaluator, CardioSmart Explorer for iPad 2, CardioSource Mobile App, CardioSource WorldNews for iPad, Heart Songs (to learn heart sound interpretations), and JACC iPad Edition for electronic journal delivery and reading. Additional point-of-care tools are anticipated with respect to newer guidelines such as valvular heart disease.

**Web-Based Learning With Respect to the American Board of Internal Medicine Board Certification and Maintenance of Certification (MOC)**

Ongoing educational programs in interventional cardiology relate not only to managing a rapidly changing knowledge base, guidelines, and clinical trial results, but also have direct implications for certification and credentialing. The American Board of Internal Medicine (ABIM) has recognized that processes designed to expand and measure knowledge and performance every 10 years are no longer sufficient. The ABIM has thus implemented additional requirements that apply to all ABIM board-certified physicians, regardless of when they were initially certified.\(^\text{24}\) Beginning in 2014, in addition to reporting board certification on its website, the ABIM has begun reporting whether or not each ABIM board-certified physician is “Meeting MOC Requirements” (ie, continuously engaging in MOC activities). Many interventional cardiologists are ABIM board-certified in 3 specialties: Internal Medicine, Cardiovascular Disease, and Interventional Cardiology. The Interventional Cardiology board certification was initially offered in 1990, and thus, there are no “grandfathered” physicians in interventional cardiology with respect to interventional board certification. Additionally, a valid ABIM certification in cardiovascular disease is required to maintain certification in interventional cardiology (although it is noted that one does
not need to maintain certification in Internal Medicine to maintain certification in Cardiovascular Disease). Thus, the new ABIM rules have direct implications for interventional cardiologists of all generations with respect to board certification and/or MOC requirements.

Cardiosource (www.cardiosource.com)

Cardiosource offers a significant web-based learning environment structured with a learning portfolio to support the life-long learning process associated with the new MOC requirements. The site includes self-assessments, educational activities, MOC tracking, and recommendations for both online and in-person activities that carry credit toward certification. This includes a “MOC Status Report” for American College of Cardiology Foundation (ACCF) educational activities in support of ABIM certification and/or MOC requirements. The “self-assessment” environment is particularly rich with quizzes including echocardiography; cardiac arrhythmias; heart failure; peripheral, vascular, aortic, and carotid disease; imaging; pericardial disease; congenital heart disease; valvular heart disease; pulmonary artery hypertension; and invasive and interventional practice. Cardiosource is managed by the ACCF.

The Society for Cardiovascular Angiography and Interventions (www.scai.org)

The Society for Cardiovascular Angiography and Interventions (SCAI) offers a broad array of e-learning courses and programs that are organized into the SCAI eLearning Library. SCAI has a membership of over 4000 adult and congenital interventional cardiologists, organized into 20 committees that focus on areas such as establishing standards and guidelines for cardiac catheterization and angiography, training, credentialing, and safety and quality assurance for cardiovascular procedures.

The majority of the educational programs are included with membership, although some programs require payment for CME credit. The eLearning library includes an online curriculum covering multiple topics including a transradial interventional program (TRIP), a fellows in training curriculum (Interventional Cardiologists Institute), high-risk percutaneous coronary intervention (PCI), mastering fractional flow reserve (FFR)–intravascular
ultrasound (IVUS), peripheral vascular disease, a SCAI-QIT (quality improvement toolkit) webinar series, and a SCAI Scientific Sessions meeting on demand.

Each of these courses contains a detailed curriculum and starts with a pretest to assess knowledge and concludes with a posttest to assess learning.

TRIP includes lectures in starting a program and developing as a radialist, primary PCI, radial access, hemostasis and postprocedural management, catheter selection, guide catheter selection and manipulation, right heart catheterization from the arm, and radial approaches to peripheral procedures.

The Interventional Cardiologists Institute includes a wide array of courses including basic concepts for the interventional cardiologist; cath lab basics; valvular, structural, and congenital heart disease; intracoronary imaging and physiology; patient- and lesion-specific approaches; acute myocardial infarction; anticoagulation; coronary stenting; advanced PCI techniques and devices; high-risk groups and complications; cardiac imaging; peripheral vascular disease; and carotid artery disease.

The High-Risk PCI Online Curriculum includes the rationale and evidence for cardiac assist in high-risk PCI, hemodynamic principles of acute percutaneous circulatory support, identifying high-risk patients, available support devices, hemodynamics of percutaneous left ventricular support devices during high-risk coronary interventions, management issues (including noninvasive assessment) while on support, high-risk PCI case presentations, and support for ST-segment elevation myocardial infarction, cardiac arrest, and right ventricular failure.

The extensive FFR-IVUS Curriculum includes fundamentals of coronary pressure and flow derivation of FFR, technique, pitfalls and artifacts of FFR, fundamentals of IVUS imaging, technique, artifacts and image interpretation, clinical applications, appropriate use criteria, and guidelines.

The Peripheral Vascular Disease Curriculum includes acute limb ischemia, critical limb ischemia, claudication, aortoiliac occlusive disease, femoropopliteal disease, brachiocephalic arterial disease, venous thromboembolic disease, abdominal aortic aneurysms, mesenteric disease, renal artery stenosis, catheter-based interventions for failing hemodialysis accesses, infrapopliteal peripheral arterial disease, and intracranial arterial stenotic disease.

The e-learning section also includes an extensive “slide library” of
archived PowerPoint presentations. Future online offerings from SCAI will include sections entitled “Image of the Week,” “Cath Conference,” “Journal Scan,” and “Annotated Bibliographies.”

**The American Heart Association (www.heart.org)**

The American Heart Association (AHA) is extensively involved in e-learning across a range of cardiovascular conditions that are common in the practice of interventional cardiology including training in ST-segment elevation myocardial infarction, basic life support for healthcare providers, pediatric advanced life support, workplace training with respect to basic life support, cardiopulmonary resuscitation (CPR), automatic external defibrillation (AED), and advanced cardiovascular life support including training for experienced providers. Because the AHA and the International Liaison Committee on Resuscitation (ILCOR) coordinate much of the scientific work that underlies these important aspects of cardiovascular care, these organizations are uniquely positioned to organize guidelines and statements while providing much of the instructor network infrastructure that supports such training. The AHA provided the first CPR guidelines in 1966 and updates them every 5 years. AHA courses have trained millions of people and created a national network prepared for basic life support emergencies.

Interventional cardiologists are involved at multiple levels in the care of cardiac arrest survivors in the acute phase including evaluation in the emergency department, cardiac catheterization laboratory, or coronary care unit, making determinations regarding immediate therapies to be offered such as immediate coronary angiography and reperfusion therapy and/or therapeutic hypothermia. The timing, sequencing, and management of such interventions is not straightforward. As leaders of the hospital-based cardiology teams caring for such patients, interventional cardiologists play a central role in both developing systems of care and participating in direct patient care.

The AHA has extensively integrated e-learning systems into the widespread instruction of emergency cardiovascular care for healthcare providers and for the general public. Many of these courses offer blended learning experiences where didactic teaching is done using web-based teaching while a “hands-on” experience is provided in a more traditional, face-to-face setting. Depending on course specifics, e-learning courses are
delivered into 1, 2, or 3 parts. Courses that only involve cognitive learning can be completed online in 1 part. For courses that contain psychomotor skills such as CPR, students must complete an in-person “skills session” in addition to online learning. A skills session is composed of skills practice and skills testing. This e-learning system effectively blends cognitive learning with skills training.

**European Society of Cardiology (http://www.escardio.org)**

The ESC eLearning platform of the European Society of Cardiology contains a rich environment of e-learning tools focused on interventional cardiology through the European Association of Percutaneous Cardiovascular Interventions (EAPCI). EAPCI is open to health specialists including cardiologists, angiologists, radiologists, surgeons, cardiovascular technicians, physicians working in the industry, and researchers. More than 5600 colleagues from 125 different countries globally hold membership in EAPCI. The e-learning material is organized into sections entitled Knowledge, Skills, and Professional Development. The Knowledge module consists of 48 courses assigned among topics including basic science, pharmacology, imaging, procedural techniques, indications and patient selection, and management of complications. The site is rich in multiple-choice questions. The Skills module includes a case logbook with a focus on primary PCI, PCI in unstable angina, PCI in stable patients, and complicated cases. There is additionally a focus on procedural skills, safety, complications, and the laboratory accreditation process. A Professional Development module organizes a professional profile and 360-degree appraisals.

**TCTMD (www.tctmd.com)**

TCTMD contains an extensive catalog of online e-learning resources related specifically to interventional cardiology. The web environment includes recent news from cardiology conferences globally and focuses on information about the latest devices and drugs used in the daily practice of cardiovascular medicine.

TCTMD is produced and administered by the Cardiovascular Research Foundation (CRF; www.crf.org). Subscription to the basic features of TCTMD is free after registration. Paid annual subscription access to more
advanced content at TCT is also available. “Prime TCTMD” is designed for e-learning and self-assessment and includes presentations from the TCT Board Review Course with self-assessment in PowerPoint slides and in web case format. At additional cost, “Gold TCTMD” includes a library of case videos from TCT meetings and other meeting materials. “Platinum TCTMD” additionally adds live broadcasts from the main arena of the TCT conference and other TCT venues as well as archived versions of live broadcasts for 1 year.

TCTMD reports that the majority of funding for its e-learning environment is derived from unrestricted sponsorships and grants from medical device and pharmaceutical companies.

**WebMD, Medscape, and theHeart.org**

Medscape is a part of the WebMD Health Professional Network that includes theHeart.org and provides health information across a wide array of topics. For cardiovascular e-learning, the integrated Medscape Cardiology/theHeart.org environment provides both news and an e-learning environment. The combined website contains features such as “Test Your Knowledge,” HeartWire news, news from major conferences, and most popular news. Additionally, there are editorial series, columnists, business of medicine, trials slides of the month, and journal articles.

Medscape and HeartWire ([theHeart.org](http://theHeart.org)) also maintain a regular and ongoing collection of audio podcasts that can be obtained by (free) subscription or individual download to computers or mobile devices such as cell phones or personal players (such as iPods). These are available from sights such as Apple iTunes. A broad range of current and late-breaking information is regularly presented including renal denervation, transcatheter aortic valve replacement, prevention, and other areas.

**Apps**

Numerous useful apps are available for computers, tablets, and mobile devices from sources such as Apple iTunes. Apps related to interventional cardiology include CARDIO3 Atlas of Interventional Cardiology and the ASCVD Risk Estimator, but a nearly endless collection of useful cardiology and medical apps is available covering a wide range of topics from
electrocardiogram interpretation to clinical trials information to American College of Cardiology courses. These apps can provide structured educational content or “just-in-time knowledge chunks” that can assist the interventional cardiologist at the bedside. Apps are available in small-screen formats and in larger formats for tablets such as iPad, and additional apps regularly appear on the market.

**Massive Open Online Courses (MOOC)**

To date (2017) MOOCs related specifically to interventional cardiology have not been developed.

**E-Books**

E-books bridge the divide between print-based publishing paradigms of previous generations and the evolving web-based e-learning opportunities presented by modern digital technologies. Amazon reported that their e-book sales surpassed printed book sales in April 2011 and that e-book sales made up 23% of the total book market in 2012. Currently popular e-book platforms include the Kindle, Nook, iPad, and smartphones. E-books can also be read on a computer. Distinct advantages of e-books include rapid (nearly immediate) delivery on demand, presentation of multimedia material such as digital video (angiograms and echocardiography), decreased production and distribution costs, implementation of “widgets” than can allow additional interaction with content, increased ease of translation to other languages, ability to modify font size for ease of reading, ability to read in the dark on many platforms, and text-to-speech software. Numerous e-books are available related to interventional cardiology (and even more related to cardiology generally), and these increasingly leverage the multimedia capabilities of the platform. Board review books, handbooks, traditional textbooks, books regarding coronary stenting, and many others are available through Amazon’s Kindle Store, through Apple iBooks Store, or from other vendors.

Digital publishing software for creating e-books with enhanced multimedia capabilities is rapidly evolving and becoming available to the consumer market. Programs such as Adobe Digital Publishing Suite for eBooks and Apple’s iBooks Author allow creation of multimedia e-books for
various platforms, and the latter allows the author to create e-book galleries, video, interactive diagrams, 3-dimensional objects, and standard text-based content for delivery by, and only by, iTunes to iBooks.

Medical Simulation in Interventional Cardiology

Andrew Klein
John C. Messenger

Medical simulation comprises the artificial representation of a real-world medical environment with sufficient realism to facilitate learning through immersion, reflection, feedback, and practice without the risks inherent to a similar real-life experience. As a result, simulation’s re-creation of a real-world process/system permits operators to practice/rehearse various scenarios that may range from routine practice to rare events including complications. One central purpose of simulation is for “safe learning,” ie, learning without a real-world consequence if errors occur. As such, simulation has a long history of use in professions that require the execution of precise physical and neurocognitive tasks in high-risk environments. For example, simulation has been used to train pilots and other professions where mistakes can have disastrous consequences. We know from the aviation industry as well as other nonmedical fields that simulators are effective teaching tools, improve learner success, enable repetitive practice of tasks in a range of conditions, and enhance task safety. Despite the ability of simulators to recreate numerous high-risk and complex environments, the uptake of simulation for the training and assessment of interventional cardiologists has lagged. This chapter will review the use of medical simulation in the realm of interventional cardiology as it stands today in hopes that it will continue to grow and be integrated more effectively into training and practice.
Interventional cardiology is a relatively new field, having only been in existence for just over 3 decades. Many current operators have been practicing since its inception and have vast experience, essentially precluding a need for simulation prior to the turn of this century. Previously, coronary interventions were only being performed in high-volume centers by high-volume operators. However, since Andreas Gruentzig’s first foray into the heart in September 1977, there have been many changes in the landscape of interventional cardiology. No longer are we as a profession performing only coronary interventions. Where previously invasive surgery represented the only option for patients, thanks to countless technologic advancements and the pioneering nature of numerous physicians/scientists/industry partners, patients with structural heart disease, peripheral arterial disease, and coronary disease now have minimally invasive options. However, with the expansion of interventional cardiology beyond the coronary vessels has come the challenge/inability of most interventionalists to practice all 3 subsets of interventional cardiology, ie, coronary, structural, and peripheral. This fact, coupled with demands for “centers of excellence,” along with an ever competitive market further underscore the need for an environment where the interventional cardiologist can assimilate new skills, rehearse rare emergency procedures, and perhaps provide evidence of their own. Simulation can provide such an environment.

In fact, interventional cardiology is a field well suited for simulation.\(^8\) Simulation can be used to both educate and improve performance by enabling repetitive practice of tasks in a range of difficult clinical conditions.\(^9\)\(^-\)\(^11\) Education in an era where work hour restrictions are a reality has also proven challenging. This, in addition to the well-publicized decrease in coronary percutaneous coronary intervention (PCI) volume over the past decade, drug-eluting stents, and appropriate use criteria, has led to a newer generation of interventionalists who will never attain the clinical experience/volume of their predecessors. Compounding this are the constant advances in techniques and devices and the ever present pressure to reduce costs while enhancing quality all within an environment where patient safety is paramount.\(^12\) The emergence of hospital departments, national bodies, high-profile conferences, and scholarly journals focused solely on patient safety seeks to serve the growing societal pressure for transparency in medical practice, in concert with public expectations for reductions in medical error.\(^13\) Thus, there is a resounding need for a “safe” environment where physicians may practice
their current skill set and/or attain new skills without subjecting patients to real harm. The days of “see one, do one, teach one” are gone and perhaps will be replaced with “see one, do several in a simulated environment and then more with a proctor, and then only after a certain volume be permitted to teach one.” Fortunately, technology has also advanced in the realm of medical simulation, and today there are multiple high-fidelity medical simulators available that can provide operators with a wide range of clinical scenarios in all 3 realms of interventional cardiology. Simulation provides a medium by which providers can learn and practice despite explosions in technology and limitations in procedural volume and work hours. Simulation thus provides an answer of how to train, test, and practice in the 21st century where only the highest quality health care will be accepted.

Another application of simulation has been its use to test individuals in a “safe environment.” The Federal Aviation Administration and several other nonmedical professions require simulation as part of routine training and/or maintenance of competency and annual skills training. Recently, governing bodies such as the American Board of Internal Medicine (ABIM), the National Board of Medical Examiners (NBME), and the Accreditation Council for Graduate Medical Education (ACGME) have been investigating the use of simulation to assure procedural competency and patient safety. Indeed, the ABIM has incorporated the use of simulation into their Maintenance of Certification program, and the ACGME has mandated that simulation be a current component of all interventional cardiology fellowship training programs. These applications of simulation have come despite a lack of large-scale studies showing improved patient outcomes with simulation in the field of interventional cardiology.

EVIDENCE FOR SIMULATION

Although the comprehensive review of the evidence of all simulation studies is beyond the scope of this chapter and has been performed elsewhere, it is important to review the origins of simulation in procedural fields. The evidence that a simulation-based curriculum is useful and valid in procedural fields originates from the surgical realm, specifically from laparoscopic surgery. In the 1980s, with the advent of minimally invasive laparoscopic surgery followed by a large number of patient complications from this new
technique, several credentialing societies developed guidelines on the proper 
acquisition of laparoscopic skills prior to performing this surgery on real 
patients.\textsuperscript{17} Although initially performed in animals, with the advent of newer 
technologies, simulated laparoscopic training eventually became possible. 
Scott et al,\textsuperscript{18} in 2000, clearly demonstrated that a 4-week simulation course 
on “box simulators” enhanced the performance of laparoscopic 
cholecystectomy in the operating room.\textsuperscript{18} To date, there have been 2 large 
randomized clinical trials\textsuperscript{19,20} that confirm the ability of a virtual reality 
simulator to enhance operative speed and economy of movement and 
decrease technical error. This was further confirmed in a Cochrane review\textsuperscript{21} 
that involved 23 trials with over 600 participants. The benefits of virtual 
reality training extend beyond practicing on a model as the trainee can 
practice in an educationally oriented and safe environment, at progressively 
more challenging levels, which leads to a proficiency-based approach to 
skills acquisition.\textsuperscript{13} It is a logical extension that if simulation training can be 
used to enhance the proficiency of surgeons performing a laparoscopic 
cholecystectomy, such training should be valid in enhancing the skills of an 
interventional cardiologist.

In this era with heightened emphasis on cost containment, quality, and 
outcomes, simulation has shown some promise. Although not in 
interventional cardiology per se, simulation-based training of residents in the 
proper aseptic insertion of central venous catheters was shown not only to 
reduce the incidence of catheter-related bloodstream infections, but also to 
have a net savings of $700,000 from reduction in rates of infections.\textsuperscript{22} To 
date, there are no studies that have shown simulation training in 
interventional cardiology to be able to reduce healthcare costs. However, one 
can imagine a simulation-based training module for interventional cardiology 
that would incorporate various aspects of cost-savings measures such as 
proper guide selection or stent selection, thus precluding the current trial-and-
error technique often employed by inexperienced operators.

\textbf{INTERVENTIONAL CARDIOLOGY 
SIMULATION}
Diagnostic Cardiac Catheterization

Diagnostic cardiac catheterization is now over half a century old and has evolved to include both femoral as well as radial approaches. The sheer volume of cardiac catheterizations has made the use of simulation for diagnostic catheterization from the femoral approach limited as fellows in training usually obtain their required procedural numbers to become certified in this procedure. In fact, there is a clear dearth of studies involving this area. Simulation, however, can provide a safe arena in which operators may encounter rare complications of diagnostic catheterization. All of the major simulation vendors have simulations including diagnostic cardiac catheterization, and most provide simulated complications that permit the learner to see these potential complications and how they would treat them in a benign simulated world as well as provide feedback if their treatment was not correct.

The use of simulation for transfemoral diagnostic catheterization has likely been muted due to the large group of operators well versed in its technique. For transradial catheterization, due to the well-documented “learning curve” that comes with this technique, the limited number of highly experienced operators, and the push for increased use due to its enhanced safety, there has been a remarkable interest in the use of simulation. In fact, transradial catheterization is an ideal procedure for simulation, ie, it involves a large group of operators who already have a basic skill set/knowledge base (left heart catheterization) but who must now learn how to approach it differently. Simulation provides a venue wherein operators can safely learn to apply their skill set in this new approach. Additionally, there is the opportunity here to use simulation to assess procedural competence, although to date, this has not been studied or validated.

Most of the major simulator companies provide transradial coronary simulations (Table 77-1) and provide users with the opportunity to encounter several unique scenarios including anatomic variants such as radial and/or brachial loops, aberrant origins of the radial artery, and variations in aortic arch anatomy. Commonly encountered issues such as spasm can also be simulated. These simulations also allow operators to learn the behavior of different catheters than those used for transfemoral cases. There are numerous transradial courses currently available that incorporate simulation as part of its curricula, including the Society for Cardiovascular Angiography
and Interventions (SCAI)–sponsored Transradial Intervention Program (TRIP), which features expert proctors working with radial trainees on simulators.

</table>

An X delineates that the procedure listed is available through the simulator company. Each company is in development of additional simulators; please visit their websites for an updated list. CAE (www.caethealthcare.com); Medical Simulation Company (MSC) (www.medsimulation.com); Mentice (www.mentice.com); and Symbionix (www.symbionix.com).

Abbreviations: ASD, atrial septal defect; Evolve, percutaneous repair of the mitral valve for mitral regurgitation; EVAR, endovascular aneurysm repair; FFR, fractional flow reserve; IABP, intra-aortic balloon pump; ICE, intracardiac echocardiography; IVUS, intravascular ultrasound; LHC, left heart catheterization; OCT, optical coherence tomography; PABV, percutaneous aortic balloon valvuloplasty; PCI, percutaneous coronary intervention; PFO, patent foramen ovale; PMBV, percutaneous mitral balloon valvuloplasty; RHC, right heart catheterization; SFA, superficial femoral artery; SVG, saphenous vein graft; TAVI, transcatheter aortic valve implantation; TEVAR, thoracic endovascular aneurysm repair.

Percutaneous Coronary Intervention (PCI)

Simulation of PCI has also evolved. Currently, numerous simulations of complex clinical scenarios including acute myocardial infarction, shock, multivessel disease, chronic total occlusion, bifurcation lesions, left main intervention, and elective PCI are available. These simulations require operators to manage the whole case including periprocedural pharmacology, assessment and treatment of hemodynamic and electrical instability, and selection of equipment and interventional strategy. For performance assessment purposes, numerous metrics can be measured including catheter selection, advancement, and coronary cannulation, wire manipulation, appropriate device selection, lesion coverage, stent expansion, residual disease, and “fluoroscopic” time. In addition to standard PCI equipment, some companies have partnered with various simulation companies and offer device-specific simulations, including rotational atherectomy and distal protection devices for saphenous vein graft intervention (eg, Boston Scientific Corp. with Medical Simulation Corp.).

Structural Heart Intervention

There has been an explosion in the array of catheter-based procedures for the treatment of structural heart disease over the last decade. These procedures include closure of atrial septal defects (ASD)/patent foramen ovale (PFO), left atrial appendage (LAA) occlusion, and transcatheter mitral and aortic valve therapies. These interventions are often complex and require operators to be well versed in the hemodynamic perturbations of each process and how to determine the degree and severity of each process. Operators must have a solid understanding of all the relationships of the heart in 3 dimensions and have an understanding of the adjunctive imaging techniques such as transesophageal echocardiography (TEE) and intracardiac echocardiography (ICE) used for guidance. With limited formalized training programs available and the high demand for the development of structural heart disease programs, this arena is well suited for the use of simulation. In response to this demand, most of the companies offer these simulations (see Table 77-1). Recently, technologic advances have also permitted the incorporation of adjunctive imaging involving TEE and ICE in simulated transseptal catheterizations, further enhancing the realism of the simulations.
Although the data are scarce in this area, there is 1 small randomized trial evaluating conventional versus simulator-based training in transseptal puncture technique that showed that simulator training resulted in shorter training time and greater procedural ability and efficiency. Even with the lack of data, many device companies are using simulation to train potential customers. In fact, the US Food and Drug Administration (FDA) has actually required simulation training be part of product training for multiple approved technologies including distal embolic protection devices (FilterWire, Boston Scientific Corp.), carotid stenting, and transcatheater aortic valve replacement (TAVR) (Sapien, Edwards Lifesciences). St Jude Medical, the largest manufacturer of ASD closure devices, actually requires simulator training for certification in the use of their Amplatzer occluder devices. Finally, there are LAA occluder simulations that likely will require simulator training upon their approval.

**Endovascular Intervention**

Importantly, simulation has been extensively studied and used in the endovascular realm. This has been driven by surgical colleagues. Traditionally trained in open techniques, in the late 1990s, there began a movement to incorporate endovascular training into surgical training programs. Surgeons previously had learned how to adopt new technology via simulation with laparoscopic surgery and thus have provided the majority of the data in simulation.

The endovascular procedure that has received the most intense interest, scrutiny, and study is carotid artery stenting (CAS). In fact, CAS is ideal for simulation. CAS has a unique learning curve and disastrous outcomes if poorly performed that have been widely published. With this in mind, an FDA panel in 2004 voted to accept a proposal that virtual reality (VR) simulation would be an important component of a training package for carotid stenting. This was followed by endorsement of VR simulation for CAS by all of the major societies.

With the support of the FDA and the major societies, simulation of CAS subsequently became the most studied of any transcatheter procedure. VR simulation for CAS has been shown to shorten learning curves, assess the impact of CAS training, as well as differentiate between levels of
endovascular experience. Simulation has been used to level the “playing field,” at least a simulated playing field, between experienced and inexperienced operators, in 1 study where training on simulators permitted learners to match experts in a direct comparison study. Hence, driven by mandate and support, the use of simulation has been shown to be effective in CAS from which most of the data and support for simulation are extracted. Indeed, if simulation training can assist in making CAS safer, then it should assist in making all procedures safer.

In the lower risk arena of non-CAS interventions, all of the companies have renal, iliac, and superficial femoral artery/popliteal endovascular interventions simulated (Table 77-1). Simulators have been used in the training of vascular surgery residents to assess the impact of didactic and cognitive training, underscoring the need to incorporate both psychomotor and cognitive skill development. In one study involving renal versus iliac intervention, simulation training clearly demonstrated that the skill set for 0.035-inch versus 0.014-inch wire manipulation is separate and distinct and that a stepwise and hierarchical training curriculum should be developed for acquisition of endovascular skill using VR simulation to supplement training on patients.

There is a well-publicized “VR to OR (operating room)” randomized trial involving simulation training for catheter-based therapy for lower extremity occlusive disease. This small study involved 20 general surgery residents who were randomly assigned to either simulation-based training or none for catheter-based therapy of lower extremity arterial disease. All subjects then performed 2 “real procedures” in an angiography suite on patients and underwent global performance assessment by an attending surgeon blinded to their training status. Residents trained on a simulator scored higher than controls on the first and second operating room angiogram and intervention. This study is the only one to date to critically assess whether simulation training can actually have an impact on performance of a real vascular procedure. Whether this impact is long lasting or cost effective remains unknown.

PATIENT-SPECIFIC VIRTUAL REALITY SIMULATION
Patient-specific VR simulation (PSVR) represents the most recent and exciting technologic advancement in medical simulation. Specifically, image processing has been accelerated to permit standard computed tomography or magnetic resonance imaging Digital Imaging and Communications in Medicine (DICOM) data to be imported into some simulators. This provides operators the chance to “rehearse” a procedure in a simulated environment using the patient’s actual vascular anatomy before performing the procedure on that patient. The operator would have the ability to test various techniques/strategies without subjecting the patient to any harm. Patient-specific rehearsal is a major advancement in the use of simulation because this concept of simulated rehearsal allows practice of a specific event (ie, an intervention), as opposed to merely acting as a generic training tool to practice a specific skill. This permits procedural planning (cognitive rehearsal) and “hands-on” rehearsal (psychomotor rehearsal) but will need to be evaluated further.

Although now commercially available, a glimpse of PSVR simulation was provided in 2007. Using PSVR simulation of a real patient’s arch anatomy and carotids, an operator rehearsed CAS in a demonstration of the power of this technology that was called “mission rehearsal.” The operator was able to perform CAS using patient-specific anatomic data on the “patient” using a simulator before entering the catheterization suite and performing the real procedure. The operator was able to “work through” the challenges one might face during CAS such as arch negotiation and catheter selection and decipher the best of several possible approaches and address potential complications before performing the real procedure on the real patient. Because it is well known that tortuous anatomy, complex lesion morphology, and difficult device access lead to increased procedural time, fluoroscopy exposure, contrast use, and complications during CAS, the PSVR permitted all of this to be “practiced” in advance. Additionally, by moving the C-arm using the imported patient-specific DICOM data, one can select the optimal working view wherein vessel overlap/foreshortening is minimized, precluding contrast and radiation, as well as select stent diameter and length before the real case. In one study of PSVR CAS simulation, simulation significantly influenced the real case in terms of optimal fluoroscopy C-arm position, choice of selective catheter, choice of sheath or guiding catheter, and balloon dilatation strategy. Operators who have access to such PSVR
simulators can rehearse the procedure prior to going into the angiography suite.

**APPRAOCH TO THE INTEGRATION OF SIMULATION**

While numerous high-fidelity VR simulators (Fig. 77-1) are now available, the true challenge of simulation is how to integrate simulation into a coherent, structured, proficiency-based training program. Each transcatheter procedure requires the operator to have a concrete foundation of knowledge including an understanding of the anatomy of the area as well as all the intricacies of the pathophysiology present prior to performing the procedure.\(^{36,44}\) The learning of advanced technical skills has little or no meaning unless an operator also knows how and when to use these skills.\(^{45,46}\) Cognitive skills, including a complete knowledge of anatomy, error detection, forward planning, and decision making, must be taught concomitantly with didactic methodologies before a novice operator commences psychomotor skills training.\(^{36,47}\) These cognitive skills must be included in any training program.\(^8\)
The SCAI-sponsored Transradial Intervention Program (TRIP) represents an example of how to integrate simulation into a cohesive training program. The TRIP curriculum is comprised of (1) a cognitive module and (2) a technique module. The cognitive module is provided in a didactic fashion by experienced radial operators. In this section, trainees obtain the knowledge base of in whom to perform this technique and how. Specifically, patient selection/preparation is followed by details of radial artery access.
Periprocedural pharmacotherapy and forearm and aortic arch anatomy (normal and variations) are reviewed in depth. Proper catheter selection and various techniques to obtain hemostasis are reviewed. Trainees are provided knowledge of how to prevent and manage common complications of this technique. Following this cognitive section, the technical aspects of the procedure are demonstrated in a simulated catheterization laboratory environment. Operators learn about equipment choices and catheter manipulation in a “1-on-1” fashion with faculty, develop catheter skills, and learn tactile feedback in a simulator environment. Providing such a structure to the simulation-based learning experience increases its educational impact. The critical aspect is the use of high-fidelity simulators to develop and hone psychomotor skills in a safe environment wherein each operator starts with the knowledge base upon which these skills can be added. TRIP is unique in its composite approach and likely should serve as a model for future educational efforts involving simulation.

**POSITION STATEMENTS**

Recently, the SCAI released a document surveying the current state of medical simulation in interventional cardiology. This document examines in depth the details of each commercially available simulator within North America and the currently available simulation platforms. Embedded within this document are data from a recent ABIM/ACC/SCAI survey that was sent to all ACGME-accredited interventional cardiology programs within the United States (n = 132) in an effort to ascertain the current use of simulation in these programs since the mandate from ACGME to incorporate simulation-based training in some fashion within all training programs. This survey underscores the numerous barriers to the uptake of simulation in interventional cardiology. Few programs agreed that the simulators mimicked actual catheterization well or that the simulator experience was similar to real life or could enhance skill in the real catheterization laboratory. Although unquestionably tainted by a selection bias of surveying only academic and more experienced operators (program directors), these statements underscore the inherent challenges that simulation proponents encounter. The SCAI document also outlines a number of recommendations from the society for simulation moving forward including:

1. We anticipate the eventual requirement that fellows in invasive specialties will be expected to demonstrate competency in the procedures they are being trained to perform in practice. To prepare for this, we recommend that SCAI as a society, in conjunction with the ACC and ABIM develop a set of standardized cases that embodies the essential psychomotor and knowledge base skill sets required to be an interventional cardiologist.

2. These standardized cases should be developed and integrated with a standardized didactic curriculum that meets current evidenced based learning standards as dictated by the Accreditation Council for Graduate Medical Education (ACGME) and Core Cardiovascular Training Symposium (COCATs). This curriculum and the simulations should be available on all simulation platforms to maximize fellow training and testing at all SCAI events including the Fall Fellows Course.

3. We advocate for the initiation of large scale studies to evaluate the impact of simulation in a number of key areas including: (a) feasibility and efficacy of a simulation-based training curricula as a training modality for both fellows and more experienced operators learning new procedures and (b) reliability and validation of simulation as a tool for the maintenance of competency.

4. Finally, we recommend that formal simulation training programs be included in the annual scientific sessions and integrated into the program for fellows and practicing physicians.

FUTURE CHALLENGES AND DIRECTIONS FOR SIMULATION

Interventional cardiology has been slow to adopt simulation as part of its training programs despite the obvious benefits of its use as well as data from other fields. Part of this has been the relative dearth of data showing improved performance and a translation into real-world practice. For procedures common within cardiology, such as left and right heart catheterization, a potential explanation lies in the relatively high volume of these procedures that are performed each year. This has propelled continuation of the apprentice model wherein fellows learn by “practicing on real patients.” In turn, there is a natural reluctance to formally incorporate
simulation into training programs and hence its study for the purposes of cardiology education. Critics of simulation cite the large inherent “costs” of simulation. These costs include both monetary (eg, the cost of the simulators, upkeep) and the cost of time away from real patients. In fact, the cost of a single VR simulator can be much as $100,000, which precludes most training programs from ever having their own VR simulator. Additionally, hospitals with trainees already incur greater costs because of having trainees who are not as efficient at procedures as attending physicians. Indeed, approximately $50,000 is spent per surgical resident over a training period of 4 years secondary to increases in operative time and the inherent decreased efficiency that occurs when operating with a trainee. How can we expect these programs to also cover the cost of simulation-based training, even if it increases efficiency? Will there be an adequate return on the investment? Who is to cover these costs? These are all unanswered questions. As noted elsewhere, with numerous subspecialties now using simulation for training, perhaps institutions might see the cost-effectiveness of having a VR simulator and/or simulation center that could be used across specialties. Another cost-effective option to secure simulation-based training is to send trainees to regional simulation centers or to enhance societal efforts at exposing trainees to simulation at annual meetings.

Despite this, the major professional societies have taken substantial increased interest in incorporating simulators into training and certification. By virtue of the rapidity of exposure and programmed variations in anatomy, clinical complexity, or ensuing complications, there is little doubt that simulator training can enhance the operator learning curve and potentially improve actual patient safely. The challenge however is providing the data to definitively show this benefit and then prove it to be cost effective. Even with a lack of several large studies, the ACGME now mandates that simulation must be incorporated into each cardiology and interventional cardiology fellowship training program.

CONCLUSION

The integration of simulation-based training into interventional cardiology is long overdue, but appears to be making forward progress. Numerous randomized clinical trials, systematic reviews, and meta-analyses have
confirmed the benefits of simulation to enhance clinical practice across a multitude of specialties. The traditional approach of “see one, do one, teach one” is rapidly being replaced with the more progressive concept of “learn the operation before the operating room.” Interventional cardiologists, a pioneering group by nature, have ventured beyond the coronaries to complex arenas such as percutaneous valvular replacement, endovascular revascularization, and carotid stenting. Our profession is evolving rapidly and with this comes new devices, techniques, and challenges. Simulation provides the ability to rapidly teach techniques, hone requisite skills, and evaluate the impact of training, all within a world that is without harm to the patient. We must continue to evolve and determine how best to incorporate simulation into our training programs, our maintenance of certification programs, and our profession as a whole.

Radial Versus Femoral Access for Coronary Intervention (RIVAL), 345, 982
RADIANCE study, 872
radiation, 173–193
  absorbed dose of, 175, 176t
  air kerma of, 174, 176t
  from angiography radial approach, 345–346
  contrast media for, 283–289, 284f, 285t
    adverse reactions to, 286–289, 286t
    AKI from, 289
    cardiogenic shock from, 289
    CKD and, 293, 298
DHRs from, 288, 288f
IHRs to, 287–288
kidneys and, 293–303
cumulative air kerma of, 177–178, 178f
DAP for, 177, 178
deterministic effects of, 180
effective dose of, 175–177, 176f
equipment design for, 181–185
equivalent dose of, 175, 176f
extraneous body parts and, 189
government regulation of, 184–185
injuries from, 173–174, 174f, 175f
IRP for, 177–178, 178f
KAP for, 177
limiting exposure to, 181–185
monitoring dose of, 177–179
patient positioning for, 185–189, 187f
patient size and, 188–189, 188f
personnel safety with, 190–192
pregnancy and, 190, 192–193
room design for, 181
skin dose mapping for, 179, 180f
stochastic effects of, 180
temporal patterns of, 180–181
transient erythema from, 178, 179t
radiofrequency (RF), for lower extremity venous insufficiency, 909
Raman spectroscopy, 409
ramipril, for resistant hypertension, 869
RAND, 1079
